Contributors

Graziella Abu-Jawdeh MD
Associate Pathologist
Department of Pathology, North Shore Medical Center, Salem, Massachusetts

Kristen A. Atkins MD
Assistant Professor
Department of Pathology, University of Virginia Health System, Charlottesville, Virginia

Karoly Balogh MD
Associate Professor
Department of Pathology, Harvard Medical School; Staff Pathologist, Department of Pathology, Beth Israel Deaconess Medical Center, Boston, Massachusetts

Lucia L. Balos MD
Assistant Professor of Pathology
Department of Pathology and Anatomical Sciences, University of New York at Buffalo, School of Medicine and Biomedical Sciences; Director of Anatomic Pathology, Department of Pathology, Kaleida Health, Buffalo, New York

JosÃ© E. Barreto MD

Associate Professor
Department of Pathology, Instituto de Patologia e Investigacion; Professor, Department of Pathology, Facultad de Medicina, Universidad Catolica, Villarrica, Paraguay

Nicole A. Belsley MD
Fellow in Cytopathology
Department of Pathology, Massachusetts General Hospital, Boston, Massachusetts

Kurt Benirschke MD
Professor Emeritus
Pathology and Reproductive Medicine, Department of Pathology, University of California, San Diego, La Jolla, California; Pathologist, Department of Pathology, San Diego Medical Center, San Diego, California

Rex C. Bentley MD, PhD
Associate Professor
Department of Pathology, Duke University Medical Center, Durham, North Carolina

Gerald J. Berry MD
Professor
Department of Pathology, Stanford University Medical Center; Director of Cardiac Pathology, Associate Director of Surgical Pathology, Stanford University Hospital, Stanford, California

Margaret E. Billingham MB, BS, FRCPath
Professor Emerita of Pathology
Department of Pathology, Stanford University Medical School, Stanford, California

Jaques Bosq MD
Assistant Professor of Pathology
Department of Histopathology â€œAâ€•, Institut Gustave-Roussy, Villejuif Cedex, France

John S. J. Brooks MD, MRCPath
Professor and Vice Chair
Department of Pathology and Laboratory Medicine, University of Pennsylvania Medical School; Chair of Pathology, Pennsylvania Hospital of the University of Pennsylvania Health System, Philadelphia, Pennsylvania

Peter G. Bullough MD
Professor
Department of Pathology and Laboratory Medicine, Weill Medical College, Cornell University; Director of Laboratory Medicine, Hospital for Special Surgery, New York, New York

Peter C. Burger MD
Professor of Pathology, Neurosurgery, and Oncology
Department of Pathology, The Johns Hopkins University School of Medicine, Baltimore, Maryland

Maria Luisa Carcangiu MD
Director of Anatomic Pathology
Department of Pathology, Istituto Nazionale Tumori, Milan, Italy

J. Aidan Carney MD, PhD, FRCPI, FRCP
Professor Emeritus of Pathology; Emeritus Consultant in Pathology
Department of Laboratory Medicine and Pathology, Mayo Clinic, Rochester, Minnesota

Darryl Carter MD

Professor Emeritus of Pathology
Department of Pathology, Yale University School of Medicine, New Haven, Connecticut

Odile Casiraghi MD
Department of Histopathology â€œAâ€•, Institut Gustave-Roussy, Villejuif Cedex, France

William L. Clapp MD
Associate Professor
Department of Pathology, Immunology, and Laboratory Medicine, University of Florida College of Medicine; Chief, Anatomic Pathology, Department of Pathology and Laboratory Medicine Service, North Florida/South Georgia Veterans Health System, Gainesville, Florida

Philip B. Clement MD
Professor of Pathology and Laboratory Medicine
University of British Columbia; Consultant Pathologist, Department of Pathology and Laboratory Medicine, Division of Anatomic Pathology, Vancouver General Hospital, Vancouver, British Columbia, Canada

Thomas V. Colby MD
Consultant in Pathology
Department of Pathology, Mayo Clinic Arizona, Scottsdale, Arizona

Christopher J. Cold MD
Anatomic Pathologist
Marshfield Laboratory, Department of Anatomic Pathology, Saint Joseph's Hospital, Marshfield, Wisconsin

Laura C. Collins MD, MBBS

Assistant Professor of Pathology
Harvard Medical School; Staff Pathologist, Department of Pathology, Beth Israel Deaconess Medical Center, Boston, Massachusetts

Julian Conejo-Mir MD, PhD
Professor and Chairman of Dermatology
Virgen del Rocio University Hospital, University of Seville, Sevilla, Spain

Byron P. Croker MD, PhD
Professor
Department of Pathology, Immunology, and Laboratory Medicine, University of Florida; Chief, Pathology and Laboratory Medicine Service, North Florida/South Georgia Veterans Health System, Gainesville, Florida

Antonio L. Cubilla MD
Professor Emeritus
Department of Pathology, Facultad de Ciencias Medicas; Director of Pathology, Instituto de Patologia e Investigacion, AsunciÃ³n, Paraguay

Thomas J. Cummings MD
Associate Professor
Department of Pathology, Duke University Medical Center, Durham, North Carolina

Julia Dahl MD
Chief Medical Officer
Mosaic Gastrointestinal Research and Education Consortium; Laboratory Director, Mosaic Gastrointestinal Pathology Services, PLLC, Germantown, Tennessee

Yogeshwar Dayal BS, MB, MD
Clinical Professor
Department of Pathology, Tufts University School of Medicine; Senior Pathologist, Department of Pathology, New England Medical Center Hospitals, Boston, Massachusetts

Ronald A. DeLellis MD
Professor and Associate Chair
Department of Pathology and Medicine, Brown Medical School; Pathologist-in-Chief, Department of Pathology, Rhode Island Hospital, Providence, Rhode Island

Franco G. DeNardi MD, FRCP(C)
Department of Anatomical Pathology, Henderson General Hospital, Department of Pathobiology and Molecular Medicine, McMaster University, Hamilton, Ontario, Canada

Claus Fenger MD, PhD
Professor; Chief Pathologist
Department of Clinical Pathology, Odense University Hospital, Odense, Denmark

Henry F. Frierson Jr. MD
Professor
Department of Pathology, University of Virginia Health System, Charlottesville, Virginia

Gregory N. Fuller MD, PhD
Professor
Department of Pathology; Chief, Section of Neuropathology, The University of Texas, M.D. Anderson Cancer Center, Houston, Texas

Giulio Gabbiani MD, PhD
Professor
Department of Pathology and Immunology, University of Genevaâ€“CMU, Geneva, Switzerland

Patrick J. Gallagher MD, PhD, FRCPath
Reader in Pathology
School of Medicine, University of Southampton; Consultant Cardiovascular Pathologist, Department of Cellular Pathology, Southampton University Hospitals, Southampton, United Kingdom

Terry L. Gramlich MD
Director of Hepatopathology
AmeriPath Institute of Gastrointestinal Pathology and Digestive Disease, Oakwood Village, Ohio

Joel K. Greenson MD
Professor of Pathology
Department of Pathology, University of Michigan Medical School, University of Michigan Health System, Ann Arbor, Michigan

Nancy S. Hardt MD
Clinical Professor
Department of Pathology, University of Florida, Shands at the University of Florida, Gainesville, Florida

Reid R. Heffner Jr. MD
Professor
Department of Pathology and Anatomical Sciences, University at Buffalo School of Medicine Buffalo, New York

Michael R. Hendrickson MD
Professor of Pathology; Co-Director of Surgical Pathology

Department of Pathology, Stanford University Medical Center Stanford, California

Boris Hinz PhD
Laboratory of Cell Biophysics, Swiss Federal Institute of Technology, Lausanne, Switzerland

Seung-Mo Hong MD, PhD
Research Associate
Department of Pathology, University of Virginia, Charlottesville, Virginia

Eva Horvath PhD
Department of Laboratory Medicine, St. Michael's Hospital, University of Toronto, Toronto, Ontario, Canada

Ralph H. Hruban MD
Professor of Pathology and Oncology; Director
The Sol Goldman Pancreatic Cancer Research Center; Pathologist, Department of Pathology, The Johns Hopkins Hospital, Baltimore, Maryland

Richard L. Kempson MD
Professor of Pathology
Emeritus Active, Department of Pathology, Stanford University, Stanford, California

David S. Klimstra MD
Professor
Department of Pathology and Laboratory Medicine, Weill Medical College, Cornell University; Attending Pathologist and Chief of Surgical Pathology, Department of Pathology, Memorial Sloan-Kettering Cancer Center, New York, New York

Gordon K. Klintworth MD, PhD
Professor or Pathology
Joseph A. C. Wadsworth Research; Professor of Ophthalmology, Duke University Medical Center, Durham, North Carolina

Kalman Kovacs MD, PhD
Department of Laboratory Medicine, St. Michael's Hospital, University of Toronto, Toronto, Ontario, Canada

Kevin O. Leslie MD
Professor of Pathology
Mayo Clinic College of Medicine; Consultant, Department of Laboratory Medicine and Pathology, Mayo Clinic Arizona, Scottsdale, Arizona

Steven H. Lewis MD, FCAP, FACOG
Adjunct Associate Professor of Pathology and Obstetrics and Gynecology
University of South Florida, Tampa, Florida

Min Li MD, PhD
Associate Pathologist
Department of Pathology, St. Luke's Hospital, Bethlehem, Pennsylvania

Ricardo V. Lloyd MD, PhD
Professor of Pathology
Department of Laboratory Medicine and Pathology; Consultant, Department of Laboratory Medicine and Pathology, Mayo Clinic, Rochester, Minnesota

M. Beatriz S. Lopes MD

Professor of Pathology and Neurological Surgery
University of Virginia School of Medicine; Director of Neuropathology & Autopsy, Department of Pathology, University of Virginia Health Services, Charlottesville, Virginia

Fernando MartÃnez-Madrigal MD
Department of Pathology, Hospital General â€œDr. Miguel Silvaâ€•, Hospital General de Zona No.1, IMSS and the Medical Faculty of the Universidad Michoacana de San Nicolas de Hidalgo, Morelia, MichoacÃ¡n, Mexico

Preface

The third edition of *Histology for Pathologists* builds on the tradition of its two predecessors as a text to bridge the gap between the histology of normality and pathology. Dr. Stephen S. Sternberg, who first recognized the need for this text, shepherded the first two editions through production, and made this work a â€œmust haveâ€• for practicing pathologists, has retired as editor. It is a great honor to replace him on the third edition and continue his legacy.

It is axiomatic that in order to understand the abnormal, one must first have a clear understanding of the normal. Although normal histology appears static, at least when viewed over the life span of humans, our understanding of normality evolves at a considerably more rapid rate. Accordingly, the third edition is greatly revised and completely reorganized. Where appropriate, immunohistochemical features of normal tissues are presented, using the latest available markers. Several new chapter authors have been added and many new color illustrations are provided. Considerable effort has been expended to improve the illustrations held over from prior editions. At the time of the second edition, apoptosis was a relatively new discovery and merited a separate chapter. This now well-accepted concept is discussed in detail in individual chapters of the third edition. Although the text emphasizes normality, as in prior editions, prepathologic conditions are briefly considered in many chapters. More importantly, emphasis is placed on normal processes that may be

confused with pathologic conditions. It is this pathologic perspective that sets *Histology for Pathologists* apart from standard histology texts written by anatomists.

As in the prior two editions, our goal for the third edition remains to provide a text that both the neophyte pathology trainee and experienced anatomic pathologist will find of considerable value in their professional careers.

Preface to the First Edition

Histology textbooks exist in abundance. Some are classics of their kind and have gone through innumerable editions over many years. They have served pathologists well, for the most part, especially in terms of strict tissue and cell histology. There is, however, a borderline between histology and pathology in which information for the pathologist is often lacking.

With this textbook we made an attempt to fill the gap. The significance and function of many histological structures in terms of pathological interpretation is often absent or obscure. In particular, variations of the norm related to such variables as age, sex, and race are often not clarified in conventional textbooks. For example, the chapter on paraganglia notes that the connective tissue between the lobules in the carotid body increases with age. Another example related to age is in the pediatric kidney chapter, where it is noted that the glomeruli of fetuses are disproportionately large and are rarely seen in a state of histological â€œimmaturity.â€• While the chapter on the myofibroblast details the location, staining, ultrastructure, and cytoskeletal protein composition of this unusual cell, we also learn of its importance in the desmoplastic reaction in cancerous tissue and, most importantly, that it is not found in carcinomas which are still in situ.

Some gross observations occasionally will be found as lagniappe, such as the notation that in patients with congenital absence of a

kidney, the ipsilateral adrenal will be round rather than angulated. Another example would be that there is a crease in the earlobe associated with coronary artery disease.

Variations in staining reactions are considered, such as the failure of factor VIII to stain renal glomerular vessels. One finds that intestinal endocrine cells can be detected with hematoxylin and eosin (sic) stains by the infranuclear location of the granules. Uncommonly known fixation artifacts are uncovered; for example, the prickle-cell layer (with so-called intercellular bridges) is actually a retraction artifact of the plasma membranes with the desmosomes remaining relatively fixed.

In most chapters, â€œprepathologicalâ€• considerations are emphasized, while in others the developed pathological alterations related to the norm represent the major thrust of the chapter.

Some comments will be perceived as gratuitous, such as the remark in the penis chapter to the effect that â€œthe prepuce could be a mistake of nature.â€• Furthermore, we learn that the â€œcollagen fibers are wavy in the flaccid state and become straight during erection.â€•

The pathology neophyte as well as the many esteemed and experienced pathologists will find helpful information in this book.

Stephen S. Sternberg MD

Acknowledgments

My contributions to this text would not have been possible without the unending support of many family members, friends, and colleagues. I would like to dedicate this work to my wife, Linda, and our daughters, Elizabeth and Anne, for always being there when I needed them and for teaching me more than they will ever know about all things beyond pathology; to my early mentors in pathology, Ben Sturgill, Shannon Allen, and Bob Fechner who got me started on the right path; and to all my colleagues and our trainees at the University of Virginia from whom I continue to learn and hope to do so for a long time.

1
Normal Skin

Min Li

Carlos D. Urmacher

Introduction

The skin accounts for about 15% of the total body weight and is the largest organ of the body. It is composed of three layers: (a) epidermis, (b) dermis and (c) the subcutaneous adipose tissue. Each component has its unique and complex structure and function (1,2,3), with variation according to age, gender, race, and anatomic location. Functions of the skin are extremely diverse. It serves as a mechanical barrier against external physical, chemical, and biological noxious substances and as an immunologic organ. It participates in body temperature and electrolyte regulation. It is an important organ of sensuality and psychological well-being. In addition, it is a vehicle that expresses not only primary diseases of the skin, but also diseases of the internal organs. An understanding of the skin's normal histology is essential to the understanding of pathologic conditions.

Embryology

Epidermis

Embryologically, the ectoderm gives rise to epidermis and its appendages. The mesoderm provides the mesenchymal elements of the dermis and subcutaneous fat (4,5).

At first, the embryo is covered by a single layer of ectodermal cells. By the sixth to eighth week of development, it differentiates into two layers, the basal layer and an overlying second layer called periderm. The surface of the periderm is covered by microvilli and is in contact with the amniotic fluid. The mitotic activity of the basal layer predominates over that of the periderm, and soon the basal layer becomes the germinative layer. Additional rows of cells develop from this proliferating layer, forming a multilayer of cells between ectoderm and periderm (5). By the

twenty-third week, keratinization has taken place in the upper stratum, and the cells of the periderm have already been shed (5,6,7). Interestingly, it has been demonstrated that many of the cell junction proteins are expressed in the early two-layered embryonic epidermis and as early as the eighth week of estimated gestational age (8). By the end of the first trimester, the dermal epidermal junction with its component is ultrastructually similar to that of mature skin (9). Thus, the characteristic neonatal epidermis is well developed by the fourth month.

The majority of cells in the epidermis are keratinocytes (90 to 95%). The rest of the epidermal cells are nonkeratinocytes (5 to 10%), and they include melanocytes, Langerhans cells, and Merkel cells. The nonkeratinocytes are seen in the epidermis of 8- to10-week-old embryos. The precursor cells of melanocytes migrate from the neural crest to the dermis and then to the epidermis, where they differentiate into melanocytes during the first three months of development. During this migration, melanocytes can reside in other organs and tissue. Ultrastructually, recognizable melanosomes in melanocytes may be seen in the fetal epidermis at 8 to10 weeks of gestational age (10).

Langerhans cells are derived from the CD34+ hematopoietic precursor cell of the bone marrow. The characteristic cytoplasmic marker, the Birbeck granule, is seen ultrastructurally in 10-week-old embryos (11). The expression of a more characteristic immunohistochemical marker, CD1a is completed by 12 to 13 weeks of estimated gestational age (12,13).

Merkel cells can also be seen in the epidermis of 8- to 10-week-old embryos. The origin of Merkel cells is debatable. Some have suggested a neural crest derivation (14), whereas others suggest epidermal origin through a process of differentiation from neighboring keratinocytes (15,16,17,18). Merkel cells in the epidermis are initially numerous and later diminish with increasing gestational age, which suggests their role in growth and development (19).

Dermis

The dermis is derived from the primitive mesenchyme underlying the surface ectoderm. The papillary and reticular dermis is recognized by 15 weeks of intrauterine life (20,21).

As described by Breathnach (20), three types of cells are recognized in 6- to 14-week old embryos. Type I cells are stellate-dendritic cells with long slender processes. These are the most numerous primitive mesenchymal cells and probably give rise to the endothelial cells and the pericytes. Type II cells have less extensive cell processes; the nucleus is round, and the cytoplasm contains large vacuoles. They are classified as phagocytic macrophages of yolk-sac origin. Type III cells are round with little or no membrane extension, but they contain numerous vesicles, some with an internal content suggestive of granule-secretory type of cells. These cells could be melanoblasts on their way to the epidermis, or they could be precursors of mast cells; Schwann cells associated with neuroaxons, but lacking basal lamina, are

also identified during this period.

The type II mesenchymal cells are rarely seen after week 14 of development. However, another cell type with ultrastructure of histiocyte or macrophage is frequently seen during this time. Well-formed mast cells are also seen in the dermis.

In 14 to 21 weeks of development, fibroblasts are numerous and active. Fibroblasts are recognized as elongated spindle cells with abundant rough endoplasmic reticulum. They are the fundamental cell of the dermis and synthesize all types of fibers and ground substance (1). Type III collagen fibers are abundantly present in the matrix of fetus, whereas type I collagen fibers are more prominent in adult skin (21). Elastic fibers appear in the dermis after the collagen fiber during the twenty-second week of gestational age; and, by week 32, a well-developed network of elastic fiber is formed in the dermis (5).

Initially, the dermis is organized into somites, but soon this segmental organization ends and the dermis of the head and neck and extremities organizes into dermatomes along the segmental nerves that are being formed (22). From the twenty-fourth week to term, fat cells develop in the subcutaneous tissue from the primitive mesenchymal cells.

Epithelial Skin Appendages

Most epithelial cells of skin appendages derive from follicular epithelial stem cells localized in the basal layer of epidermis at the prominent bulge region of the developing human fetal hair follicles. Furthermore, such multipotent stem cells may represent the ultimate epidermal stem cell (23). In 10-week-old embryos, a group of mesenchymal cells of the developing dermis aggregate beneath a budding group of tightly packed basal cells (24). These epidermal cells grow both downward to the dermis and upward through the epidermis to form the opening of the hair canal. As

the growing epithelial cells reach the subcutaneous fat, the lower portion becomes bulbous and partially encloses the mesenchymal cells, descending with them to form the dermal papillae of the hair follicle. The descending epidermal cells around the dermal papillae constitute the matrix cells from which the hair layers and inner root sheath will develop. The outer root sheath derives from downward growth of the epidermis. The first hairs appear by the end of the third gestational month as lanugo hair around the eyebrow and the upper lip. The lanugo hair is shed around the time of birth. The developing hair follicle gives rise to the sebaceous and apocrine glands.

The sebaceous glands originate as epithelial buds from the outer root sheath of the hair follicles and are

developed at approximately the thirteenth to fifteenth gestational week (25). Differentiated sebaceous gland with a hair protruding through the skin surface are present at the eighteenth week of gestational age (26). They respond to maternal hormones and are well developed at the time of birth.

The apocrine glands also develop as epithelial buds from the outer sheath of the hair follicles in 5- to 6-month-old fetuses (22,24) and continue into late embryonic life as long as new hair follicles develop.

The eccrine glands develop from the fetal epidermis independent of the hair follicles (22). Initially, they are seen as regularly spaced undulations of the basal layer. At 14 to 15 weeks, the tips of the primordial eccrine glands have reached the deep dermis, forming the eccrine coils (27). At the same time, the eccrine epithelium grows upward into the epidermis. The primordial eccrine epithelium acquires a lumen by the seventh to eighth fetal month, and thus the first eccrine unit is formed. Both ducts and secretory portions are lined by two layers of cells. The two layers in the secretory segment undergo further differentiation; the

luminal cells into tall columnar secretory cells, and the basal layer into secretory cells or myoepithelial cells (5). The first glands are formed on the palms and soles by the fourth month, then in the axillae in the fifth month, and finally on the rest of the hairy skin (28).

Physiology

Epidermis

The skin not only serves as a physical barrier between internal organs and the environment, but also functions as an active immune organ (29). Langerhans cells, the antigen-presenting cells of the epidermis, function as immunologic cells by recognizing antigens on the skin and presenting them to naive T lymphocytes. They become mature after contact with the antigen (30). Melanocytes produce melanin from the substrate tyrosine, using tyrosinase, and store it in melanosomes. Mature melanosomes are then transported to adjacent keratinocytes, where they provide protection against the harmful effects of solar radiation.

The keratinocytes are responsible for the process of keratinization. The formation of keratin filaments, in association with desmosomes, hemidesmosomes, and the basement membrane provides the structural integrity of the epidermis (31). Keratinocytes produce immunologic molecules, such as interleukins, interferons, and growth factors (32). It is recognized that the epidermal keratinocytes have immune properties.

Different types of keratin intermediate filaments are expressed in fetal and adult skin, and this process is, in part, regulated by apoptosis.

Apoptosis

Apoptosis, or programmed cell death, is the mechanism by which

cells are deleted in normal tissue (33) and is the process responsible in establishing the final normal architecture of adult skin (34).

Terminal differentiation of the epidermis into a stratified squamous layer can be considered a specialized form of apoptosis (34). Apoptosis also participates in the cycling of the hair follicle (35,36,37) and is the principal mechanism by which catagen hair is formed (38,39,40). The bcl-2 proto-oncogen is a protein that blocks apoptosis and is expressed in basal cell keratinocytes and in the dermal papillae, protecting the latter from apoptosis (38).

Apoptosis affects individual cellsâ€”not groups of cells, as in necrosis (33). The basic morphologic changes include fragmentation of the nucleus, chromatin compaction, and budding of the cells to produce membrane-bound apoptotic bodies, which are ingested by neighboring cells. No inflammation is seen with the process of apoptosis (33).

By light microscopy, apoptotic cells are seen as isolated cells with bright eosinophilic cytoplasms and dark, pyknotic and fragmented nuclei (Figure 1.1).

In routine hematoxylin-eosin (H&E)â€“stained sections, apoptotic bodies are seen in a large variety of inflammatory and neoplastic diseases, such as graft-versus-host disease, lichen planus, erythema multiforme, squamous carcinoma, and malignant melanoma.

Recent study suggests that the mitogen-activated protein kinase signal transduction pathways are important in regulating the balance between keratinocyte cell proliferation, survival, apoptosis, and cell differentiation. Furthermore, it is suggested that extracellular regulated kinases induce keratinocyte proliferation and survival, whereas p38

mitogen-activated protein kinase promote differentiation and

apoptosis (41).

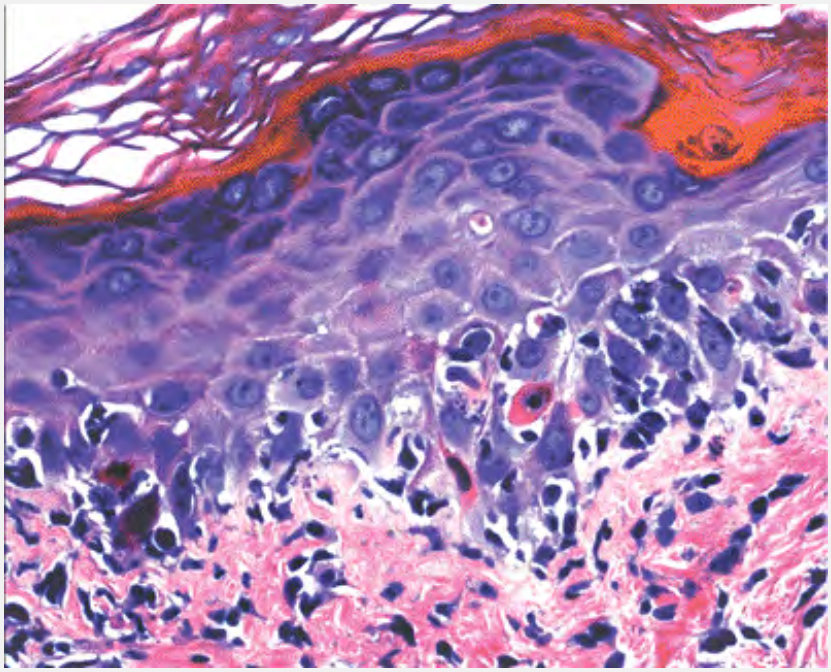

Figure 1.1 Apoptotic cell in a case of erythema multiforme. Note the eosinophilic cytoplasm and condensed nucleus.

Dermis

The dermis is a supportive, connective tissue composed of cells, fibrous molecules, and ground substance (1). The mesenchymal component of dense fibrous connective tissue provides the mechanical support, rigidity, and thickness to the skin. Collagenous and elastic fibers are closely associated with each other in the dermis. Collagen presumably provides the skin with tensile strength, whereas elastin posseses the retractile properties of the skin (42). The dermis also has immunologic functions because it contains dendritic cells, lymphocytes, other migrant leukocytes, mast cells, and tissue macrophages. Mast cells react to

inflammatory process and also participate in wound healing.

Except for the epidermis, the skin is rich in a vascular network. In addition to providing nutrients to the skin, blood vessels are involved in thermal regulation, wound healing, immune response, and control of blood pressure. The lymphatic system is important in regulating the pressure of interstitial fluid (1).

The skin is supplied with autonomic nerves and sensory nerves. Small and large nerve plexuses participate in the innervations, which are responsible for the detection of touch, pressure, vibration, pain, temperature, and itching, as well as sweat secretion and piloerection.

Eccrine and Apocrine Glands

The most important function of the eccrine glands is in the processes of thermoregulation and electrolytic balance (43). The eccrine glands are the true sweat glands, and their function begins in the neonatal period. Eccrine glands produce colorless and odorless hypotonic sweat composed of predominantly water and the same electrolytes that are present in the plasma. There are two types of secretory cells, clear and dark cells. The clear cells of the eccrine coil, responding predominantly to cholinergic stimuli, and to a lesser degree to sympathetic stimulation (44,45,46), produce an isotonic sweat. When it reaches the duct, sodium and chloride ions are reabsorbed, delivering a hypotonic solution to the surface. The function of the dark cells is still not known with certainty. It has been suggested that they permit reabsorption of sodium, potassium, and chloride (24) and may secrete sialomucin (47) to the sweat.

In addition, the eccrine duct has the important function of delivering parenteral or orally administered drugs to the surface of the skin (48). Ductal epithelium also participates in the process of wound healing (22).

The major function of the myoepithelial cells is mechanical support against a high hydrostatic pressure. The contraction of myoepithelial cells aids in delivery of sweat to the skin surface (49).

The exact role of apocrine glands and the mechanisms regulating apocrine secretory process in humans are still under investigation. Apocrine glands might also play a role in thermal regulation (50,51). In nonhuman mammals, apocrine glands are found over the entire skin surface; they are believed to serve as identifying or sexual organs (24). Apocrine secretion has a milky color and is sterile and odorless; however, when it reaches the surface of the skin, the action of regional microorganisms on the apocrine secretion makes it odorous (24). The most abundant odor component, known to be E-3-methyl-2-hexanoic acid (E-3M2H), is liberated from nonodorous apocrine secretion by microorganisms (52).

Alteration in the rate and amount of sweat secretion manifests as anhidrosis, hypohidrosis, and hyperhidrosis (53,54). Cystic fibrosis (44,49) is the disorder with alterations in the electrolyte composition of eccrine sweat. Few morphologic changes are seen in association with these diseases.

Light Microscopy

Epidermis

The epidermis is a stratified keratinizing squamous epithelium that dynamically renews itself but maintains its normal thickness by the process of desquamation. The cells in the epidermis include: (a) keratinocytes, (b) melanocytes, (c) Langerhans cells, and (d) Merkel cells. In addition, the epidermis contains the openings for the eccrine ducts (acrosyringium) and hair follicles. Recent immunohistochemical studies have demonstrated that the

epidermis contains free nerve axons in association with Langerhans cells (55).

Keratinocytes

The keratinocytes of the epidermis are stratified into four orderly layers from bottom to top: (a) the basal layer (stratum basalis, germinativum); (b) the squamous layer (prickle cell layer, or stratum spinosum); (c) the granular layer (stratum granulosum); (d) the cornified, or horny, layer (stratum corneum) (Figure 1.2). In histologic sections, the dermoepidermal junction has an irregular contour because of the upward extension of the papillary dermis to form the dermal papillae. The portion on the epidermis separating the dermal papillae are the rete ridges (Figure 1.3).

The Basal Layer

Basal cells are the mitotically active cells that give rise to the other keratinocytes. In histologic sections, basal cells are seen as a single layer of cells above the basement membrane that show some variation in size, shape, and melanin

content. Basal cells are columnar or cuboidal, with a basophilic cytoplasm. The nucleus is round or oval, with coarse chromatin and indistinct nucleolus. Basal cells contain melanin in their cytoplasm as a result of pigment transfer from neighboring melanocytes. Basal cells are connected to each other and to keratinocytes by specialized regions (known as desmosomes) located in the plasma cell membranes. They are aligned perpendicular to the subepidermal basement membrane and attached to it by modified desmosomes, hemidesmosomes (1).

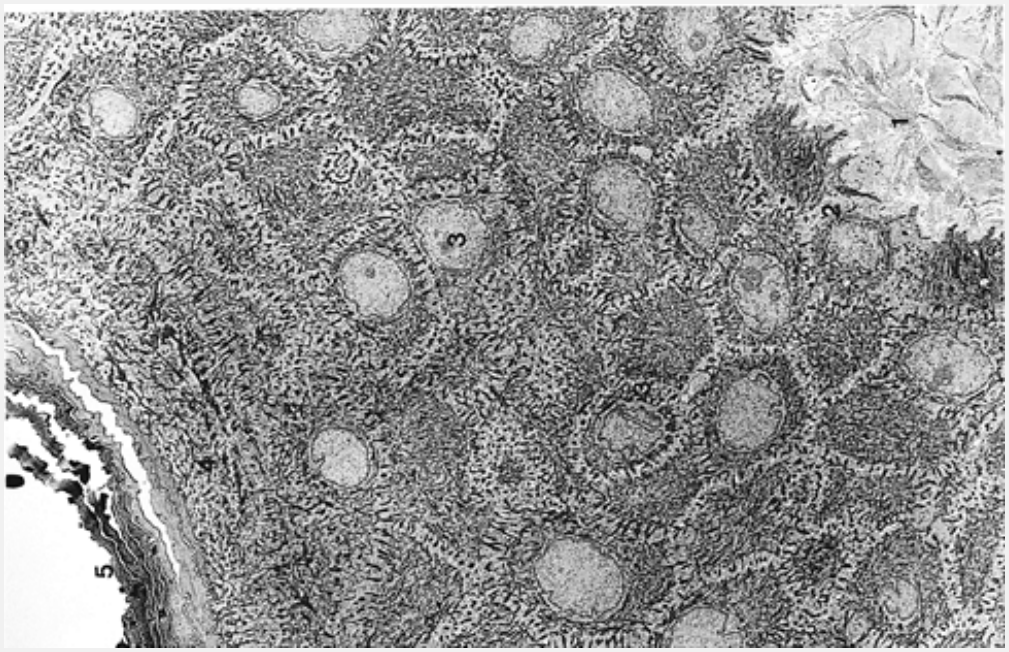

Figure 1.2 Electron micrograph of normal epidermis and portion of papillary dermis (Ã—2,100). (*1*, papillary dermis; *2*, basal cells; *3*, squamous layer; *4*, granular layer; *5*, cornified layer)

Dermatitis involving the basal layer produces vacuolar alteration of the basal cells, which may progress to the formation of subepidermal vesicles as seen in diseases such as graft-versus-host disease, lupus erythematosus, and erythema multiforme.

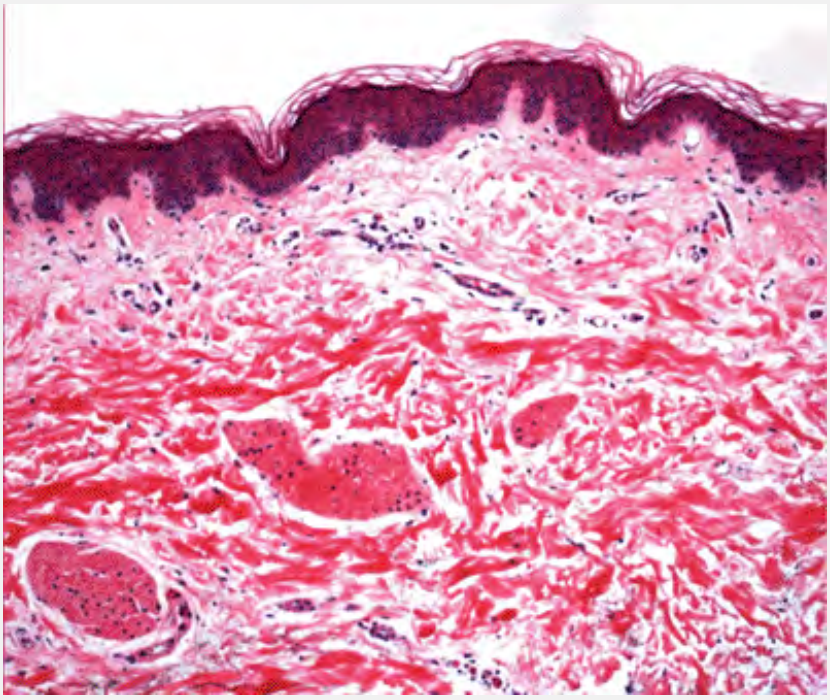

Figure 1.3 Normal skin showing stratified epidermis with rete ridges, papillary dermis and reticular dermis (H&E).

The Squamous Layer

The squamous layers are composed of approximately five to ten layers of cells with keratinocytes larger than the basal cells. The suprabasal keratinocytes are polyhedral, have a somewhat basophilic cytoplasm, and with a round nucleus. Again, melanin is seen scattered in many of these keratinocytes, where it provides protection from the damaging effect of ultraviolet light. The more superficial cells are larger, flattened, eosinophilic, and oriented parallel to the surface. The keratinocytes contain one or two conspicuous nucleoli and tonofilaments within the cytoplasm.

The squamous layer is also called the spinous or prickle cell layer because of the characteristic appearance by light microscopy of

short projections extending from cell to cell. These projections are the result of retraction of the plasma membrane during tissue processing whereas the desmosomes remain relatively fixed and correlate with intercellular bridges.

Desmosomes are composed of a variety of polypeptides; desmogleins and desmocollins as transmembrane constituents and the desmoplakin, plakoglobin and plakophilin as cytoplasmic components (5). In addition, other intercellular junctions (such as gap junctions and adherens junctions) are distinct from desmosomes in composition and distribution and provide alternative cell-to-cell adhesion mechanisms (56). An intercellular space of constant dimension (57) is present between each cell; acid and neutral mucopolysaccharides are present in the intercellular spaces as indicated by special stains (5). The pemphigus antigens are localized in the cell membranes (58) or in the

desmosomes of these cells (59). Antibodies to desmosomal proteins are used as additional markers for the study of neoplasm (60).

It is important to recognize that occasionally cells with clear or pale cytoplasms are seen in the squamous layer. These cells must be distinguished from the neoplastic cells of Paget's disease. Benign clear cells have a pyknotic nucleus surrounded by a clear halo and a narrow rim of clear cytoplasm (Figure 1.4). They lack the pleiomorphism, nuclear morphology, and intensity of the chromatin staining seen in Paget's cells (Figure 1.5). These benign clear cells are often seen in the epidermis of the nipple, the accessory nipple (61,62), and the pubic regions or in the milk line distribution (63). In the nipple, these clear cells, also called Toker cells, have been considered to be nonneoplastic mammary elements (61), although some authors hypothesized that these cells might be the precursors of mammary or extramammary Paget's diseases (62,64). Those outside of the nipple are

considered to be the result of either abnormal keratinization or aberrant derivatives of eccrine or apocrine sweat gland epithelial cells (65,66,67). They may present as hypopigmented macules or papules in a rare disorder called clear cell papulosis (63,67). The immunohistochemical and mucin staining pattern of benign clear cells may resemble that of Paget's cells. Therefore, they must be distinguished on a morphologic basis from the neoplastic cells.

Common inflammatory changes seen in the squamous layer are: (a) spongiosisâ€”intercellular edema (*e.g.,* allergic contact dermatitis); (b) acanthosisâ€”thickening of the epidermis (*e.g.,* psoriasis); (c) atrophyâ€”thinning of the epidermis (*e.g.,* discoid lupus erythematosus); (d) acantholysisâ€”detachment of keratinocytes because of changes involving intercellular junctions (*e.g.,* pemphigus); and (e) dyskeratosisâ€”abnormal keratinization (*e.g.,* squamous carcinoma).

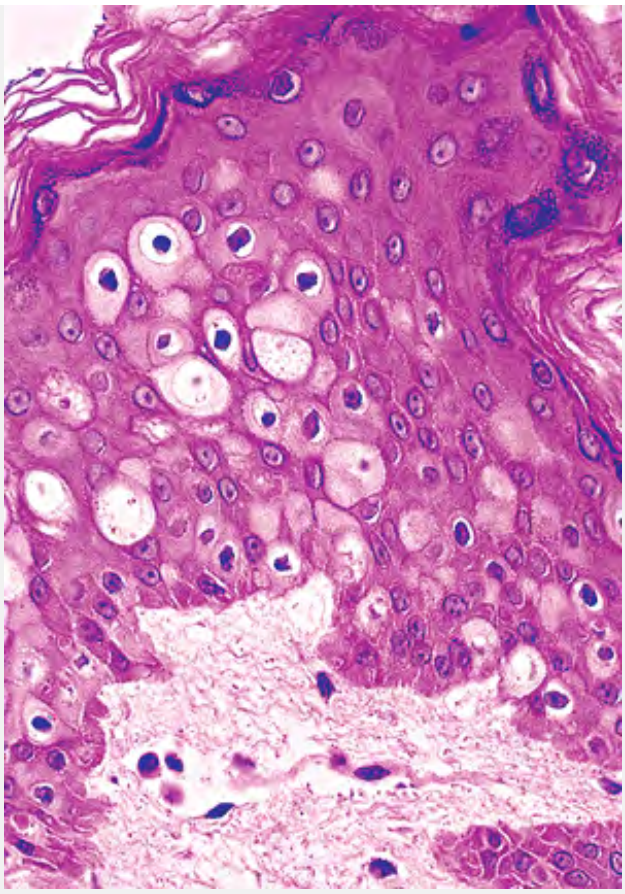

Figure 1.4 Clear cells of the nipple epidermis.

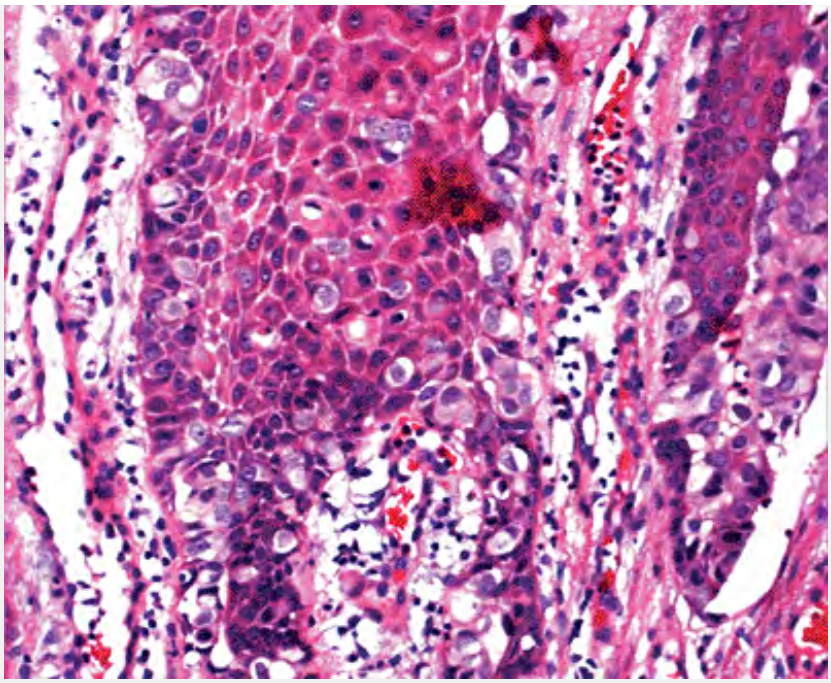

Figure 1.5 Paget's cells in extramammary Paget's disease.

The Granular Layer

The granular layer is composed of one to three layers of flattened cells lying parallel to the skin surface. The cytoplasm contains intensely basophilic-stained granules known as the keratohyalin granules. In contrast, trichohyalin granules (produced by the inner root sheath of hair follicles) are stained red on routine H&E-stained sections. The keratohyalin granules are histidine-rich and are the precursors to the protein flaggrin, which promotes aggregation of keratin filaments in the cornified layer. The granular layer is rich in lysosomal enzyme, which is crucial for the autolytic changes in the granular layer (68). The increase (*e.g.*, lichen planus) and decrease (*e.g.*, psoriasis) in the thickness of the granular layer can be used as a clue in the diagnosis of different pathologic entities.

Keratinocytes located between the squamous layer and the granular layer contain small membrane-coating granules known as lamellar granules (also called Odland bodies or keratosomes. They are composed of the acid hydrolase and of neutral sugars conjugated with proteins and lipids. These granules are present both intra- and extracellularly, are approximately 300 nm in diameter, and are not visible by light microscopy. Their functions are to provide epidermal lipids, increase the barrier property of the cornified layer against water loss, and aid in the desquamation process. This interface between the squamous and granular layer is also the site of synthesis and storage of cholesterol (57,69).

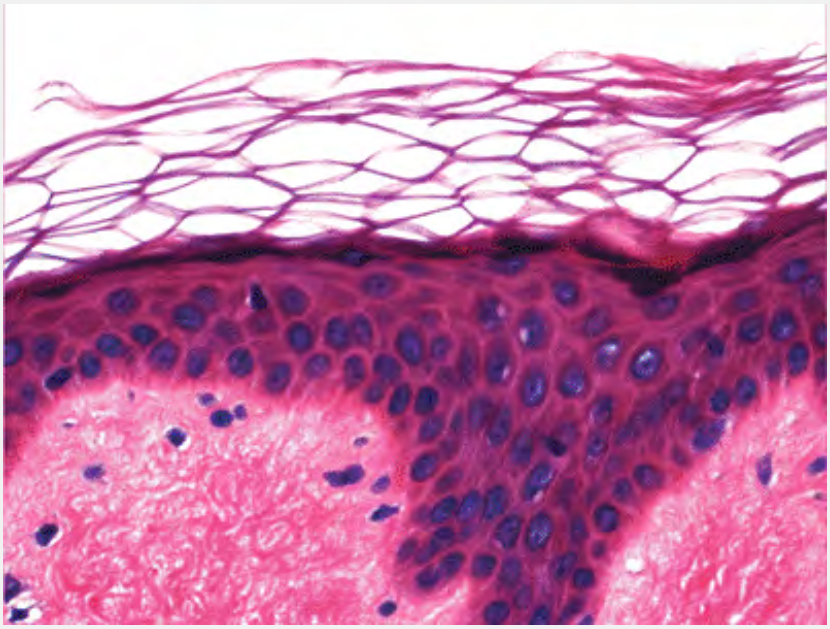

Figure 1.6 Basket-weave pattern of the cornified layer (also in Figure 1.3).

The Cornified Layer

The cornified layer is composed of multiple layers of polyhedral eosinophilic keratinocytes that lack a nucleus and cytoplasmic organelles. These cells are the most differentiated cells of the keratinization system. They are composed entirely of high-molecular weight keratin filaments. In formalin-fixed section, the cornified layers are arranged in a basket-weave pattern (Figure 1.6). These cells eventually shed from the surface of the skin. The process of keratinization takes 20 to 45 days.

In histologic sections taken from the skin of the palms and soles, a homogenous eosinophilic zone, known as the stratum lucidum is present in the lowest portion of the cornified layer (above the granular layer). This additional layer is rich in protein-bound lipids contained in the lamellar granules (5), energetic enzymes and SH groups secreted by the granular cells in molecular structure (70).

Common abnormalities of the cornified layer are: (a) hyperkeratosisâ€"increased thickness in the cornified layer (*e.g.*, ichythyosis); (b) parakeratosisâ€"presence of nuclei in the cornified layer (as usually seen in actinic keratosis); and (c) presence of fungal organisms (superficial dermatophytosis).

Basement Membrane Zone

The basement membrane zone separates the epidermal basal layer from the dermis. It is seen by light microscopy as a continuous, undulating and thin periodic acid-Schiff (PAS)-stained layer (Figure 1.7). By electron microscopy, the basal cells are attached to the basal lamina by hemidesmosomes (57). Ultrastructurally, the basement membrane zone is composed of four distinct structures, from top to bottom (Figure 1.8) (57,71):

- The plasma membrane of the basal cells containing the hemidesmosomes. Bullous pemphigoid antigen 1 is localized in the intracellular component of hemidesmosomes.

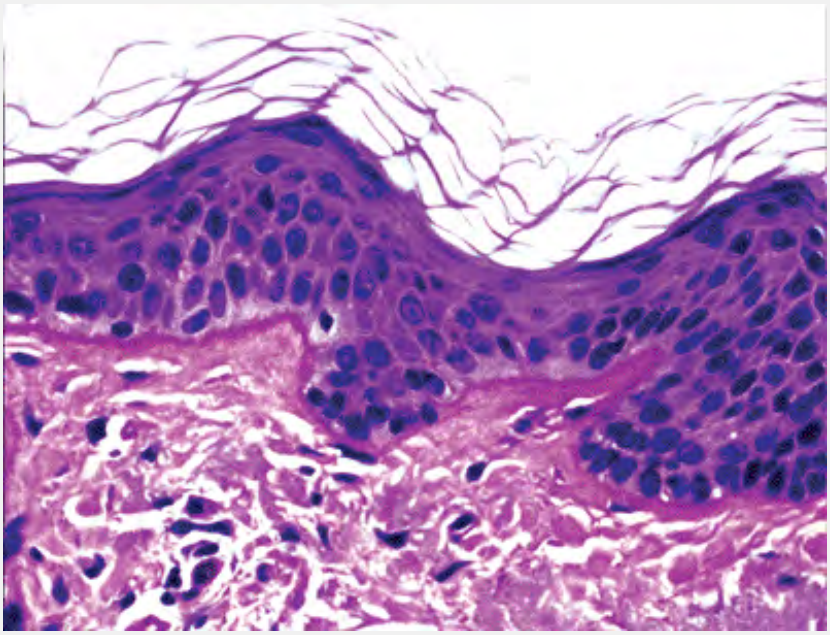

Figure 1.7 PAS-positive basement membrane.

- The lamina lucida, an electron-lucent area with anchoring filaments containing various laminin isoforms (1,72). Bullous pemphigoid antigen 2 (type XVII collagen) is associated with the transmembrane component of hemidesmosome-anchoring filament complexes in

the lamina lucida. It is also the site of the blister in dermatitis herpetiformis (73).

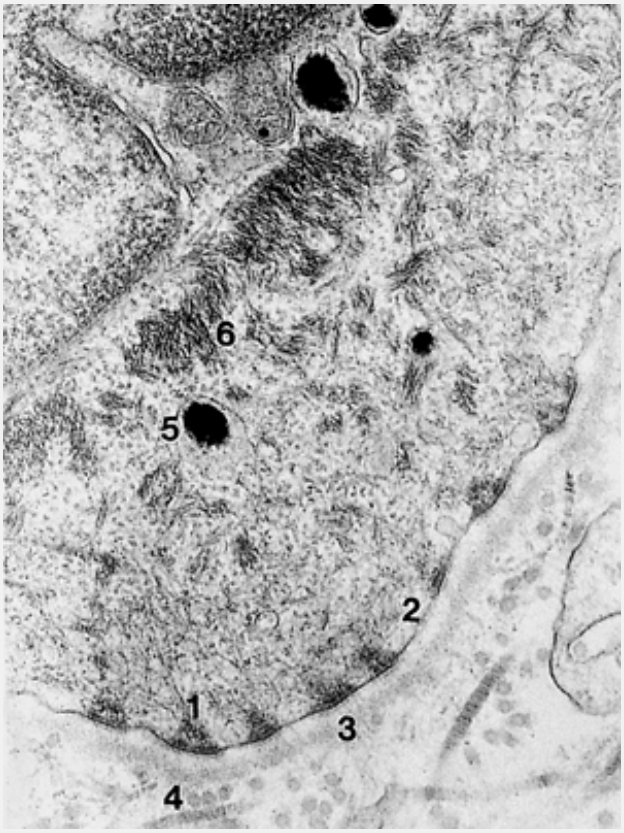

Figure 1.8 Ultrastructure of basement membrane (Ã—37,800). (*1,* hemidesmosome; *2*, lamina lucida; *3*, lamina densa; *4*, lamina reticularis; *5*, melanin; *6*, tonofilaments)

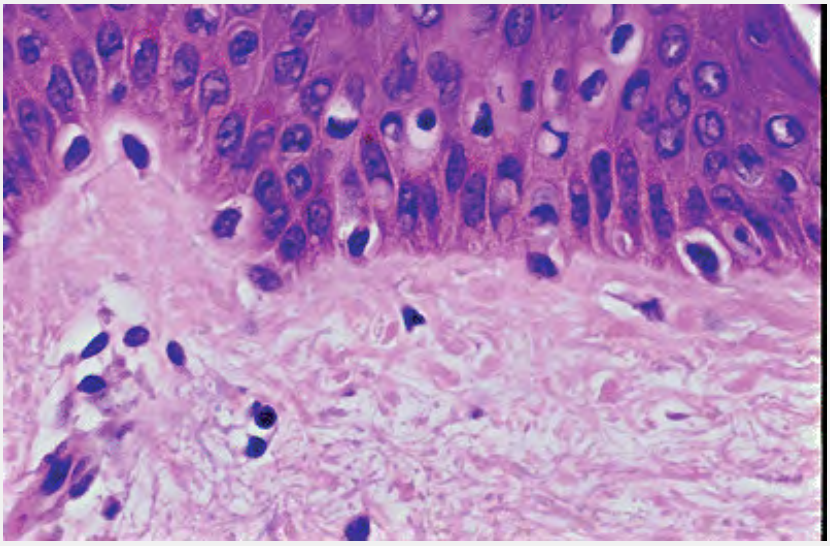

Figure 1.9 Melanocytes in the basal layer, composed of ovoid nuclei within a clear space.

- The lamina densa, an electron-dense area composed of mainly type IV collagen.
- The sublamina densa zone, or pars fibroreticularis, contains mainly the anchoring fibrils (74) (type VII collagen) that attach the basal lamina to the connective tissue of the dermis. Antibodies against epidermolysis bullosa aquisita react with the carboxy terminus of type VII collagen (75,76).

Inflammatory conditions of the basement membrane can be seen by light microscopy as thickening (*e.g.*, discoid lupus erythematosus) or by the formation of subepidermal vesicles (*e.g.*, bullous pemphigoid).

Melanocytes

Melanocytes are dendritic cells that derive from the neural crest. During migration from the neural crest, melanocytes may localize

in other epithelia. In the epidermis, the melanocytes are localized in the basal layer, and their dendritic processes extend in all directions. The dendritic nature of normal melanocytes is usually not seen in routine H&E-stained sections. In H&E preparations, melanocytes are composed of elongated or ovoid nuclei surrounded by a clear space (Figure 1.9). They are usually smaller than the neighboring basal keratinocytes. Melanocytes do not contain tonofilaments and do not attach to basal cells with desmosomes (5,77). However, anchoring filaments extend from the plasma membrane of these melanocytes to the basal lamina. Laminin-5, a component of anchoring filaments, may be a ligand for melanocyte attachment to the basement membrane in vivo (78). In addition, melanocytes that are close to the basal lamina have structures resembling hemidesmosomes of basal keratinocytes (79).

Melanocytes produce and secrete melanin. Melanin can be red (pheomelanin) or yellow-black (eumelanin) (80,81). The most important function of melanin is to protect against the injurious effects of non-ionizing ultraviolet irradiation.

Melanin is formed through a complex metabolic process in which tyrosinase is the main catabolic enzyme, using tyrosine as substrate. The synthesis of melanin takes place in melanosomes, lysosome-related organelles. In the early stages of development, melanosomes are membrane-limited vesicles, located in the Golgi-associated endoplasmic reticulum. The maturation of melanosomes undergoes four stages. Stage I melanosomes are round without melanin. These are seen in balloon cell melanoma. Stage II through stage IV melanosomes are ellipsoidal with numerous longitudinal filaments (5). Melanin deposits start at stage II. In stage III, melanin deposits are prominent. Stage IV melanosomes are fully-packed, with melanin obscuring the internal structures.

The developing melanosomes, with their content of melanin, are transferred to the neighboring basal keratinocytes and hair

follicular cells. The mechanism of melanin transfer is a complex process (82,83), with the end result being phagocytosis of the tip of melanocytic dendrites by the keratinocytes (Figure 1.10) in a process called pigment donation (84). The â€œepidermal melanin unitâ€• refers to one melanocyte with associated 36 keratinocytes to which the melanocytes deliver melanosomes (1).

The number of melanocytes in normal skin is constant in all races, the ratio being one melanocyte for every 4 to 10 basal keratinocytes (77,80). Thus, the color of the skin is determined by the number and size of melanosomes present both in keratinocytes and melanocytesâ€”and not by the number of melanocytes. The number of melanocytes decreases with age. As a result, the availability of melanin to keratinocytes diminishes, so the skin becomes lighter in color and the incidence of skin cancer increases.

Melanin is both argentaffin and argyrophilic. It can be recognized by Fontana-Masson silver stains. In addition,

melanocytes and their dendritic processes are identified by the dopa reaction in histologic slides prepared from frozen sections and in paraffin-embedded sections with immunohistochemical stains with S-100 protein. The latter is highly sensitive but not specific for cells of melanocytic lineage. The S-100 protein can be detected in various types of cells, such as Langerhans cells, schwann cells, eccrine, and apocrine gland cells. Melanocytes can also be identified with monoclonal antibodies to Melan A/MART-1 (Melanoma Antigens Recognized by T cells-1), a melanocytic differentiation marker. The MART-1 antigen is expressed in normal melanocytes, common nevi, Spitz nevi, and malignant melanoma (5). Under normal conditions, the melanoma-associated antigen HMB-45 does not react with adult melanocytes (85). It is expressed in embryonic melanocytes, hair bulb melanocytes and activated melanocytes (86). It is usually seen reacting with most melanoma cells, Spitz nevi, the junctional component of common

nevi, and dysplastic nevi.

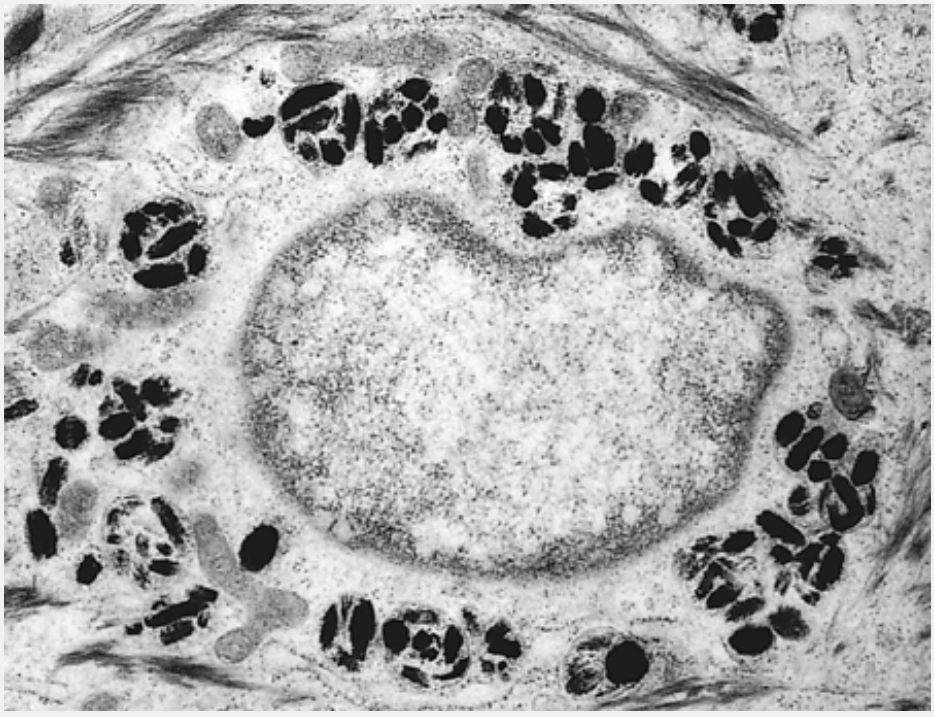

Figure 1.10 Electron micrograph showing membrane-bound phagocytized melanin in keratinocyte (Ã—19,200).

A decrease or absent number of melanocytes is seen in vitiligo. In albinism, there is a defect in the synthesis of melanin, but the number of melanocytes is normal in a skin biopsy. Melanocytic hyperplasia is seen in lentigo, benign and malignant melanocytic neoplasm, and as a reaction pattern in a variety of neoplastic and nonneoplastic conditions (*e.g.,* dermatofibroma). In a freckle, there is an increase in pigment donation to adjacent keratinocytes rather than melanocytic hyperplasia (84).

Langerhans Cells (LCs)

Langerhans cells (LCs), discovered by Paul Langerhans in 1868,

are mobile, dendritic, antigen-presenting cells present in all stratified epithelium and predominantly in the mid to upper part of the squamous layer. In H&E-stained sections, LCs can be suggested as they appear to lie within lacunae having darkly stained nuclei with indented, reniform shape at high magnification (Figure 1.11). As with melanocytes, their dendritic nature cannot be seen in routine sections. Langerhans cells can be recognized by histoenzymatic stains for adenosine triphosphatase (ATPase); they can also be detected in formalin-fixed, paraffin-embedded tissue using immunoreactivity for S-100 protein and, more specifically, the antibody to the CD1a antigen (Figure 1.12). With histoenzymatic and immunohistochemical stains, the extensive dendritic nature of LCs becomes evident.

By electron microscopy, LCs show no desmosomes, tonofilaments, or melanosomes. They contain small vesicles, multivesicular bodies, lysosomes, and the characteristic Birbeck granule (Figure 1.13) (87), a rod-shape organelle varying in size from 100 nm to1 Âµm (88). It has a centrally striated density and an occasional bulb at one end with a unique tennis racquet appearance. Their function is still undetermined. Langerin is a protein implicated in Birbeck granule biogenesis and represents a key molecule to trace LCs and study their function (89,90).

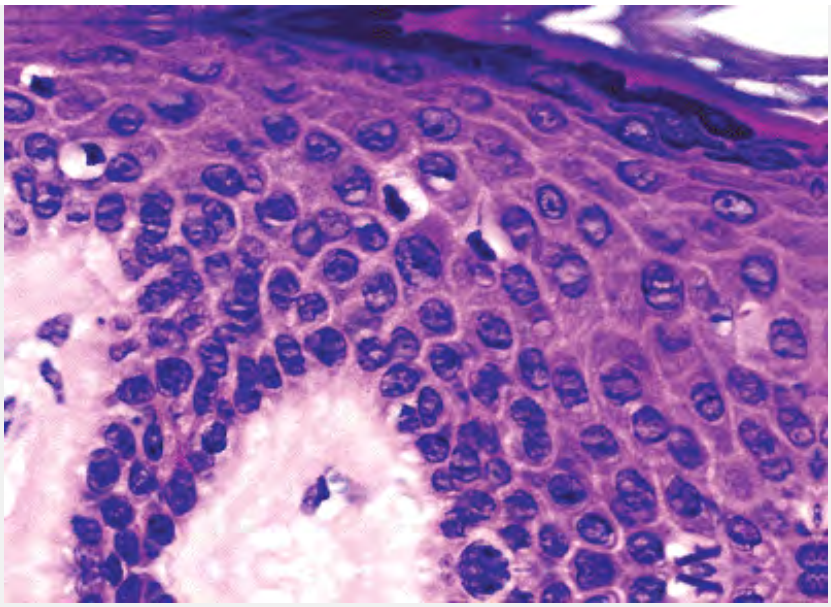

Figure 1.11 H&E section of possible Langerhans cells composed of elongated nuclei surrounded by a clear space in the mid-epidermis.

Langerhans cells are also present in epithelia, lymphoid organs, and dermis and are increased in the skin in a variety of inflammatory conditions, such as contact dermatitis, where they can be seen as minute nodular aggregates in the epidermis. Langerhans' cell granulomatosis is a reactive lesion most commonly seen in bones but also appearing at other sites.

Merkel Cells (MCs)

Merkel cells (MCs), first described by F.S. Merkel in 1875, are scattered and irregularly distributed in the basal cell layer in the epidermis. They may group together in clusters coupled with enlarged terminal sensory nerve fibers to form slowly adapting mechanoreceptors; within the epidermis, they mediate tactile sensation (91,92,93). They are

located in higher concentration in the glabrous skin of the digits, lips, and oral cavity (9), in the outer root sheath of hair follicles (94), and in the tactile hair disks (95).

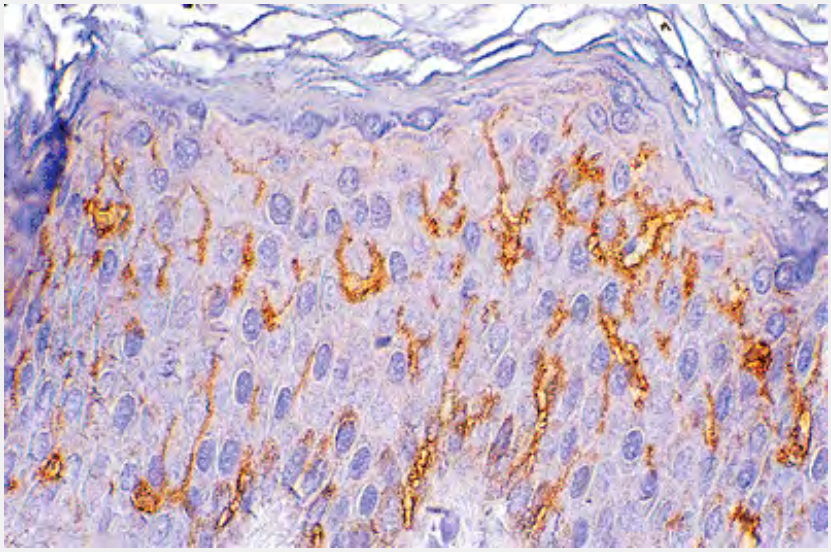

Figure 1.12 CD1a-specific reaction of Langerhans cells. Note the dendritic processes.

Merkel cells are not recognized in routine histologic preparations. Electron microscopy and immunostaining are required for their identification. By electron microscopy, MCs are attached to adjacent keratinocytes by desmosomes. They have scant cytoplasms, invaginated nuclei, a parallel array of cytokeratin filaments in the paranuclear zone, and the characteristic membrane-bound dense core granules that are often, but not always, related to unmyelinated neurites.

By immunostaining techniques, normal and neoplastic MCs may express neuron-specific enolase, chromogranin, synaptophysin, neural cell adhesion molecule, and various neuropeptides and other substances (96,97,98). However, the expression of these substances in MCs is heterogenous and variable. The constant

pattern seen in MCs is the presence of paranuclear aggregates of cytokeratins (16,98,99), which include low-molecular weight keratins 8, 18, 19, and 20. The most specific cytokeratin is CK20 because, in addition to MCs, they are expressed in simple epithelial cells and not in adjacent keratinocytes (100,101) (Figure 1.14).

Pilar Unit

The pilar unit is composed of the hair follicle, sebaceous gland, arrector pili muscle, and (when present) eccrine gland and apocrine gland.

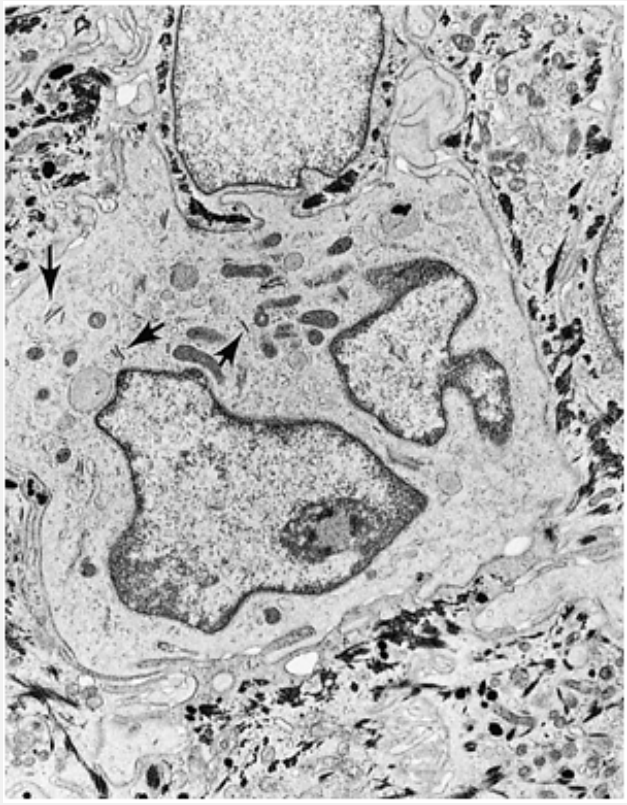

Figure 1.13 Electron micrograph of a Langerhans cell containing Birbeck granules (*arrows*) and multisegmented nucleus (Ã—8,000).

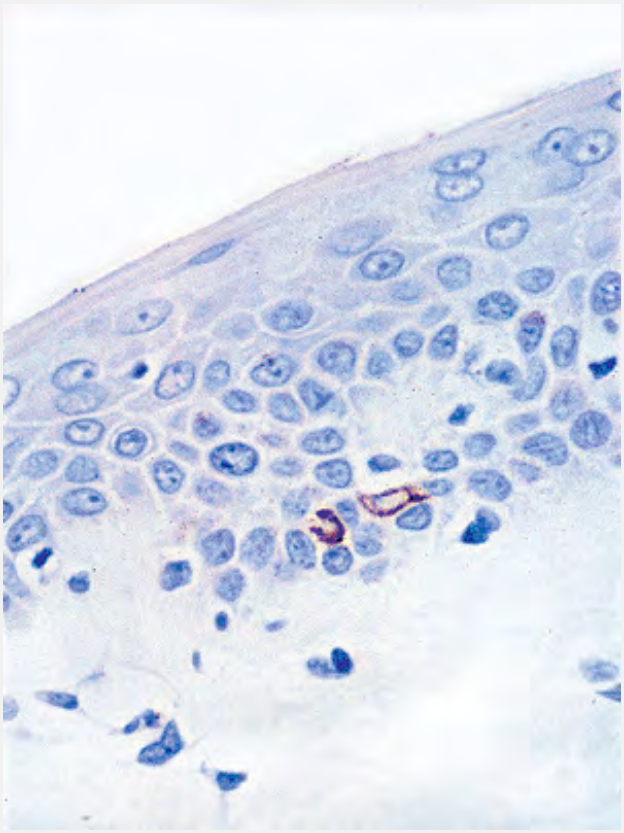

Figure 1.14 Cytokeratin-20 staining a Merkel cell in the basal layer of the epidermis.

Hair Follicle

The hair follicle is divided into three segments from top to bottom: (a) the infundibulum, which extends from the opening of the hair follicle in the epidermis to the opening of the sebaceous duct; (b) the isthmus, which extends from the opening of the sebaceous duct to the insertion of the arrector pili muscle; and (c) the inferior segment, which extends to the base of the follicle. The inferior segment is bulbous and encloses a vascularized component

of the dermis referred to as follicular (dermal) papilla of the hair follicle (Figure 1.15).

The microanatomy and function of the hair follicle is very complex. The cells of the hair matrix differentiate along six cell linings. Beginning from the innermost layer, they are: (a) the hair medulla; (b) hair cortex; (c) hair cuticle; and (d) three concentric layers of the inner root sheath, which are the cuticle of the inner root sheath, Hexley's layer, and Henle's layer.

The inner root sheath of the hair follicle is surrounded by the outer root sheath (Figure 1.16), which is composed of clear cells. These glycogen-rich cells are seen in some of the neoplasm with hair follicular differentiation (*e.g.,* trichilemmoma). A PAS-positive basement membrane separates the outer root sheath from the surrounding connective tissue. Thus, the hair shaft is formed from the bulb region that occupies the hair follicular canal.

Dendritic melanocytes are present only in the upper half of the bulb, whereas inactive (amelanotic) melanocytes are present in the outer root sheath. These melanocytes can become active after injury, migrating into the upper portion of the outer root sheath and to the regenerating epidermis (5).

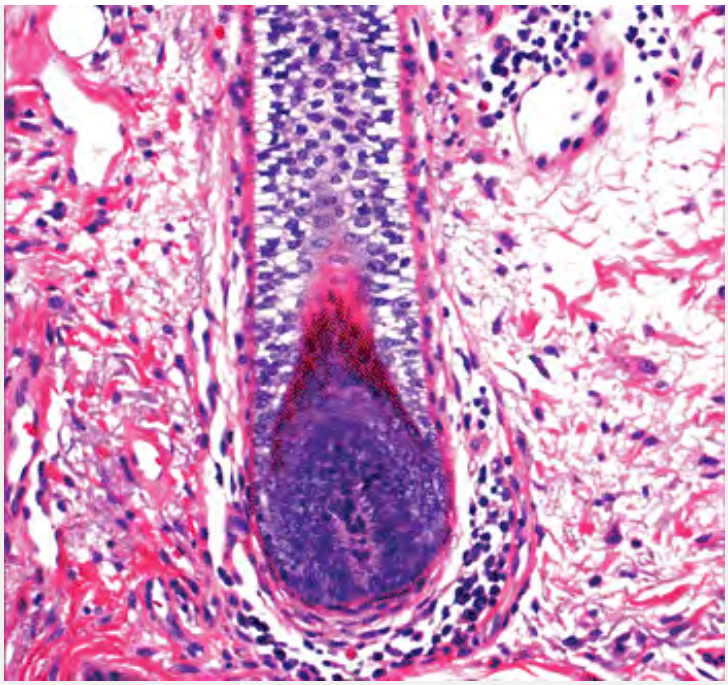

Figure 1.15 Inferior segment of the hair follicle, showing the hair papilla.

At the level of the isthmus, the cells of the inner root sheath disintegrate and disappear, whereas the cells of the outer root sheath begin an abrupt sequence of keratinization. This process is called trichilemmal keratinization (102). Trichohyalin granules are red in routine H&E-stained sections, as opposed to the blue granules of the keratohyalin of epidermal keratinization and of the epithelium of the follicular infundibulum of the hair follicle. The staining features of these granules permit neoplasms and cysts to be distinguished from either pilar or epidermal origin.

Under normal circumstances, microorganisms like *Staphylococcus epidermis*, yeasts of *Pityrosporum* (Figure 1.17), and the *Demodex folliculorum* (Figure 1.18) mites are encountered in the follicular infundibulum.

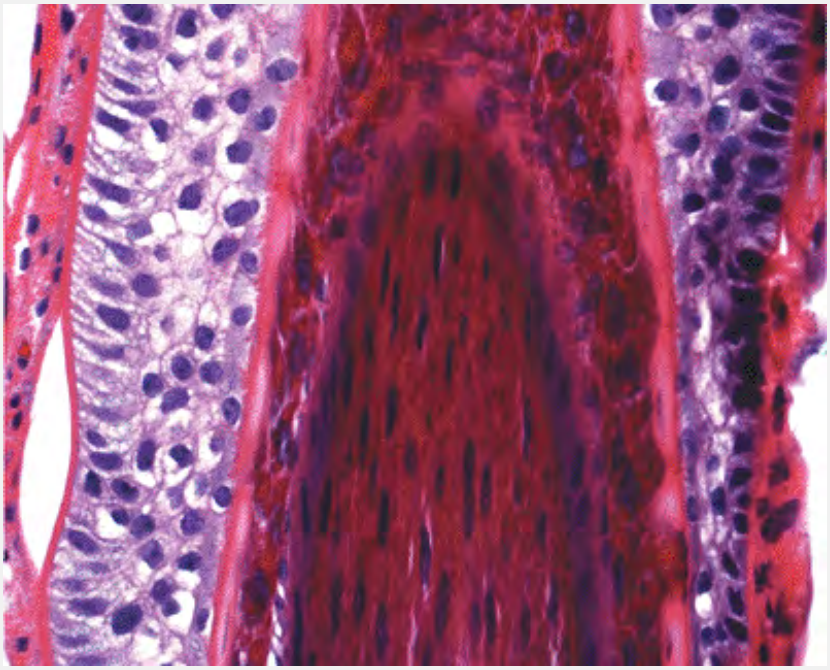

Figure 1.16 Hair follicle showing the hair shaft (*center*) surrounded by the inner root sheath, which contains trichohyalin granules. The outer root sheath is composed of clear cells.

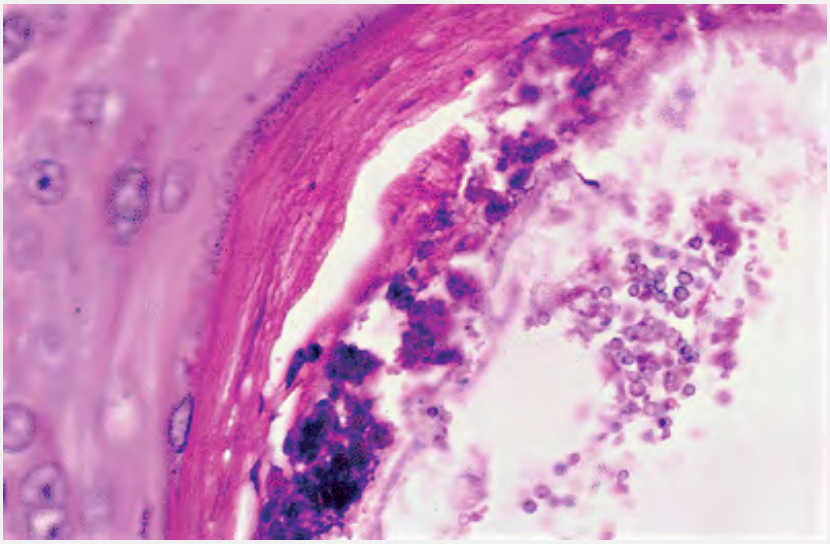

Figure 1.17 Yeasts of *Pityrosporum* in the follicular infundibulum.

The mantle hair of Pinkus (103) is a hair follicle in which proliferation of basaloid epithelioid cells emanating from the infundibulum is seen. Sebaceous proliferation is present in those cords (Figure 1.19). The significance of this hair follicle is not known.

The hair growth is in lifelong cyclic transformation. Hormones and their receptors play prominent roles in hair cycle regulation (104). Three phases are recognized: (a) anagenâ€"active growth phase; (b) catagenâ€"involuting phase (apoptosis-driven regression); and (c) telogenâ€"relative resting phase. The histologic features previously described correspond to the anagen hair.

During the catagen phase, mitosis and melanin synthesis cease at the level of the hair bulb. The hair bulb is then replaced by a cornified sac formed by retraction of the outer root sheath around the hair bulb, and a club hair is formed. A thick glassy basement membrane surrounds the hair follicle. Apoptosis of single cells in the outer root sheath is a characteristic finding during the catagen phase (40).

During the telogen phase, the club hair and its cornified sac retract even further to the insertion of the arrector pili muscle, leaving behind the dermal papilla, which is

connected to the retracted hair follicle by a fibrous tract (Figure 1.20) (24). When the cycle is complete, a new anagen phase begins with the formation of new hair matrix.

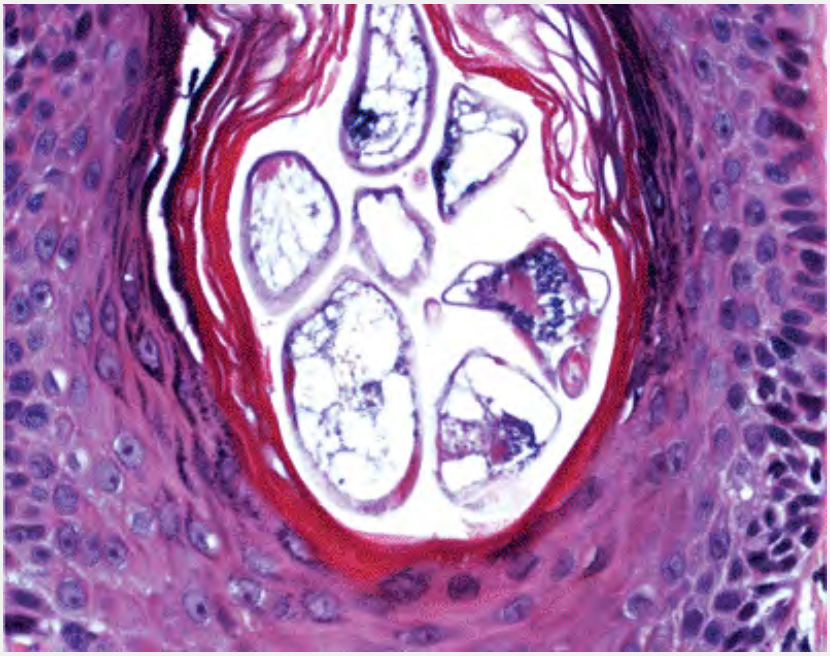

Figure 1.18 *Demodex folliculorum* mites in the follicular infundibulum.

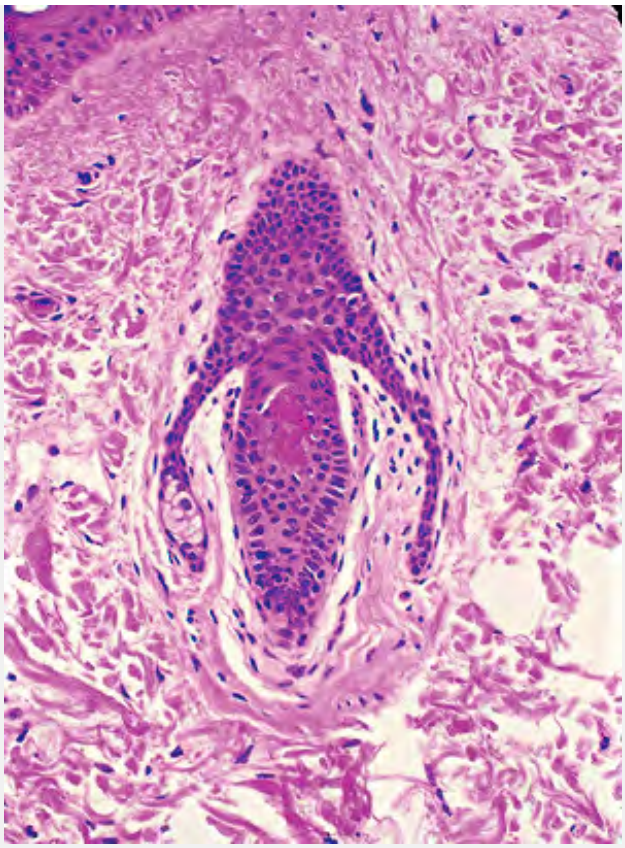

Figure 1.19 Mantle hair of Pinkus with lateral extensions containing sebaceous cells.

The duration of the normal hair cycle varies. The anagen phase is measured in years for the scalp, but it is measured in shorter periods of time for the anagen cycle in other regions of the body. The length of the hair is also related to the amount of the anagen hair. More than 80% of hair present in normal scalp is anagen hair. The catagen phase takes two to three weeks, and the telogen phase may last a few months.

The color of normal hair depends on the amount and distribution of the melanin in the hair shaft (24). Normal human epidermal melanocytes may synthesize both eumelanin and pheomelanin (105). The melanins in black hair are eumelanin (characterized by

the presence of ellipsoidal eumelanosomes), while those in red hair are mainly pheomelanin (ascribed to spherical pheomelanosomes) (105,106). Fewer melanosomes are produced in the bulbar melanocytes of blond hair. A relative absence of melanin and fewer melanosomes are seen in gray hair. Multiple internal or external regulatory factors are involved in hair pigmentation. There might be some correlation between tryptophan content and tyrosinase expression with hair color (107,108).

Another structure related to the pilar unit is the hair or pilar disk (the Haarscheibe). The Haarscheibe is a specialized spot in close vicinity to hairs. This structure is usually not recognized on routine histologic section. It may present as an acanthotic elevation of the epidermis, limited by two elongated rete ridges laterally (1). The epidermis in this area has more Merkel cells in the basal layer, and the dermal component is well vasculized, containing myelinized nerve fibers in contact with Merkel cells (22,95). It is considered as a highly sensitive, slowly adapting mechanoreceptor (1,109).

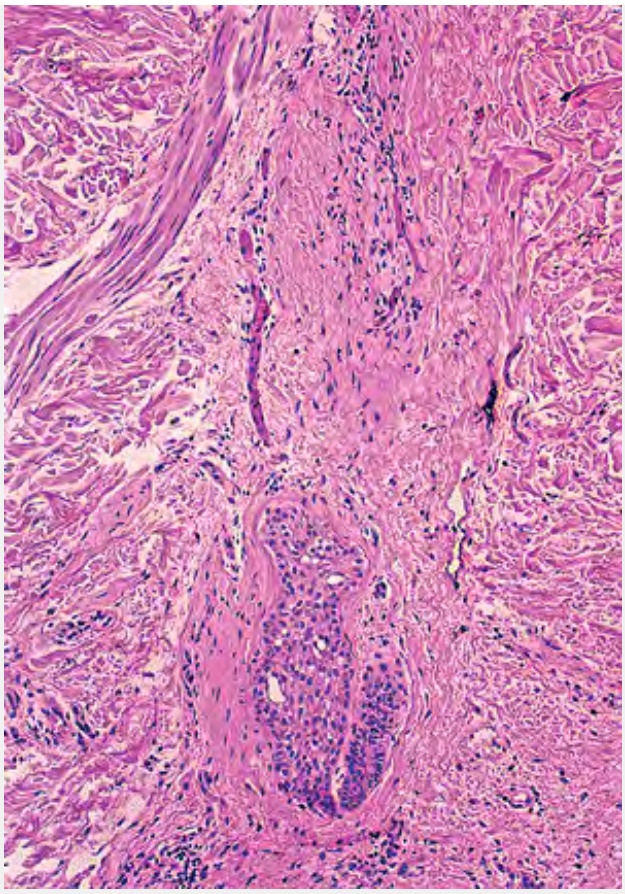

Figure 1.20 Catagenâ€“telogen hair follicle located entirely within the dermis.

Sebaceous Glands

The sebaceous glands are holocrine glands associated with hair follicles. Their secretions are made of disintegrated cells. The palms and soles are the only regions devoid of sebaceous glands. Sebaceous glands are prominent in facial skin. They are also seen in the buccal mucosa, vermilion of the lip (Fordyce's spot), prepuce, labia minora, and, at times, in the parotid gland.

The sebaceous glands are lobulated structures composed of multiple acini in some locations like the head and neck; in other

sites, such as chest, they are composed of a single acinus. The periphery of the lobules contains the germinative cells, which are cuboidal and flat with large nucleoli and basophilic cytoplasms without lipid droplets. As differentiation occurs, several inner layers show lipid droplet accumulation in the cytoplasm until they fill the cell.

The more differentiated cells (sebocytes) have a characteristic multivacuolated cytoplasm (Figure 1.21). The nucleus is centrally located and scalloped due to the lipid imprints. The more differentiated cells disintegrate and discharge the cellular debris (sebum) into the excretory duct, which opens into the hair follicle in the lower portion of the infundibulum. The excretory duct is short, shared by several lobules, and lined by keratinized squamous epithelium.

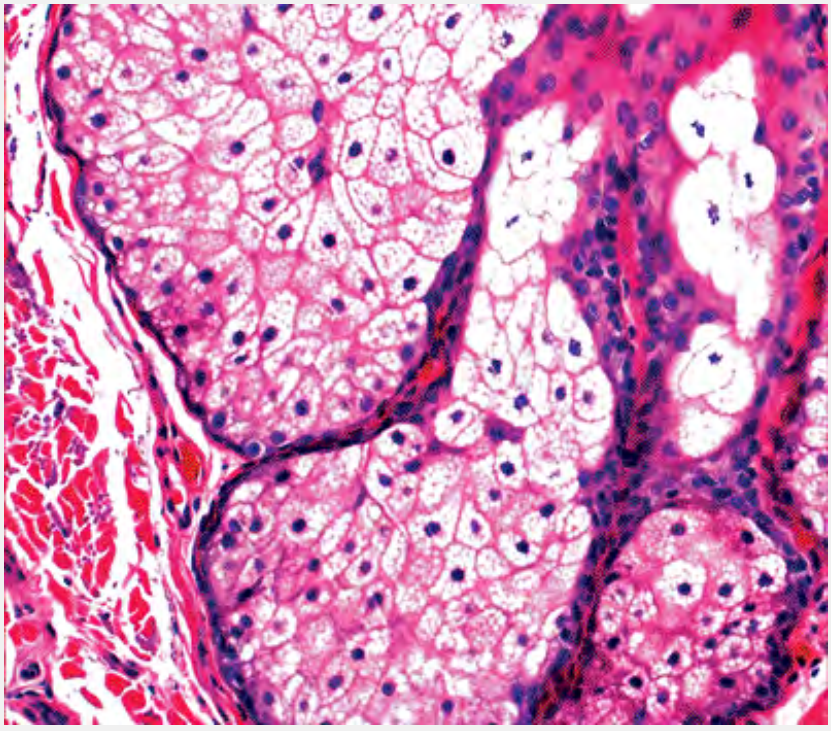

Figure 1.21 Sebaceous glands with peripheral germinative cells and, toward the center, the differentiated vacuolated

cells.

Within sebaceous glands, the germinative cells express appreciable quantities of keratins. Mature sebocytes demonstrate cytoplasmic reactivity for high-molecular weight keratins and epithelial membrane antigen (1).

Eccrine Glands

The eccrine glands are the true sweat glands responsible for thermoregulation. They are found in higher concentration in palms, soles, forehead, and axillae and have dual secretory and excretory functions.

The secretory portion of an eccrine gland is a convoluted tube located in the dermis, in the interface with the subcutaneous tissue, and, rarely, within the subcutaneous tissue. In cross-sections, it appears that several glandular structures with a central lumen form the secretory coils. These are seen as lobular structures often surrounded by fat even when located within the dermis (Figure 1.22).

Three types of cells are identified in the eccrine coil: clear cells, dark cells, and myoepithelial cells. The clear cells are easily seen H&E-stained sections (Figure 1.23). They rest directly on the basement membrane and on the myoepithelial cells. Clear cells are composed of pale or finely granular cytoplasms with a round nucleus usually seen in the center of the cell. Deep invaginations of the luminal membranes of adjacent clear cells form intercellular canaliculi lined with microvilli (Figure 1.24) (110). The intercellular canaliculi often persistent in neoplasms derived from eccrine glands. The clear cells contain abundant mitochondria and variable amount of PAS-positive, diastase-labile glycogen.

The dark cells border the lumen of the glands. Electron microscopy shows that they contain abundant secretory granules that have glycogen-staining characteristics. They contain sialomucin (PAS-positive, diastase-resistant (PASD) mucopolysaccharides) and high concentration of proteins (5,111). The dark cells are difficult to identify in routine H&E-stained sections. However, the acid-fast, PASD, and S-100 protein stains will highlight the granularity of the cells (Figure 1.25) (22).

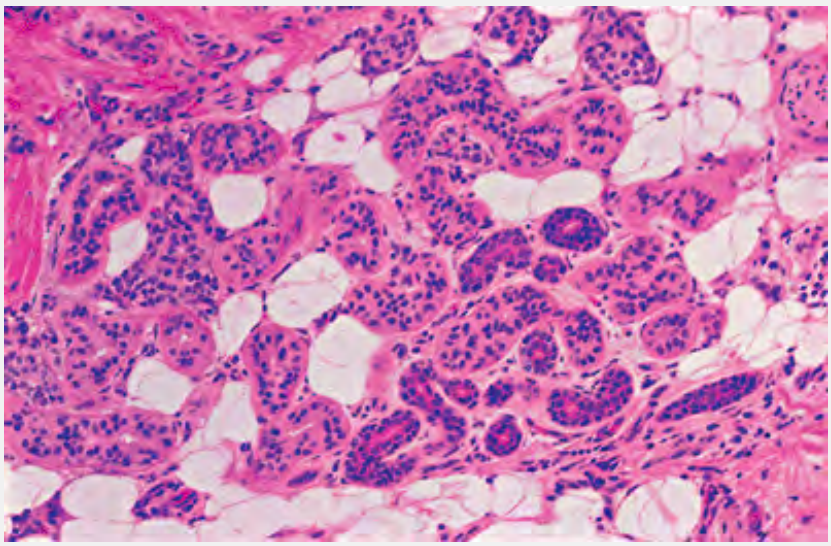

Figure 1.22 Eccrine lobule containing fat, glands, and ducts.

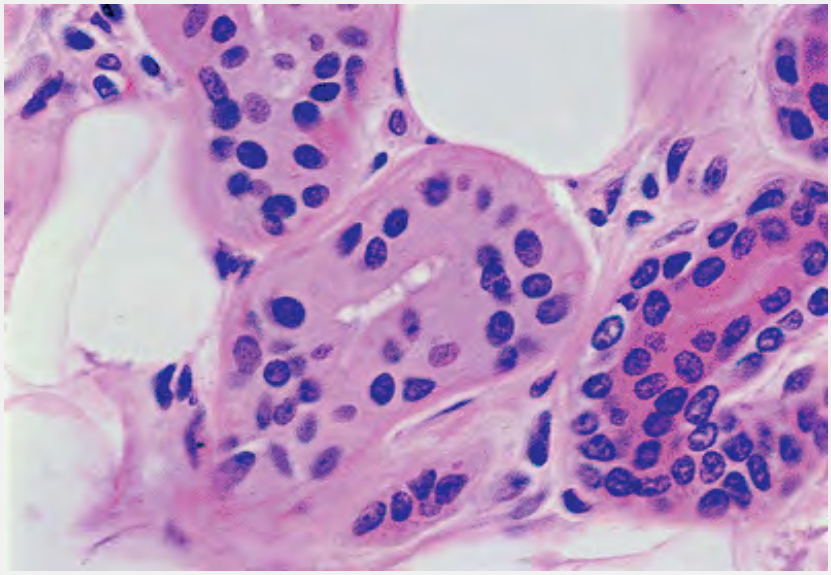

Figure 1.23 Clear cells of the eccrine glands.

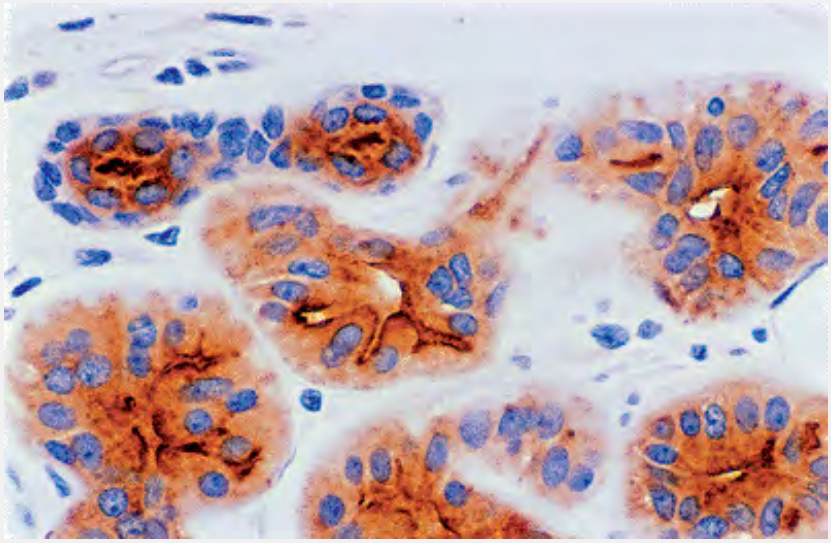

Figure 1.24 Intercellular canaliculi (anti-CEA).

The myoepithelial cells are contractile spindle cells that surround

the secretory coil (Figure 1.26). In turn, they are surrounded by a PAS-positive basement membrane. Elastic

fibers, fat, and small nerves are present in the adjacent stroma.

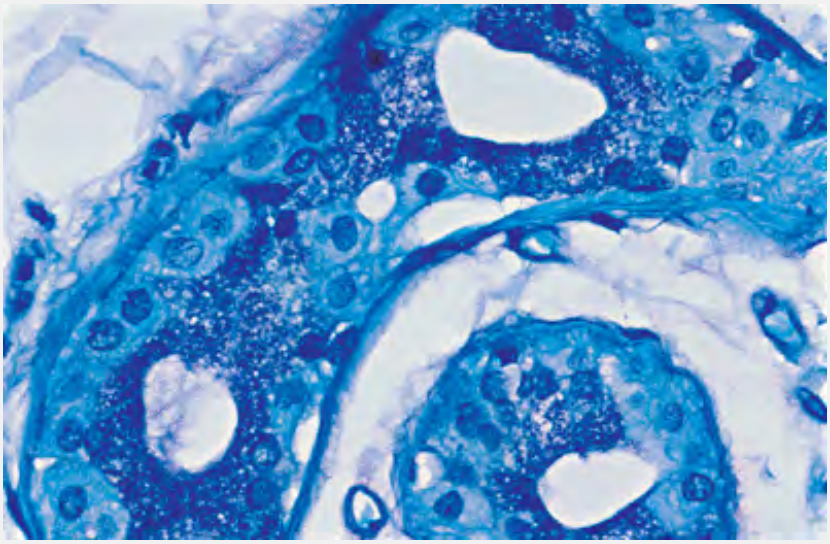

Figure 1.25 Dark cells with granular cytoplasm (acid-fast stain).

The excretory component of the eccrine gland is composed of three segments: (a) a convoluted duct in close association with the secretory unit (Figure 1.27); (b) a straight dermal component; and (c) a spiral intraepidermal portion, the acrosyringium, which opens onto the skin surface (Figure 1.28). The transition between the secretory and excretory component is abrupt. Both convoluted and straight dermal ducts are histologically identical. They are narrow tubes with a slitlike lumina lined by double layers of cuboidal cells. The luminal cells have a more granular eosinophilic cytoplasm and a larger round nucleus than the peripheral row of cells. The peripheral cells are rich in mitochondria.

The luminal cells produce a layer of tonofilaments near the luminal

membrane that are often referred to as â€œthe cuticular border,â€• which is a PASD eosinophilic cuticle (5). This cuticular border often persists in the eccrine neoplasm (*e.g.*, eccrine poroma). There are no myoepithelial cells and peripheral hyalin basement membrane zone in the eccrine ducts (5).

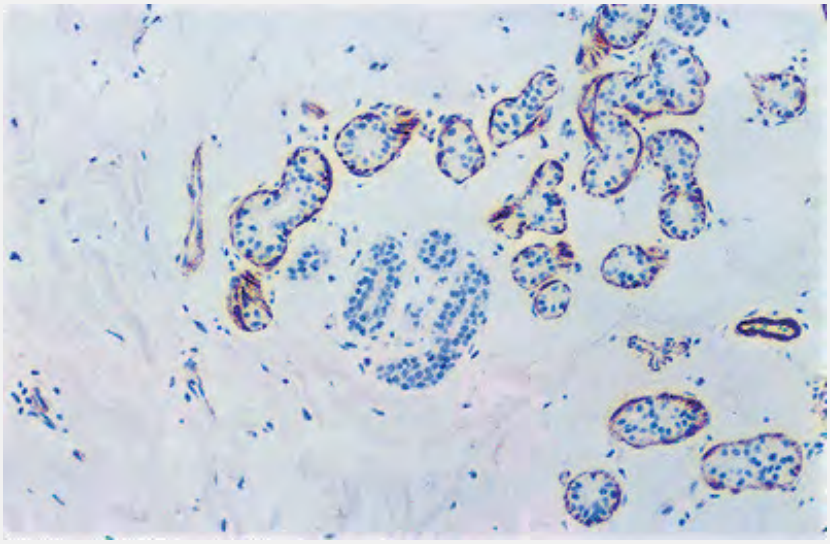

Figure 1.26 Glands, but not the ducts, are surrounded by myoepithelial cells (anti-HHF35).

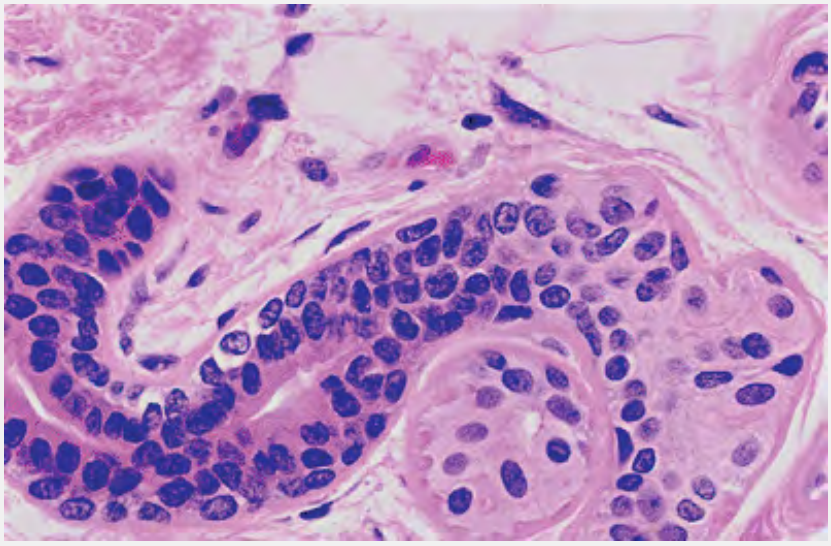

Figure 1.27 Eccrine duct. Note the abrupt transition from the secretory portion.

The intraepidermal segment of eccrine duct, known as acrosyringium has a unique symmetrical and helicoidal course in the epidermis with its length correlated to the thickness of the epidermis (43). It consists of a single layer of luminal cells and two or three rows of concentrically oriented outer cells. The presence of keratohyalin granules in acrosyringium in the lower levels of the squamous layer indicates that they keratinize independently. The intraepidermal lumen is lined by acellular eosinophilic cuticle before keratinization (5,24). Melanin granules are absent.

Apocrine Glands

The apocrine gland (Figure 1.29) has a coiled secretory portion and an excretory (ductal) component. The secretory portion is much longer than its eccrine counterpart; and it may reach 200 Âµm in diameter, compared to 20 Âµm for the eccrine glands (77).

subcutaneous fat or in the deep dermis. They are lined by one layer of cuboidal, columnar, or flat cells (luminal cells), and an outer layer of myoepithelial cells, which is surrounded by a PAS-positive basement membrane. The luminal cells are composed of eosinophilic cytoplasm, which may contain lipid, iron, lipofuscin, PASD granules (24), and a large nucleus located near the base of the cell. Detached fragments of apical cytoplasm are found in the lumen of the glands. The secretion from apocrine glands releases secretory materials accompanied with loss of part of cytoplasm (112), although other forms of secretion have been observed, including melocrine (granular contents within numerous vesicles are released without loss of cytoplasm) and holocrine type (the entire cell is secreted into the glandular lumen) (50,112).

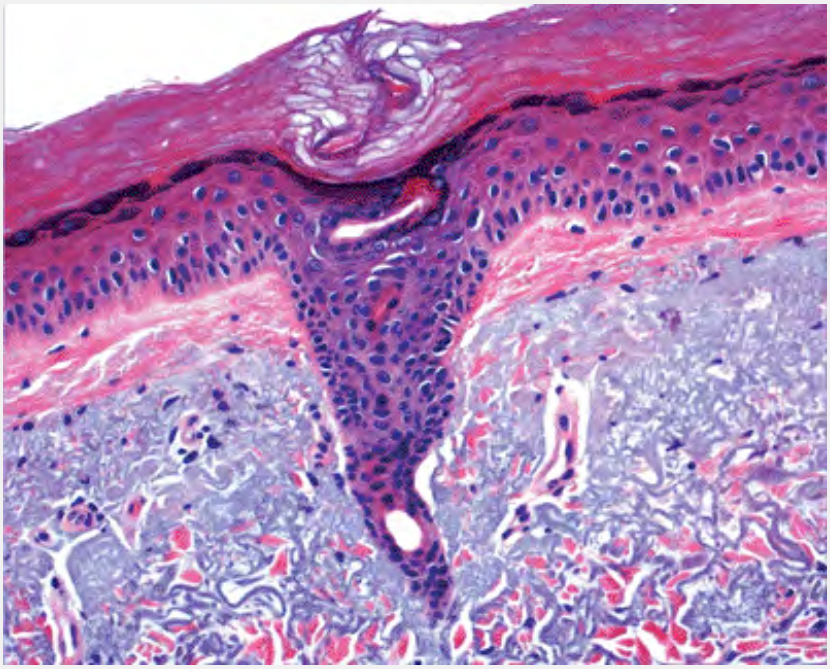

Figure 1.28 Acrosyringium.

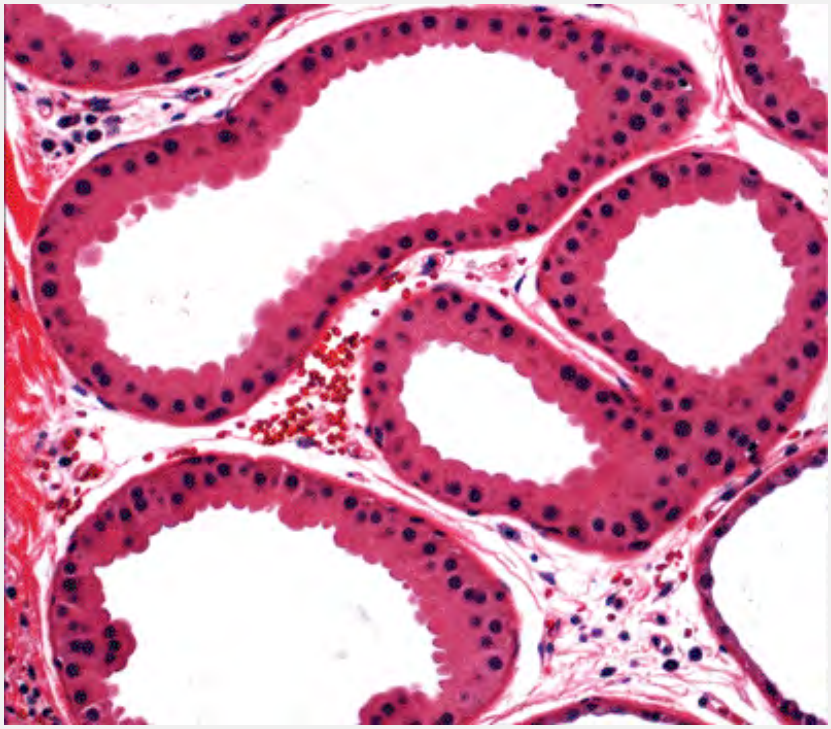

Figure 1.29 Secretory apocrine glands.

Similar to the eccrine duct, the excretory (ductal) component of the apocrine gland has a double layer of cuboidal cells. Microvilli are identified on the surface of the luminal cells and keratin filaments are in their cytoplasms, the latter giving the eosinophilic hyalin appearance to the inner lining of the duct. No myoepithelial cells and peripheral basement membrane are identified in the excretory duct. Apocrine glands are always connected to a pilosebaceous follicle. The intrafollicular or intraepidermal portion of apocrine duct is straight other than the spiral as seen in acrosyringium (5).

Apocrine glands are mostly located in the axillary, anogenital areas, mammary region, eyelids (Moll's glands), and external ear canal (ceruminous glands), and their presence is characteristic in

Nevus sebaceous Jadassohn.

A third type of sweat gland, so-called â€œapoeccrine glandsâ€• of the human axillae (113), are composed of a dilated secretory portion that, by electron microscopy, is indistinguishable from the apocrine glands; however, they retain the intercellular canaliculi, as well as the dark cells of the eccrine glands. The duct does not open in the hair follicle but in the epidermis. These glands, which develop from eccrine glands during puberty, account for as much as 45% of all axillary sweat glands in a young person. Recently, it was reported that the obstruction of intraepidermal apoeccrine sweat ducts by apoeccrine secretory cells might be the possible causes of Fox-Fordyce disease (114).

The most useful marker of sweat gland differentiation is carcinoembryonic antigen (CEA), found mainly in the luminal borders of secretory cells of eccrine glands and excretory eccrine ducts and, to a less extent, on apocrine glands. Gross cystic disease fluid protein-15 (GCDFP-15) and epithelial membrane antigen (EMA) are also detected in both eccrine and apocrine sweat glands (1,115). Myoepithelial cells lining the secretory sweat glands express smooth muscle actin and keratin K17 (1).

Dermis

The dermis is a dynamic, supportive connective tissue harboring cells, fibrous tissue, and ground substances with adnexal structures and vascular and nerve plexuses running through it (1). The dermis (Figure 1.30) consists of two zones: the papillary dermis and reticular dermis. The adventitial dermis (116) combines the papillary and the periadnexal dermis.

The papillary and periadnexal dermis can be recognized by a loose meshwork of thin, poorly organized collagen composed of predominantly type III collagen (117,118,119) mixed with some type I collagen and a delicate branching network of fine elastic

fibers. The papillary dermis also contains abundant ground substance, fibroblasts and the capillaries of the superficial arterial and venous plexuses.

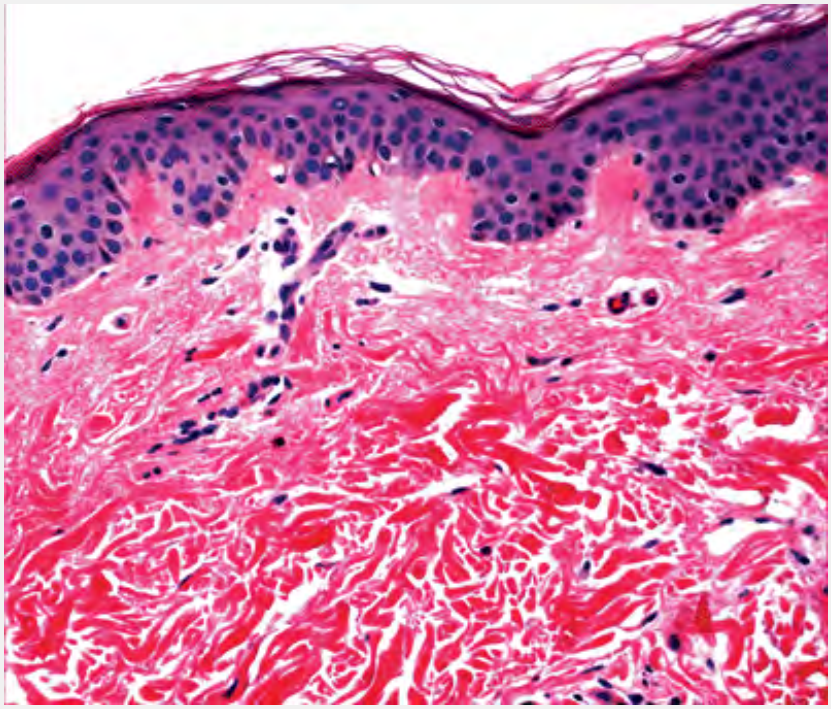

Figure 1.30 Dermis with papillary and thick reticular dermis.

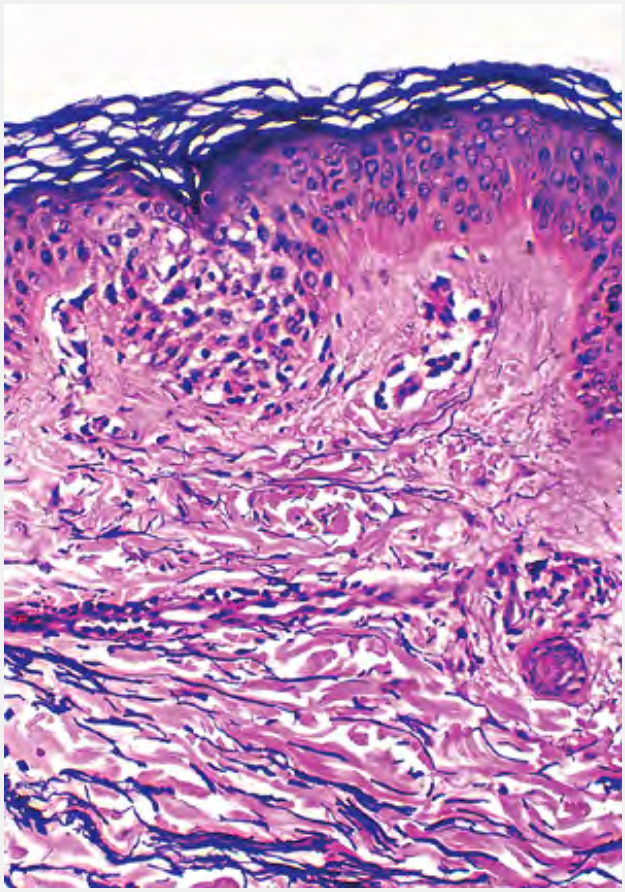

Figure 1.31 Distribution of elastic fibers. Elastin fibers are thin and branching in the papillary dermis and thick and fragmented in the reticular dermis.

The reticular dermis is thicker than the papillary dermis and is composed of multiple layers of well-organized thick bundles of collagens, predominantly type I collagen, mostly arranged parallel to the surface (117,118,119). These layers are built from overlapping of individual fibers of uniform size. The plates are oriented randomly in different directions (120). There are also thick elastic fibers with fragmented appearance detected by special elastic tissue stains (Figure 1.31). Some ground substance and the vessels of the deep plexuses are also present in the

reticular dermis.

The resident cells in the dermis mainly include dermal dendritic cells, fibroblasts, and mast cells (1). Dermal dendritic cells are a group of cells with immunophenotypic and functional heterogeneity located in the dermis and possessing a dendritic morphology (121). There are multiple subsets of dendritic cells. At least three types of dermal dendritic cells are recognized as distinct cell types with unique immunophenotype in vivo (122,123).

- Factor XIIIa+ dermal dendrocytes are in the perivascular distribution in the papillary dermis and around sweat glands (1,122). Dermal dendrocytes, also known as dendrophages (126), express some markers of mononuclear macrophages (124) and have phagocytic function (125).
- CD34+ dendritic cells are present in the mid- and deep dermis around adnexae (1,122).
- The dermis harbors a true dendritic cell population, also in a perivascular distribution. These are Langerhans' cellâ€“like dendritic cells involved in dermal antigen presentation, expressing HLA-DR and CD1a except for lack of Birbeck granules (123,127,128).

Fibroblasts are the dynamic and fundamental cells of the dermis, synthesizing all types of fibers and ground substances (1,119). They appear as spindle-shaped or stellate cells, which are not reliably differentiated from other dermal spindle-shaped cells and dendritic cells in H&E-stained sections. Ultrastructurally, they contain prominent, well-developed rough endoplasmic reticulum.

Mast cells are derived from bone marrow CD34+ progenitor cells and are sparsely distributed in the perivascular and periadnexal dermis. They are recognized by a darkly stained ovoid nucleus and granular cytoplasm, which is highlighted by Giemsa and toluidine blue stains. Mast cells are positive with tryptase and c-kit (CD117)

immunohistochemical stains (129,130,131). Mastocytosis is characterized by abnormal growth and accumulation of mast cells in various organs with heterogenous manifestation. Urticaria pigmentosa is the most common cutaneous manifestation of mastocytosis (132,133).

Macrophages are also seen in the normal dermis; they become visible when pigments or other ingested material is present in the cytoplasm of the cells.

Besides fibrous tissue and cellular components, the dermis also contains amorphous ground substance filling the spaces between fibers and dermal cells. It mainly consists of glycosaminoglycans or acid mucopolysaccharides (the nonsulfated acid mucopolysaccharides [predominantly hyaluronic acid] and, to a lesser degree, sulfated acid mucopolysaccharide [largely chondroitin sulfate)]) (1,5). The ground substance is present in small amounts and is seen as empty spaces between collagen bundles in routine H&E-stained sections; it also is hardly identified with Alcian blue and toluidine blue special stains. In pathologic conditions such as lupus erythematosus, granuloma annulare, and dermal mucinosis, the excessive quantity of ground substance produced can be seen without the aid of special stains as strings of bluish material.

Subcutaneous Tissue

Subcutaneous tissue, also called subcutis or hypodermis, is crucial in thermal regulation, insulation, provision of energy, and protection from mechanical injuries. It is composed of mature adipose tissue arranged into lobules. The mature adipocytes within the lobules are round cells rich in cytoplasmic lipids, which compress the nucleus to the side of the cell membrane. The adipocytes express S-100 protein and vimentin in immunohistochemical stains (123). These lobules of mature adipocytes are separated by the thin bands of dermal connective

tissue that constitute the interlobular septa (Figure 1.32). Thus, inflammatory changes involving the subcutaneous tissue can be divided into septal panniculitis (*e.g.*, erythema nodosum) and lobular panniculitis (*e.g.*, panniculitis associated with pancreatitis) (24).

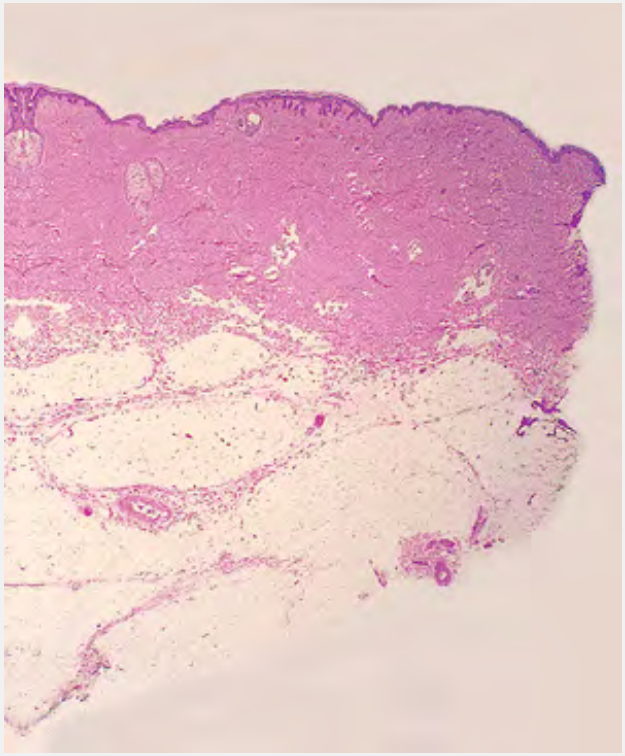

Figure 1.32 Septa and lobules of subcutaneous fat.

Blood Vessels, Lymphatics, Nerves, and Muscle

The large arteries that supply the skin are located in the subcutaneous tissue, usually within the interlobular septa, and are accompanied by large veins. Smaller arteries, venules, and

capillaries constitute the main vasculature seen in the dermis and within the lobules of the subcutaneous fat.

A network of these smaller vessels is located in the papillary dermis (superficial plexus) and in the deep reticular dermis (deep plexus). Superficial vascular plexuses separate the papillary dermis from the reticular dermis, whereas the deep vascular plexuses define the boundary between the reticular dermis and subcutaneous tissue. The division of superficial and deep plexuses is important in the classification and recognition of many inflammatory diseases of the skin in which characteristic infiltrates are located around the superficial, deep, or superficial and deep plexuses. Blood endothelial cells express von Willebrand factor (factor VIII-related antigen), vimentin, CD34, and CD31 antigens (1,123).

Vasculitis is the inflammatory process that involves the blood vessels. It is important to remember that strict criteria are applied for the diagnosis of cutaneous vasculitis, and they include: (a) the presence of inflammatory cell infiltrate within the vessel wall, and (b) the presence of vascular injury, in a spectrum from edema and extravasations of red blood cells, leukocytoclasis, thrombi within the lumina of these blood vessels to fibrinoid necrosis and/or destruction of the blood vessel wall (Figure 1.33). The presence of fibrinoid necrosis of the vessel wall is essential for diagnosis of true vasculitis. Perivascular inflammation alone is not a sign of vasculitis.

Mainly in the acral skin, special arteriovenous anastomosing structures known as glomera are present in the reticular dermis. Each glomus is composed of an arterial segment (the Sucquet-Hoyer canals) connected directly with venous segments. Each Sucquet-Hoyer canal is surrounded by four to six layers of glomus cells, which are considered as vascular smooth muscle cells serving as a spincter. Glomus is involved in thermal regulation (1,5).

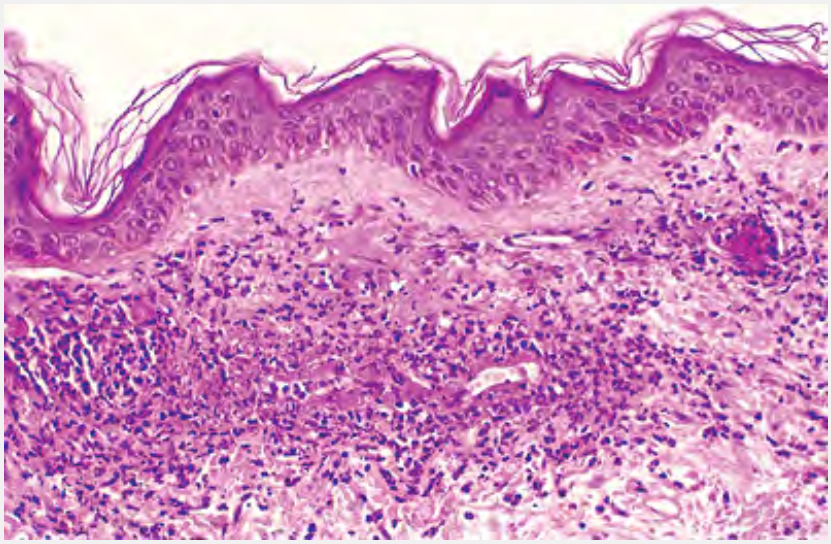

Figure 1.33 Vasculitis. Case of leukocytoclastic vasculitis showing damage to the capillary wall.

The lymphatics of the skin (134) accompany the venules and are also located in the deep and superficial plexuses. Unless valves are seen within these vessels, their recognition in routine sections is impossible. Under normal conditions, they are surrounded by a cuff of elastic fibers. In contrast to blood endothelial cells, lymphatic endothelium do not react with antibodies to von Willebrand factor (factor VIII-related antigen) and CD34 (123).

Large nerve bundles are seen in the subcutaneous fat and in the deep reticular dermis; however, small nerve fibers are present throughout the skin, reaching the papillary dermis. As mentioned earlier, recent immunohistochemical studies have demonstrated that the epidermis contains free nerve axons in association with Langerhans cells (55).

In sections of the palm and sole, some sensory nerves form nerve ending organs. Meissner corpuscles are seen in the papillary dermis, which is composed of several parallel layers of Schwann

cells containing an axon; they function as rapid mechanical receptors for the sense of touch. In weight-bearing areas, the Vater-Pacini corpuscles consist of concentrically arranged Schwann cells with an axon and are located in the deep dermis and subcutaneous fat. They serve as receptors for sense of deep pressure and vibration (Figure 1.34).

Smooth muscle is represented in the skin by the arrector pili muscles, which arise in the connective tissue of the dermis and insert into hair follicles below the sebaceous glands. Melanocytes of congenital nevus are often seen within the arrector pili muscle. Smooth muscle is also seen in the skin of external genitalia (tunica dartos) and in the areolae.

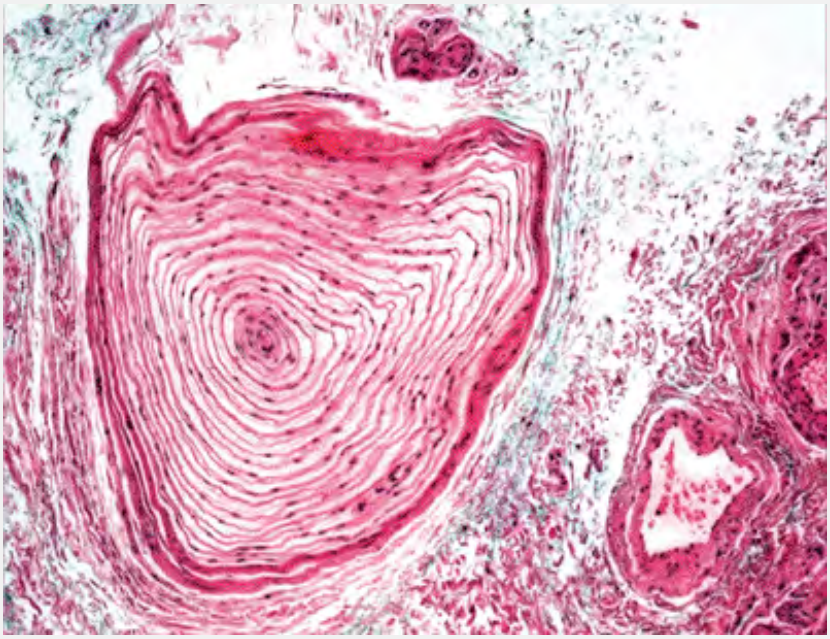

Figure 1.34 Vater-Pacini corpuscle.

Strands of striated muscle are found in the skin of the neck, face, and particularly the eyelids as muscle of expression.

Histologic Differences of Skin with Age

Newborns and Children

The epidermis of newborns and children is usually of the same thickness as in adults, with the exception of the acral skin. There is a greater density of melanocytes and Langerhans cells.

The dermis is more cellular than in the adult with a higher concentration of ground substance. The number of eccrine glands is higher at birth, while apocrine glands are not well developed until after puberty (135). The sebaceous glands are developed in children, but sebaceous secretion begins at puberty under the influence of androgen stimulation (136).

The adipocytes of the subcutaneous tissue in newborns and children are thin-walled and larger than the adult adipocytes. In addition to white fat as seen in adults, infants possess brown fat, which initially comprises up to 5% of body weight then diminishes with age to virtually disappear by adulthood. Brown adipocytes are rich in mitochondria and contain multiple lipid droplets of varying size in the cytoplasm with centrally located nuclei. Brown fat contains an abundance of blood-filled capillaries and is of particular importance in neonates because it has the ability to produce heat (thermogenesis) by degrading fat molecules into fatty acids (137,138).

Elderly

In the elderly, the histologic differences are mainly due to atrophy and to reduction of most cutaneous elements (139,140,141). The cells of the epidermis are arranged haphazardly because of aberrant proliferation of the basal cell layer, which may predispose to the development of neoplasms (142). There is a marked decrease in the number of melanocytes and in the number of

melanosomes, leading to reduced pigmentation (140,143) and, consequently, more exposure to the damaging effects of ultraviolet light. The Langerhans cells also decrease in number and function with advanced age (140,143), which increases the damaging effects of contactants and partially contributes to age-associated deterioration of immune function (144).

In the elderly, the dermis is thinned, relatively acellular, and avascular. The dermal collagen, elastin, and ground substance are altered and reduced (139,142). Elastic fibers show structural and biochemical alterations that change the elasticity of the skin. Collagen bundles are thicker but stiffer. The net effect is that age-associated alterations make the dermis less stretchable, less resilient, and prone to wrinkling (145). Fibroblasts, dendritic cells, and mast cells are also reduced in number.

Because of the reduction in the cutaneous vascular supply, there is a decrease in inflammatory response, absorption, and cutaneous clearance (146).

Both eccrine and apocrine glands are also reduced, with diminished secretions in the elderly. Sebaceous glands increase in size and manifest clinically as sebaceous hyperplasia, but paradoxically their secretory output is lessened by decreased activity (139,147).

With age, the number and rate of growth of hair follicles decreases, vellus hair will develop into terminal hairs in unusual

sites, such as the ear, nose, and nostrils, resulting in possible cosmetic problems. There is also a decreased functioning of Meissner's and Vater-Pacini corpuscles (148). Finally, there is diminished subcutaneous tissue especially in the face, shins, hands, and feet, but it increases in other areas, particularly the abdomen in men and the thighs in women (139).

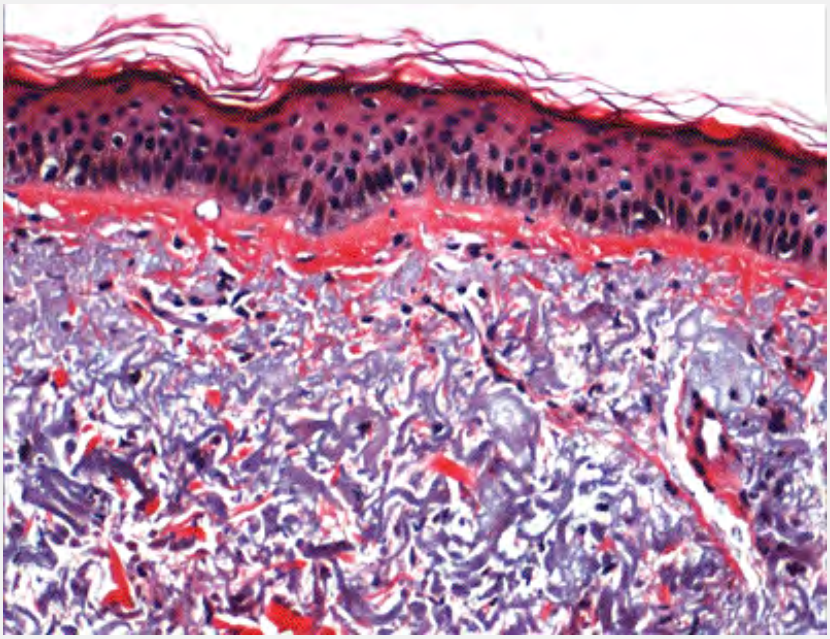

Figure 1.35 Solar elastosis in the dermis.

The pathologic hallmark of extrinsic aging is solar elastosis (Figure 1.35), whereas wrinkling is due to the intrinsic factors mentioned previously (149).

Histologic Variations According to Anatomic Sites

Regional variations of the normal histomorphology are important to recognize so as to avoid misinterpretation of variation as abnormality.

The normal scalp and other densely hair-containing regions show hair follicles extending through the dermis into the subcutaneous fat (Figure 1.36). This is usually not seen in areas with less concentration of hair. Abundant vellus hair is seen in sections taken from the skin of the ear. The skin of the face shows

characteristically many pilosebaceous units (Figure 1.37), and large sebaceous glands are seen on the nose.

The squamous layer of the eyelid epidermis is thin and composed of two to three layers of cells and basoloid epithelial buds. Modified apocrine glands (Moll's glands) and vellus hairs are seen in the dermis.

Sections taken from the skin of the trunk, especially the back, show a normally thickened reticular dermis when compared to other sites (Figure 1.38). Unawareness of this normal variation may lead to the erroneous diagnosis of processes producing thick collagen, such as scleroderma. The skin around the umbilicus also shows thick and fibrotic dermis (Figure 1.39).

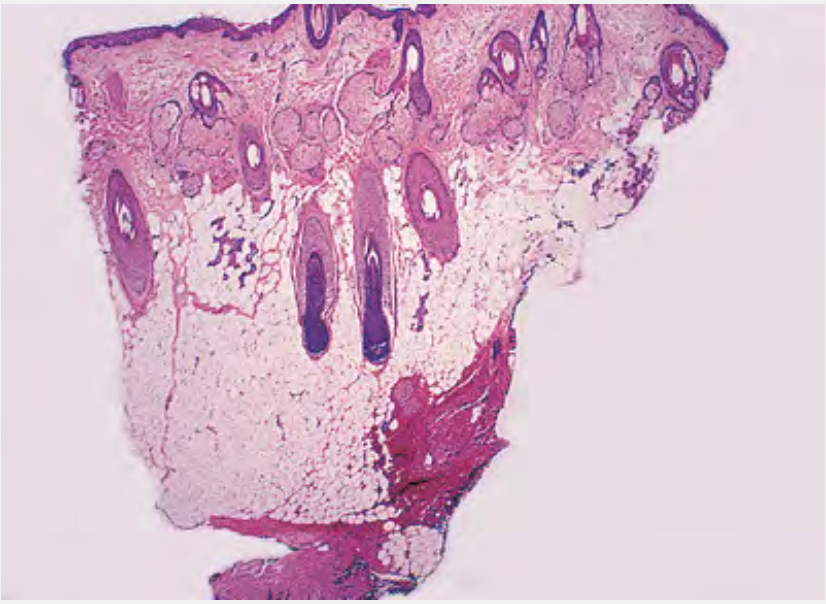

Figure 1.36 Section of scalp showing hair follicles extending into the subcutaneous tissue.

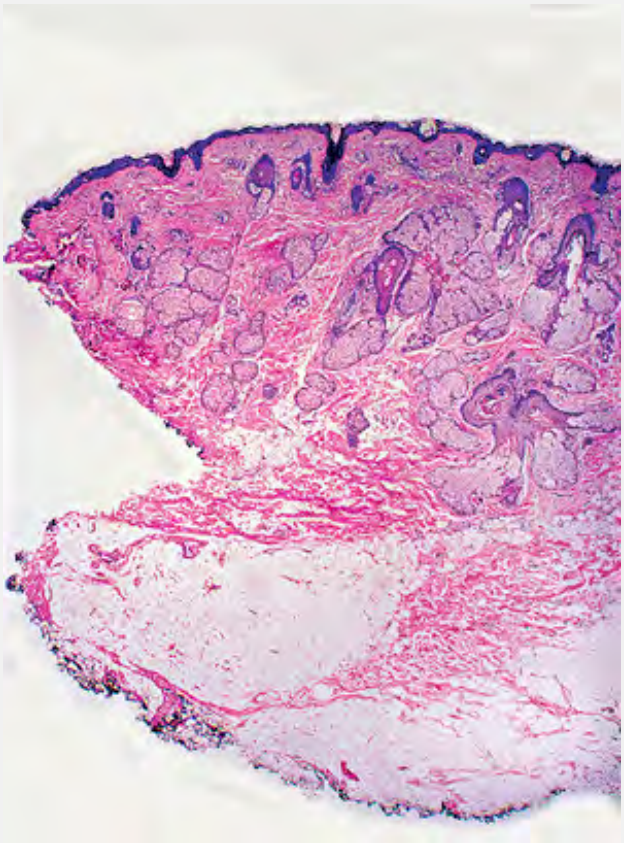

Figure 1.37 Skin of face with pilosebaceous units.

The palms and soles contain stratum lucidum and show a thick, compact cornified layer with loss of the characteristic basket-weave pattern (Figure 1.40). In addition, there are numerous eccrine units, nerve end organs, and glomus structures seen in the dermis. There are no pilosebaceous units. Sections of the skin of the lower leg may show thicker blood vessels in the papillary dermis as a result of gravity and stasis (Figure 1.41). Smooth muscle fibers are seen in the dermis of the skin of external genitalia and areola of the nipple. Cutaneous-mucosal junctions may lack granular and cornified layers, and cells of the squamous layers are larger, with higher glycogen content.

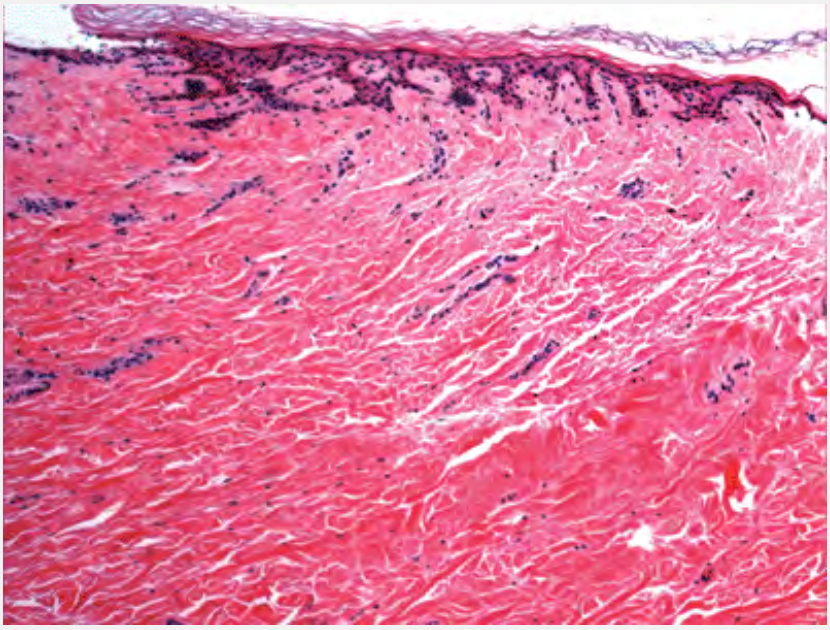

Figure 1.39 Umbillicus with dermal fibrosis.

Pathologic Changes Found in Biopsies and Interpreted as â€œNormalâ€• Skin

Biopsies taken from clinically abnormal skin lesions may be interpreted histologically as normal because of the presence of subtle changes. The following are some examples.

- Dermatophytosis is seen in the cornified layer (Figure 1.42) of an otherwise normal skin.
- A thick or absent granular layer may indicate an abnormal process of keratinization like psoriasis or an ichthyosiform dermatosis.Vitiligo (Figure 1.43, 1.44) may give the histologic impression of normal skin unless one searches for melanocytes.

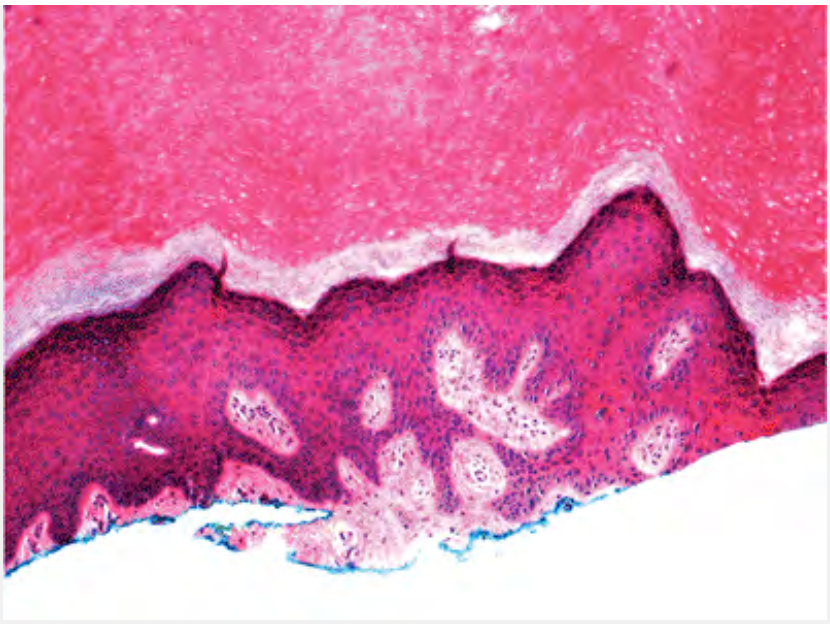

Figure 1.40 Histologic section of the palm with compact cornified layers and stratum lucidum.

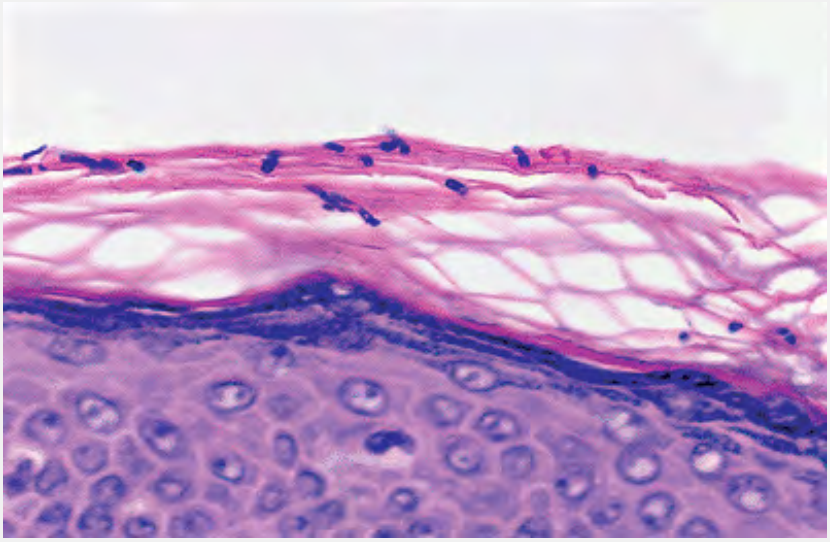

Figure 1.42 Superficial dermatophytosis (PAS stains).

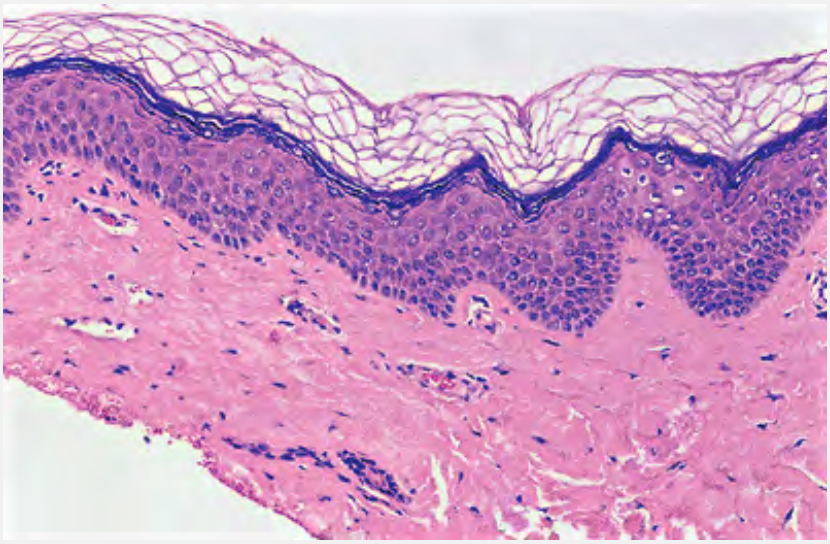

Figure 1.43 Vitiligo. Note the absence of basal melanocytes.

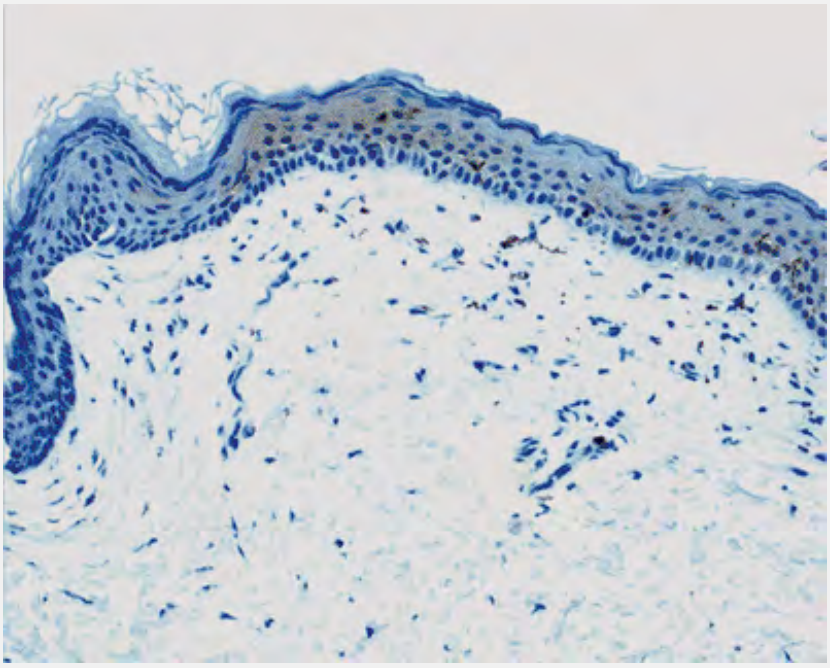

Figure 1.44 Vitiligo. S-100 protein stains show the absence of basal melanocytes.

- Macular and lichen amyloidosis (Figure 1.45) may be overlooked because the pink globules of amyloid seen in the papillary dermis can be mistaken for normal dermis.
- Urticaria (Figure 1.46) produces only edema, which in routine sections is seen as separation of the collagen bundles in the dermis. Similar changes are seen in the case of dermal mucinosis, in which deposition of mucinous material may be inconspicuous in routine sections. Special stains for mucin will

be helpful.

- In telangiectasia macularis eruptive perstans, a subtype of cutaneous mastocytosis, the changes may be quite subtle and are composed of dilated blood vessels in the upper dermis with a scant infiltrate of mast cells. The infiltrate must be confirmed with appropriate stains for mast cells.
- Trichotillomania is a hair pulling habit resulting in areas of alopecia. Although histologic changes can be numerous (24), at times hair follicles devoid of hair are the only changes seen, which give an impression of normal skin in the biopsy material.

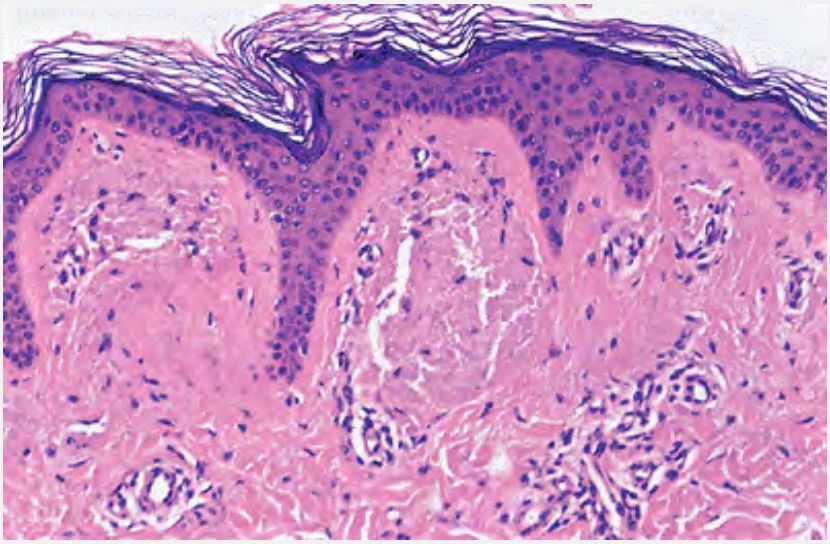

Figure 1.45 Lichen amyloidosis composed of pink globules in the papillary dermis.

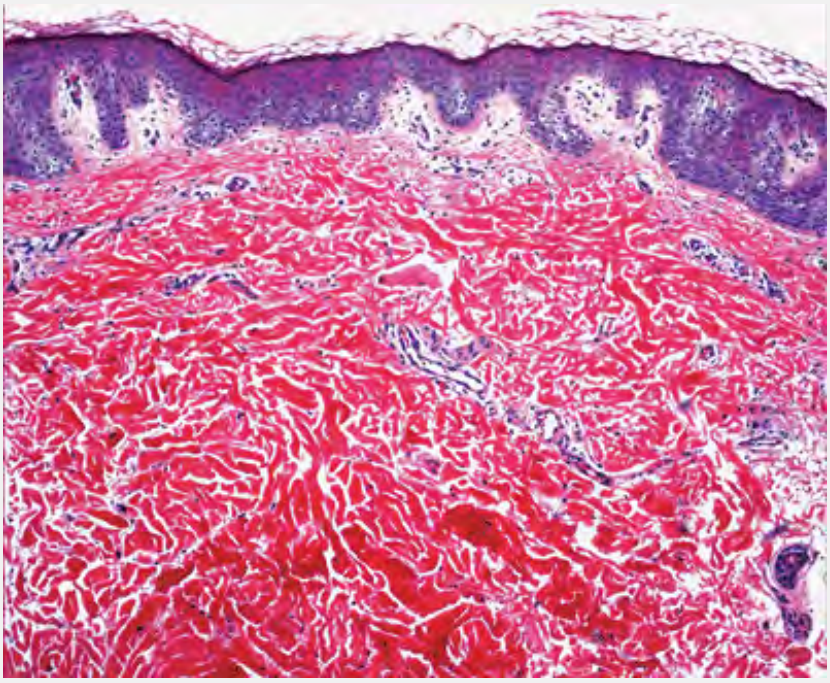

Figure 1.46 Urticaria shows only dermal edema.

- Some degenerative disease of skin, such as anetoderma, can represent only as partial loss of elastic fibers in the dermis, which will be demonstrated by special stains of elastic tissue.
- The so-called â€œconnective tissue nevusâ€• representing a hamartoma with an overproduction of collagen bundles and increased, normal or decreased elastic tissue in the dermis is another condition that can be erroneously interpreted as normal skin.

Other conditions that might be missed as â€œnormal skinâ€• include cafÃ©-au-lait spots, cutis laxa (elastolysis), myxoedema, scleromyxedema, and more. Therefore, the clinical information combined with careful histological examination, sometimes special stains, or immunohistochemical studies of the biopsy material is crucial to avoid misinterpretation of skin disorders as normal

tissue.

Specimen Handling

Once the biopsy is done, the specimen should be placed in formalin fixative immediately for the purpose of routine histological examination. Specimens needed for direct immunofluorescent study ideally should be placed in Michel's medium or, alternatively, put in saline-moistened gauze if it is going to be processed within 24 hours. Specimens required for flow cytometry, molecular studies, and electron microscopy are sent fresh in saline-soaked gauze; they should be processed as soon as possible. If the specimens are excisional biopsies or larger surgical material,

proper sharing of the specimen is done, always with consideration that histology has priority if no prior diagnosis exists for that particular patient.

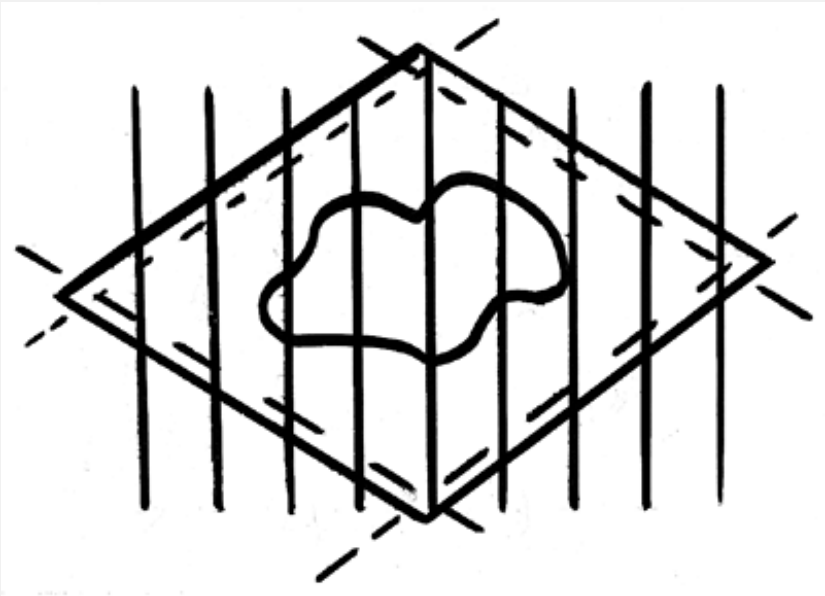

Figure 1.47 The entire neoplasm in the center of the lesion is

examined by â€œbread-loafingâ€• the specimen; the deep margin is also evaluated. The lateral margins are included in each section submitted for histologic evaluation, or they can be submitted separately by cutting them along the depicted interrupted lines.

Punch and shave biopsies are described grossly and either embedded intact or sectioned, depending on the size of the biopsy. Then the specimen is embedded on â€œedgeâ€• (vertical). Five levels are usually obtained for histologic examination.

Excisional biopsies and surgical specimens obtained for neoplasm are described grossly, and the entire deep and lateral margins of the specimen are inked prior to sectioning. The margins are evaluated by cutting along all margins or, most commonly, by entirely â€œbread loafingâ€• the specimen (Figure 1.47). The entire neoplasm is also evaluated using the bread-loafing technique.

Artifacts

Poor histologic preparation as a result of artifacts will hamper the evaluation of slides by the pathologists. These artifacts can be the result of a variety of factors.

- Fixation problems such as poor or no fixation of the specimen prior to cutting, old solutions being used, insufficient fixation time, or inadequate volume of fixative (ideally, the specimen must be properly fixed in a solution 15 to 20 times the volume of the specimen) (150).
- Improper monitoring of the multiple steps involved in the preparation of a slide, such as cutting, temperature of the water bath, freshness of the staining solutions employed, and other factors.

- Artifacts produced at the time of excision, such as cautery (Figure 1.48) and excessive squeezing of the specimen.

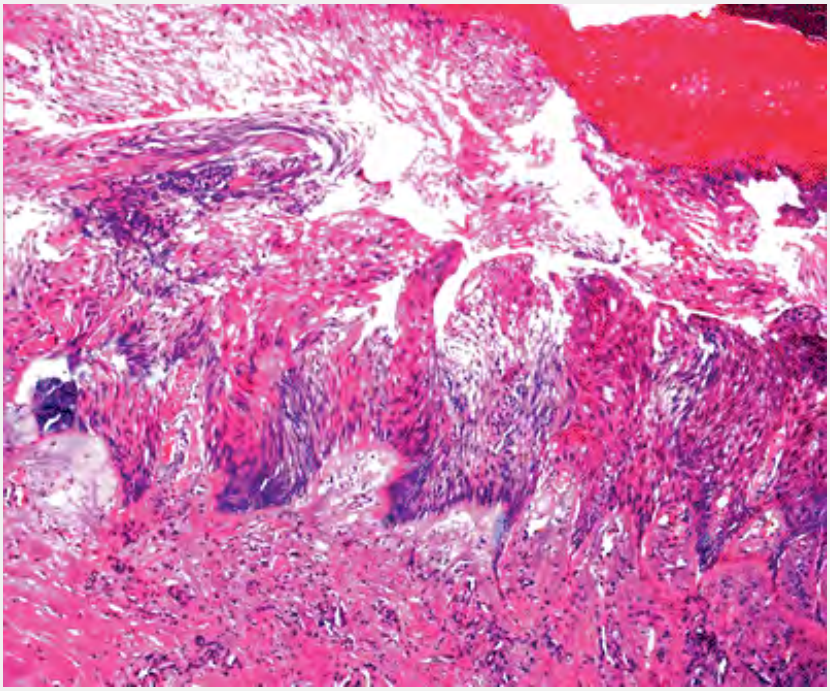

Figure 1.48 Cautery effect with vertical elongation of keratinocytes; such a sample is difficult to evaluate.

- Specimens stored at low temperatures, giving freezing artifacts (Figure 1.49).
- Artifacts characteristically seen in certain pathologic processes, such as tissue holes in basal cell carcinoma (Figure 1.50) and the lack of epidermis in sections from toxic epidermolytic necrolysis.

Staining Methods

The majority of the skin lesions can be diagnosed with well-

prepared H&E-stained sections. However, they will not provide an adequate answer in all cases. A comprehensive review of â€œspecial stainsâ€• is beyond the scope of this chapter because every case is different and may require a specific approach. The following are the most common stains used in our laboratory in the study of cutaneous tissue.

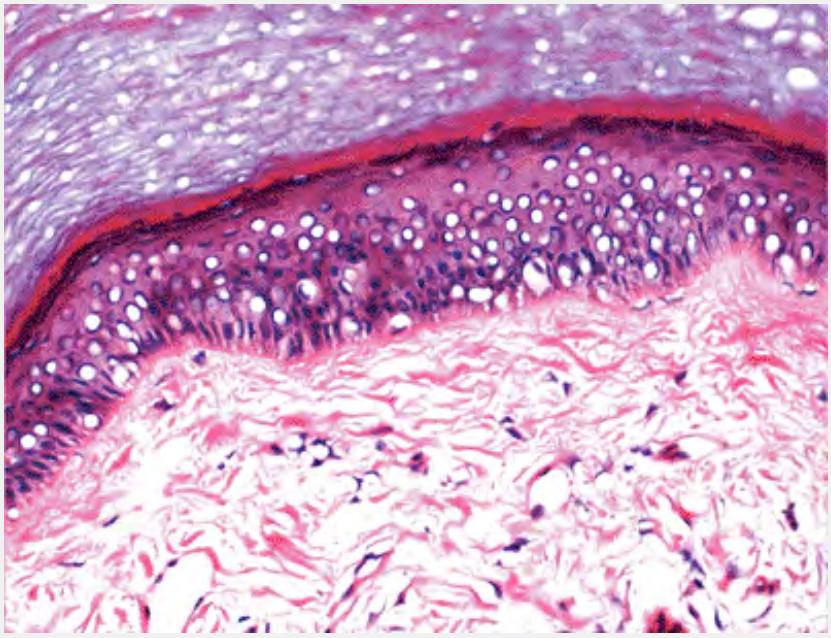

Figure 1.49 Freezing artifacts of a specimen with vacuolar changes in the epidermis.

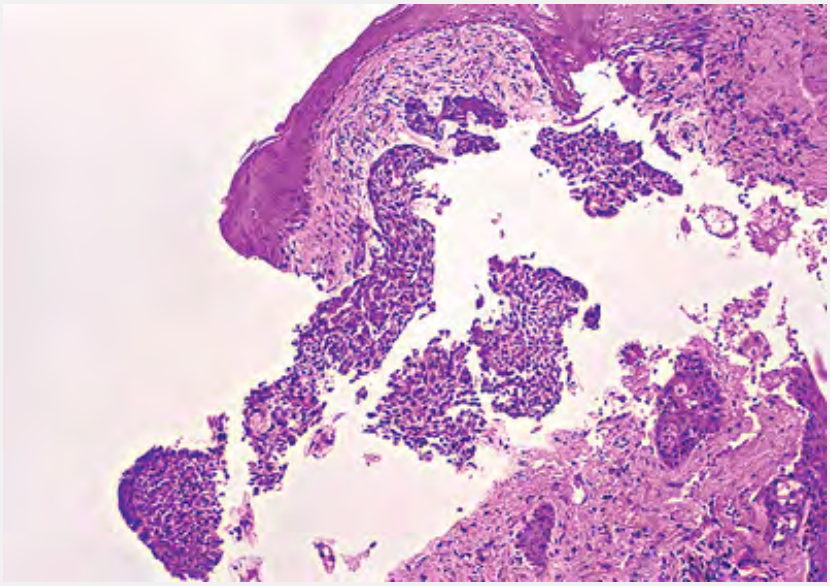

Figure 1.50 Tissue defects in a basal cell carcinoma, which appear in the spaces after multiple sections were performed.

Histochemical Stains

- PAS: to study the thickness of the basement membrane, for glycogen (diastase liable) and fungal organisms (diastase resistant)
- Gomori's methanamine silver: for fungal organisms and cutaneous *Pneumocystis carinii*
- Ziehl-Nielsen and Fite stains: for acid-fast organisms
- Gram's stains: for bacteria
- Steiner and Warthin-Starry stains: in cases of bacillary angiomatosis and for spirochetes
- Giemsa: for mast cells and protozoan organisms, such as

Leishmania

- Mucicarmine: for mucin
- Alcian blue: for acid mucopolysaccharides (pH 2.5) and sulfated mucopolysaccharides (pH 0.5)
- Congo red: for amyloid
- Elastic van Gieson (EVG): for elastic fibers
- Fontana-Masson: for melanin
- Von Kossa: for calcium

Immunofluorescence

Immunofluorescence plays an important place in the diagnosis and evaluation of skin disorders such as lupus erythematosus and autoimmune blistering diseases. Either direct immunofluorescence using tissue or indirect immunofluorescence using serum of patients is available for diagnosis of skin diseases. Direct immunofluorescent studies are performed on cryostat sections of skin specimen using fluorescein isothiocyanateâ€“conjugated antisera to examine for the presence of immunoglobulins A, G, and M, as well as fibrinogen and complement.

Immunohistochemical Stains

Immunohistochemical stains are used widely now in combinations of H&E-stained sections for diagnosis of difficult cases, such as poorly differentiated malignant tumors, spindle cell neoplasms, and lymphoproliferative malignancies. Most of the times, these stains are used in panels and not as single preparations. The most commonly used in our laboratory are:

- Epithelial markers: Cytokeratin CAM 5.2 (Figure 1.51) (low-molecular weight cytokeratin), a combination of cytokeratins

AE1/AE3 (low- and intermediate-molecular weight keratin, carcinoembryonic antigen (CEA), and epithelial membrane antigen (EMA): They are used in the differential diagnosis of epithelial tumors, adnexal tumors, and Paget's disease.

- Melanocytic markers: S-100 protein, Melan A/MART-1, and HMB-45.
- Mesenchymal markers:
    - Vimentin: dendritic cells, macrophages;
    - Factor XIIIa: fibroblast-like mesenchymal cells, dermal dendrocytes;
    - Factor VIII-associated antigen, CD31 and CD34: endothelial cells; CD34 in combination with Factor XIIIa are useful markers in the diagnosis of dermatofibrosarcoma protuberans (151);
    - HHF35 (muscle specific actin), smooth muscle actin and desmin: muscle differentiation;
    - S-100 protein: nerve, fat, and cartilage.
- Lymphoid markers: all available CD markers for the characterization of lymphoid proliferations and other hematologic conditions are used.
- Histiocytic markers: CD68 (KP-1) and lysozymes
- Langerhans cells and Langerhans cell granulomatosis: CD1a and S-100 protein.
- Neuroendocrine cells: neurospecific enolase (NSE), chromogranin and synaptophysin. These markers are also expressed in Merkel cell carcinoma; however, cytoplasmic stains for cytokeratin CK20 is most characteristic.
- Cell proliferation marker: Ki-67 is an excellent marker for determining the so-called growth fraction of a given

cell population (152). Higher staining intensity in malignant lesions might be correlated with significant proliferative capabilities in tumor; Ki-67 labeling may have some value in the differentiation between benign and malignant lesions (153,154).

Introduction

Fingernails are an important epithelial mini-organ system of the hand, wit decades. They are important in certain animals for the apprehension and different functions: as a protective plate and to enhance sensation of the commonly known, but the sensation function is equally important. The fing volumes of information about objects we touch. The nail acts as a counte when an object is touched.

Although most pathological specimens from the nail show well-known cha malignant tumors, a broad spectrum of other changes may be found. For more common variations is important in establishing a correct diagnosis. U troublesome and confusing because a great profusion of names and concep newer concepts of the embryology, physiology, genetics, immunohistochem textbooks. This chapter emphasizes those observations and theories relat

History

Historical interest can be traced to the works of Galen in the second centu structure. However, the real study of the nail begins at the end of the ni Kolliker (2), and Unna (3). The first studies dealt with embryology and). After the initial spark of interest, the nail literature was enriched by m

both on the embryology and the anatomy of the human nail (6 ,7). Beca interpreted the nail plate as formed entirely by the matrix cells and concl formation of the plate.

During the 1950s, Lewis (8) challenged this view and published his idea and ventral nail, with differentiation based on the use of a silver-proteinat unit, including the proximal nail fold, the matrix, the nail bed, and the hy nail.

During the last 25 years, most studies on the nail have fundamentally tri on analyzing nail growth; also considered were ultrastructure and, most r time, new conditions, particularly tumors, unknown until a few years ago, especially keratoacanthomas, merkelomas (Merkel cell tumors), and subun publications have been very scarce following the great proliferation of pa

Difficult biopsy access, as well as the complicated orientation and specim are the main reasons why there are few histologic and histopathologic stu

Embryology

Whereas the embryonic development of the fetal skin has been divided in the embryonic development of the nail shows only five stages (11 ,12): squamous phase; and (e) definitive nail phase, or end phase (Table 2.1).

The earliest recognizable fingers are seen in 42- to 45-day-old embryos (1 seen at 52 to 54 days of age (18.5 mm) (13). Studies using optical micr embryonal age of 10 weeks, with a smooth, shiny quadrangular surface o phalanx is the primary nail base of Zander (1) or primary nail field of Za proximal nail groove).

Studies we performed using scanning electron microscopy showed that the age of seven weeks, with an accumulation of strongly active cells, abund the presence of T lymphocytes in the primary nail base (Figure 2.1). Thi accumulated cells following a transversal band in the dorsal area of the d is the most important step in the nail's development because it permits a the hair follicle except for one difference: in the hair follicle, the process s in nail development in this first phase only. Yet, the two processes are so

compared with those of the hair follicle. The result is the formation of a nail fold.

Plaque phase
Indifferent epithelium phase
Flattened surface phase
Elevated surface phase
7â€“10 weeks
Fibrillar phase
Incipient bleb formation phase
2.5â€“3 months
Granular phase
Single bleb formation phase
3â€“4 months
Squamous phase
Complex bleb formation phase
4â€“5 months
Definitive nail phase
Cornification phase
Up to 5 months

Genetics and Nail Keratins

Epithelial cells possess three cytoskeletal systems: actin microfilaments, protective structural role of keratins was clearly revealed in the early 199 in a variety of human genetic diseases characterized by fragility and/or). It is not precisely known how mutations in these keratins lead to hyper keratinocytes presumably leads to release of cytokines and other inflamma matrix and produce overgrowth of the nail (16).

Keratins are a large family of intermediate filament proteins encoded by m these are the epithelial keratins that are found in soft epithelial tissues of sulphur hard keratins of which hair and nail is composed. Both epithelial type I and type II proteins on the basis of their size, charge, and amino that the human hair keratin family consists of nine type I and six type II within the type I and type II epithelial keratin gene domains on chromos type I (*K9â€“K23; Ha1â€“Ha8*) and type II keratin genes (*K1â€“K8; Hb1* human and mouse genomes. The pairwise and differentiation-related regula unique handle to track differentiation within epithelial tissue (19). A fam epithelial cells with the ability to withstand mechanical and other forms o

Accordingly, mutations in keratin genes are responsible for a number of types in skin and other epithelia (20 ,21). Among type I keratin genes, *K* is first expressed in ectodermal cells committing to a nonepidermal cell fa mesenchymal induction (22). Concomitant with skin maturation, *mK17* e compartments within all major types of epithelial appendages. Both *hK17* genes (e.g., *K5* , *K6a* , *K6b* , *K6hf*) in mature epithelial settings (23). I appendages, *K17* expression is induced in mature interfollicular epidermis ultraviolet light exposure, inflammation) or during diseases (e.g., psoriasi segment of *hK17* 's coding sequence can cause distinct disorders of the s

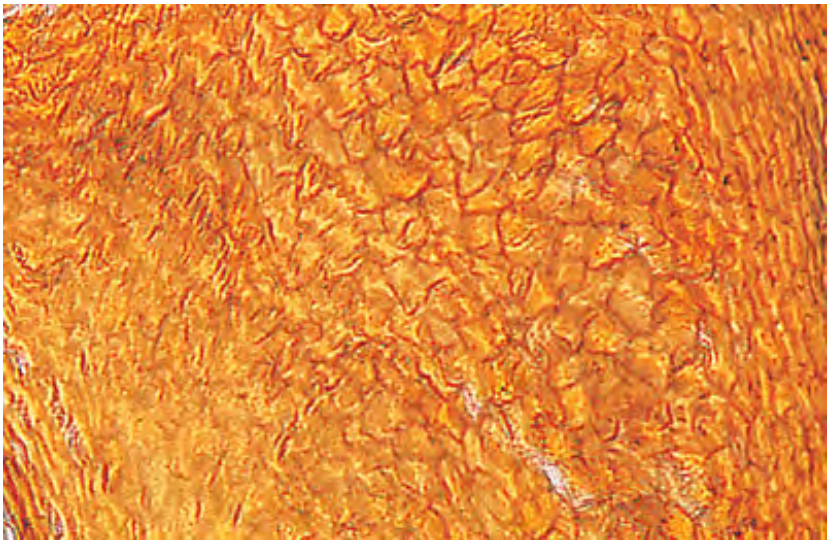

Figure 2.10 Horizontal section of the dorsal nail plate. Corneocytes show not contain nuclei or elements (VVG stain, Ã—200).

Microscopic Anatomy

The Nail Plate

Microscopically, the nail plate consists of closely packed, adherent, interd 2.10 ,2.11). Many intercellular links, including tight, intermediate, and d made-up of three layers: a thin dorsal layer, a thick intermediate layer, a

layer from the nail bed. The cells of the surface of the nail plate overlap reason, the dorsal surface of the nail plate is smooth, whereas the palm can also be observed with optical microscopy, scanning electron microscop technique, Garson et al. (48) demonstrated three different layers in the the keratin molecules from the outer to the inner side of human nail. Th intermediate, and ventral plates. The hairlike type Î±-keratin filaments (81 (accounting for approximately two-thirds of the nail width) and are perfec plane. Keratin filaments of stratum corneum (epidermis) type, found in th directions; parallel and perpendicular to the growth axis. This â€œsandwic intercellular junctions gives the nail high mechanical rigidity and hardness,

Lipid bilayers (49 Ã… thick) parallel to the nail surface fill certain ampulla ventral plate. Using x-ray microdiffraction, Garson et al. also showed tha during the synthesis phase. No keratohyalin granules were seen, but acid Montgomery, are occasionally seen in older age groups.

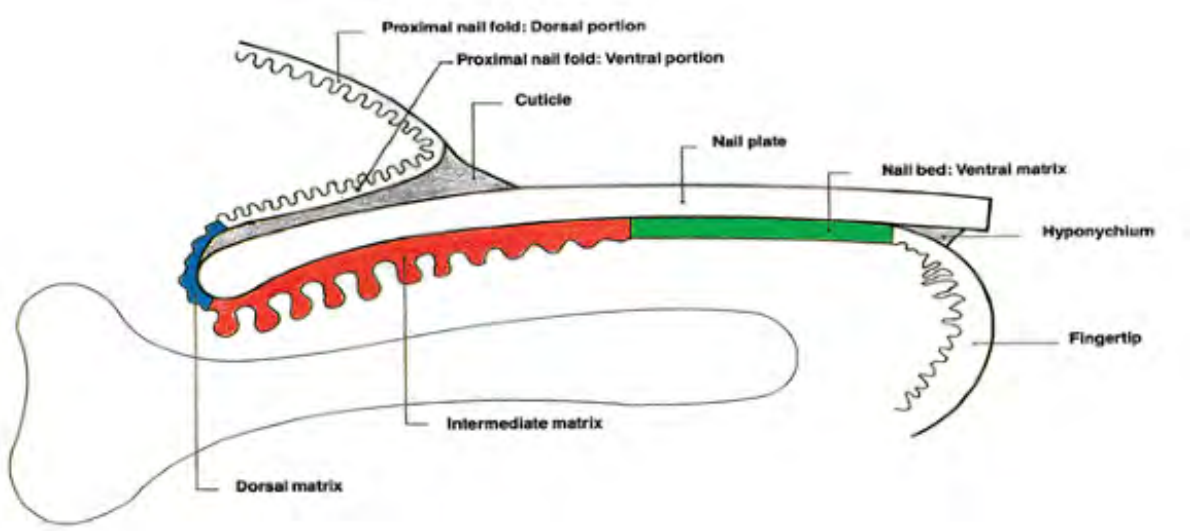

Figure 2.11 Schematic diagram of a sagittal section through the nail uni

Hamilton et al. (49) believed that the progressive increase in the thickne size of the cells in the plate, consecutive to the frictional loss of nail; hov toenails to find the determinant of final nail thickness and length at its p confirmed that the increase of nail thickness with age is independent of t that fracture of the nail plate occurred because the energy to cut nails t needed (approx. 6 kJ/m^2) to cut them longitudinally (51).

Corneocytes of the human nail plate have been studied by Germann et al. are irregular and polyhedral, nonnucleated, and with distinctly irregular ne with age: babies have small cells, adults have significantly larger cells, a younger adults. These authors also commented that the faster-than-norma corneocytes from psoriatic patients are smaller than normal, whereas cor having lichen planus or dyskeratosis congenita, are larger than normal.

Frequent gap junctions were observed near the area where lamellar granu

Matrix		Nail Bed		Nail Plat	
Dorsal	Intermediate	Basal Layer	Malpighian Layer	Ventral	Intermedi

Table 2.3 Histochemistry of the Nail [a]

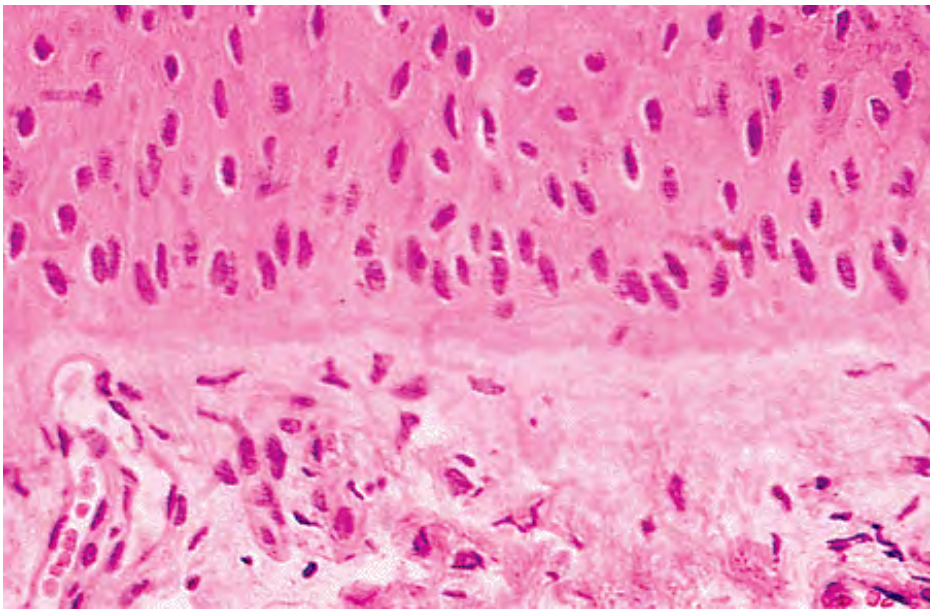

Figure 2.22 Detail of the nail bed zone. The epithelium shows a few acti it is possible to observe larger vessels than in the normal skin.

Histochemical studies of the nail bed prove the presence of bound phosph can be detected in the transition zones: acid phosphatase and nonspecific (39 ,56).

Immunohistochemical studies have demonstrated that nail bed expressed basement membrane. In particular, there was normal expression of the pemphigoid antigens, and the Î±6Î²4 integrin. There was also normal exp laminin. Sinclair et al. (91) pointed out that the dermal-associated comp antigen, the extracellular matrix glycoproteins chondroitin sulphate, type V poorly characterized antigen for LH24 and LH39 were all normally express nail fold, nail matrix, and hyponychium.

The presence of antimicrobial peptides in nails (mainly cathelicidin LL-37, against relevant nail pathogens) may account for the ability of the nail ur

in the absence of direct access to the cellular immune system (92).

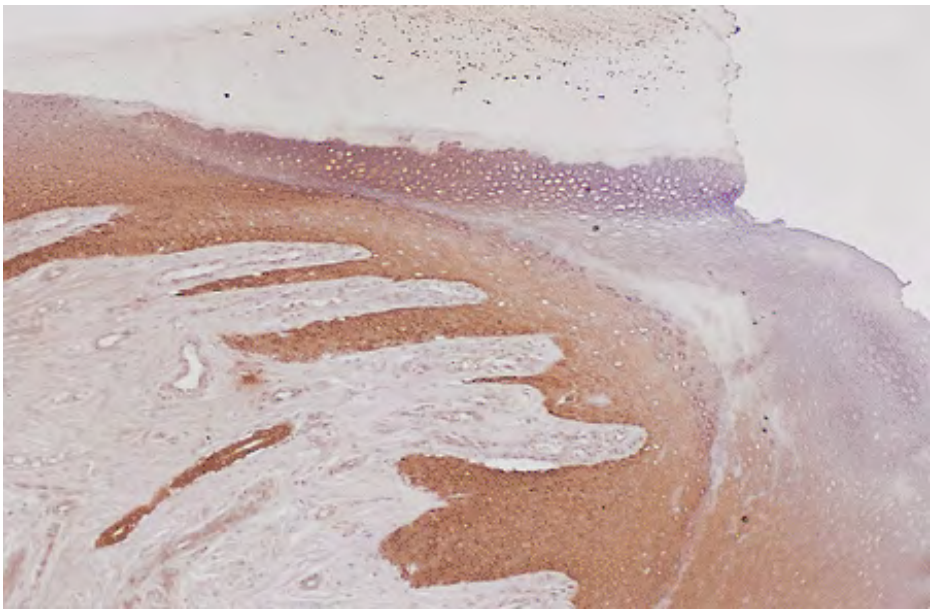

Figure 2.23 Panoramic view of the hyponychium (cytokeratin stain, Ã—1

Hyponychium

The most distal portion of the nail bed is the hyponychium, representing t 2.23); its histologic characteristics are rather peculiar. This transition zor millimeters because the epithelium undergoes keratinization similar to that acanthosis and hyperplasia with the crests oriented almost horizontally; th area of abundant keratohyalin granules is present, and the horny layer pr plate, producing a keratin horn similar to the cuticle. The hyponychium is ,13) and of all epidermis in the embryo (93). The function of this anato protect it from external agents (94). If this structure fails, dermatophyte

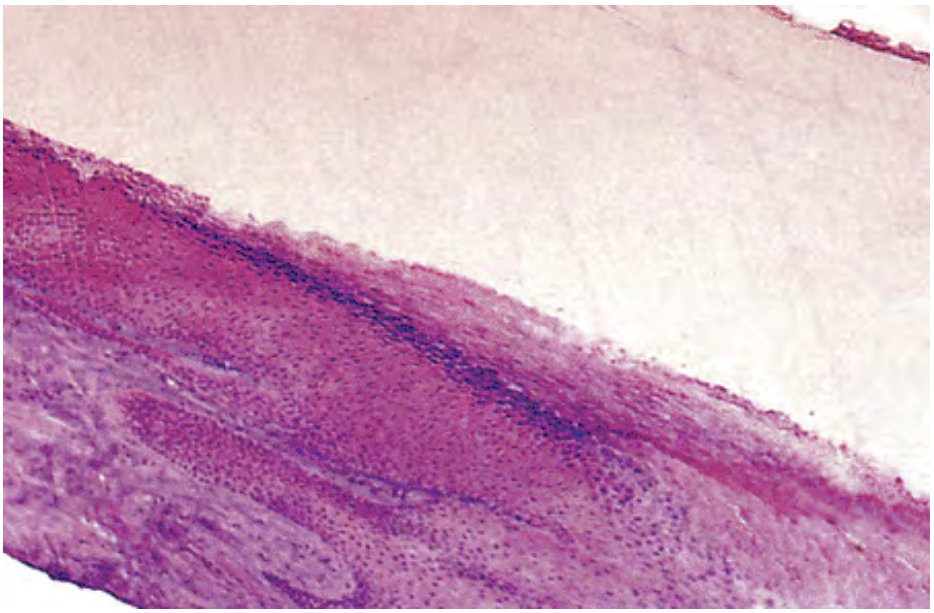

Figure 2.24 Hyponychium zone. The most important feature of this zone plate.

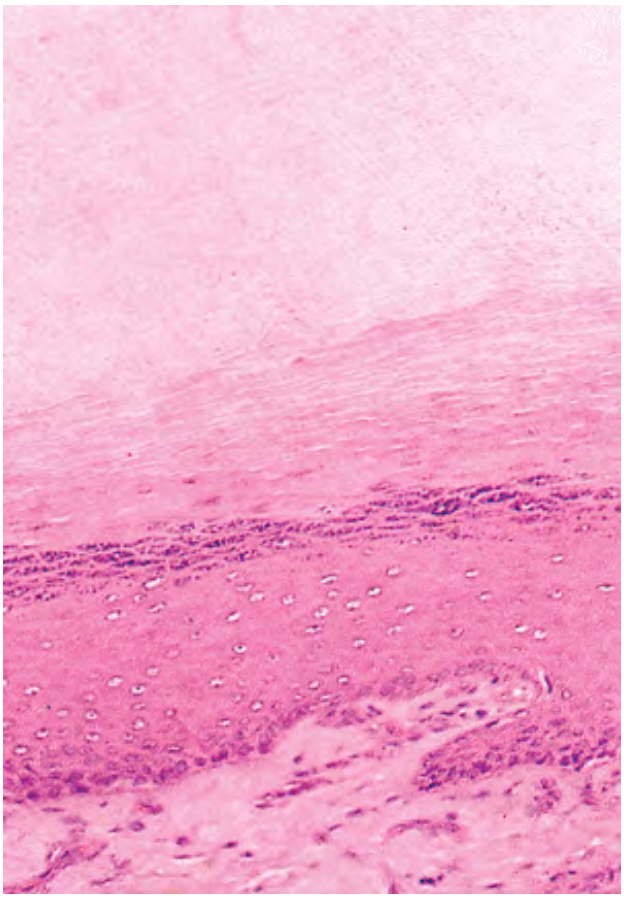

Figure 2.25 Detail of the hyponychium zone. Note the great keratin layer epithelium shows an acanthotic aspect, with transversal papillae.

Terry (41) describes an intermediate zone between the nail bed and the speculated that this area, normally from 0.5 to 1.5 mm wide, had a blood later confirmed by other authors (42). For this reason, the color is paler translucent quality. The onychodermal band occasionally changes its color,

Lateral Nail Folds

The lateral nail folds have a structure similar to the adjacent skin but ar sebaceous units. Acanthosis and hyperplasia of the epithelium are present the nail folds proceeds by keratohyalin formation in the granular layer (Fi contribute to the formation of the nail plate except in the most proximal the epidermis of the proximal nail fold or matrix.

When the lateral border of the nail plate pathologically breaks this fold, onychocryptosis, a frequent pathologic alteration of the great toenail.

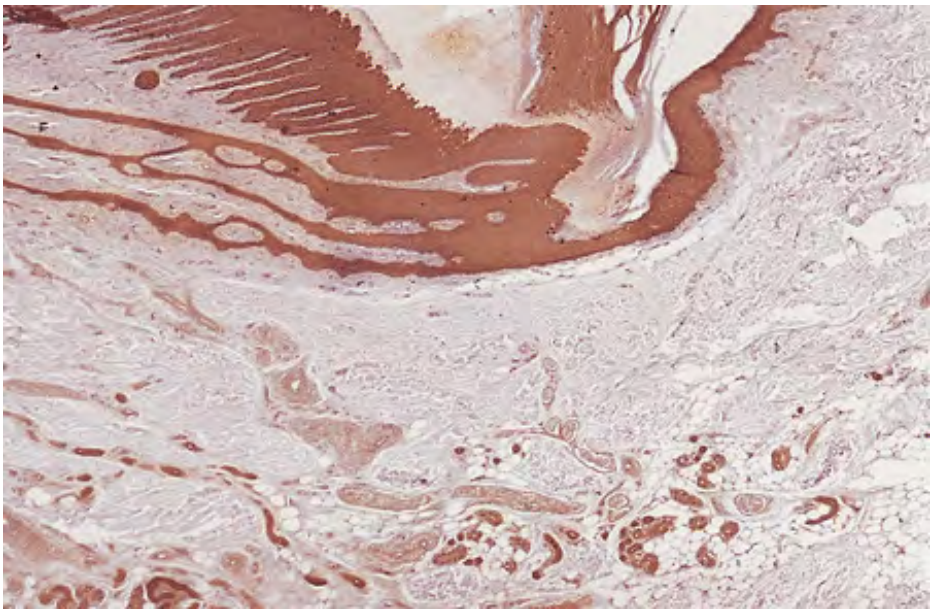

Figure 2.26 Lateral nail fold. Observe its acanthotic epithelial layer and t (cytokeratin antibody, Ã—4).

Immunohistochemistry of the Nail Unit

Nail Plate

The cornified envelope of the epidermis is formed by several precursor sciellin, 195-kDa protein, keratin, and filiagrin. Baden and Kvedar (96) is present in the nail fold and proximal matrix, and sciellin is detectable i human nails (which contain hard keratins), the use of immunofluorescenc have shown that trichohyalin, a 200-kDa protein of the inner root sheath the nail bed; a few scattered cells stained for trichohyalin were observed

Heid et al. (98) studied the keratin expression patterns observed in the from both skin- and hair-type differentiating cells. Kitahara and Ogawa (9 nail matrix. Because AE13 antibody recognized hard keratins that are cha

adult nail develops in such a way that hair-type differentiation is confined results (100 ,101).

Keratinocytes

Expression of keratins in the different compartments within the nail unit h ,104 ,105 ,106 ,107 ,108 ,109 ,110 ,111 ,112). The characteristics of th to our understanding of the biology of the normal nail and changes seen

Analysis of human nail plate by gel electrophoresis demonstrates a range formerly (see Genetics and Nail Keratins). Soft, or epithelial, keratins r from human skin but constitute only 10 to 20% of the keratin found in na differentiation, exist in the same acid-base heterodimer configuration as Molecular classification of hard keratin proteins on gel electrophoresis des (Hax and Hbx) proteins, all of which are probably present in human nail (into at least seven type I Ha keratins and six type II Hb keratins. Further addition to the hard keratins, epithelial keratins isolated from the nail plat nail (102 ,103) (Figure 2.27).

Ha1 is one of the major hard keratins found in nail, where hard keratin re and K10 were also detected in the nail. Since Berker et al. (102) have f K1 and K10 in the keratogenous zone of the ventral matrix, this feature v

Keratins K6, K16, and K17 are normally found in hyperproliferative epiderr of proliferative compartments in the nail unit suggest that the nail bed is r ventral aspect of the proximal nail fold and not the nail bed is the source bed provides K17. Keratin K14 is synthesized in the basal layer, and K14 noted in other tissues. However, the marker of basal keratin conformation, unusual and may reflect the absence of the expression of the suprabasal h epitopes detected by LH6 in normal stratified epithelium. This persistence c hair follicle; because this is also the site of expression of K16, K6, and K1 nail bed and outer root sheath (107). However, expression of K1 and K10 superficial to the level of the sebaceous gland.

The absence of K1 and K10 from the nail bed correlates with a reduction in mucosal epithelium in combination with the presence of K16 and K17. of K4 and K13, which was absent in the nail bed (108). The exact signifi

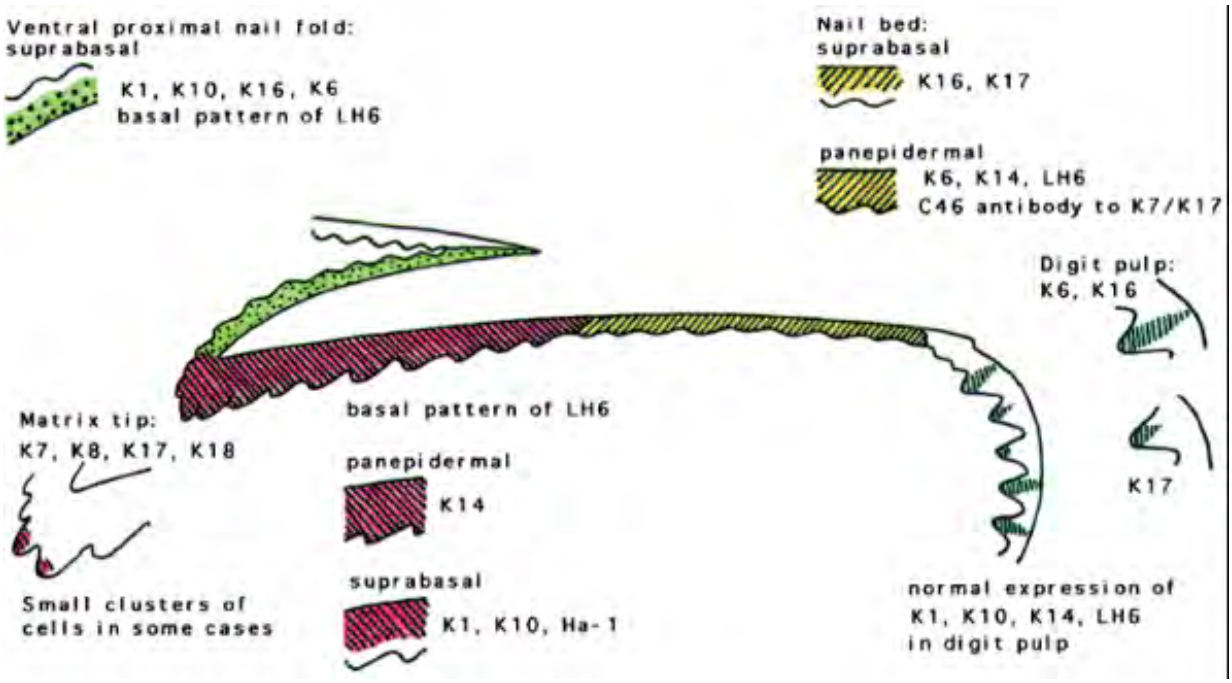

Figure 2.27 Keratin expression in the normal nail unit: markers of regic De Berker D, Wojnarowska F, Sviland L, Westgate GE, Dawber RPR, Leigh regional differentiation. *Br J Dermatol* 2000;142:89â€“96.

Additional molecular studies have demonstrated the homology between ha was originally identified as an orphan G-protein coupled receptor (oGPCR) (GPCR5B, GPCR5C, and GPCR5D) have since been classified into the RAIG: distribution of GPCR5D and its mechanism of expression by in situ hybridi tongue. They found that GPCR5D is expressed in differentiating cells that shaft, the keratogenous zone of the nail, and in a central region of the f in hair follicles during mid- and late anagen, and catagen but not at telc *trans* retinoic acid, induces GPCR5D expression in cultured hair bulb cells relationship with hard keratins that constitute the major structural protein GPCR5D on acid hard keratins.

Analyses of cultured cells showed that transient overexpression resulted i gene expression. The expression was maintained in the hair follicles of *wl* regulated by a signal pathway different from that of hair keratin synthesi molecular mechanisms of GPCR5D function in hard keratinization.

For the expression of hard keratin by matrical keratinocytes is primordial demonstrated that, even in nonâ€“nail-matrical keratinocytes, expression c fibroblasts. These investigators constructed three different skin equivalents digit) were cocultured with ventral fibroblasts (group A); (b) ventral ker (group B); and (c) nail-matrical keratinocytes were cocultured with vent with antihard keratin antibody (HKN-7) revealed hard keratin expression ir continuously in the entire epithelial strata or in the suprabasal layer in g spottily in group C. This study indicated extrinsic hard keratin induction fibroblasts and suggests that nonâ€“nail-matrical epidermal grafts may be In addition, it is possible that lost nails could be reconstructed with graf

Human carcinoembryonic antigen (CEA) and CEA-related molecules play an Egawa et al. (111) demonstrated that a CEA family antigen with NCA (C nail. A strong expression of the NCA-like antigen was only seen in the ke the major central portions of the nail bed, to which the nail plate is firml of the nail bed and was absent in the nail matrix, the hyponychium, and plate is firmly bonded to the nail bed, less so proximal to the matrix marg the same speed as the nail plate, indicating that the bed epithelium has a

Table 2.5 Integrin Expression in Human Nail Matrix [a]

The proximal end of the human toenail is composed of several layers of make the distinction between a proximal dorsal, apical, and ventral matri them. They found that the cells composing the proximal matrix were: (a) lamina; (b) relatively large, round, or polygonal squamous cells filling the Langerhans cells; and (e) Merkel cells.

Moreover, there exists a system of attachment to the dermis, showing the elongations that interdigitate with the papillary dermis (Figure 2.28). Th bundles of very fine fibrils (11 to 12 Âµm). The subjacent dermis of the fibers, with abundant basic matrix.

The basal cells are very active, with frequent mitotic figures. They showe slender projections (villi) intricately interdigitated with neighboring cells. T interposition of the nuclear clear zone in which the majority of mitochon located. The suprabasal matrix cells are also round, with frequent mitotic oriented axiodistally, suggesting the direction of their migration. Large in cells. The extensive interdigitation of the peripheral villi as seen in the b alone connected these cells (Figures 2.29 and 2.30).

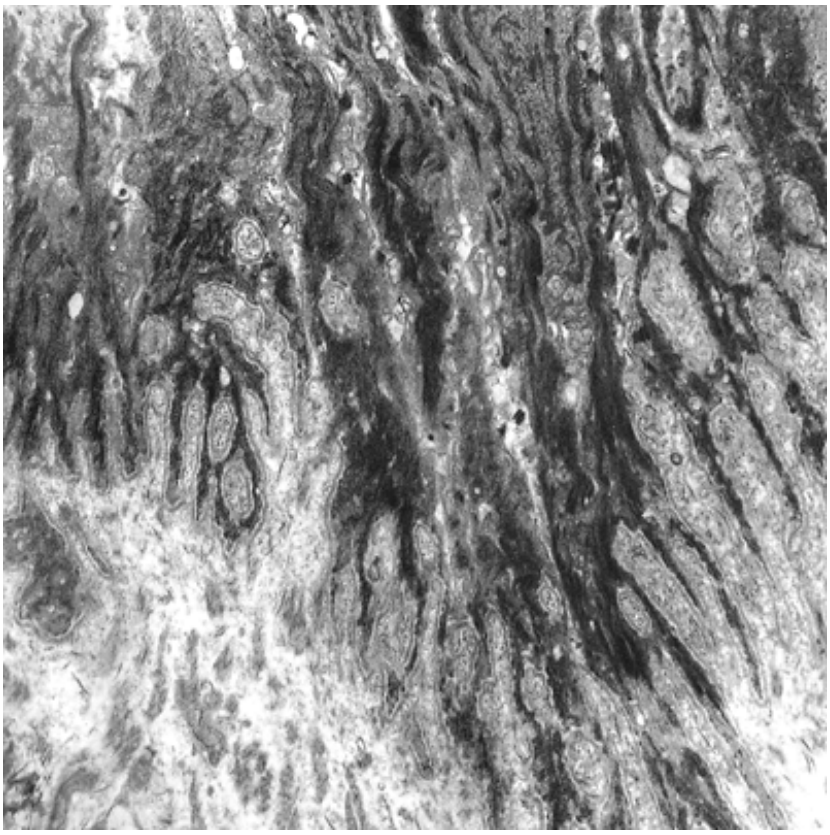

Figure 2.28 Ultrastructural appearance of the dermoepidermal junction of accentuated digitiform distribution, with multiple intermediate filaments

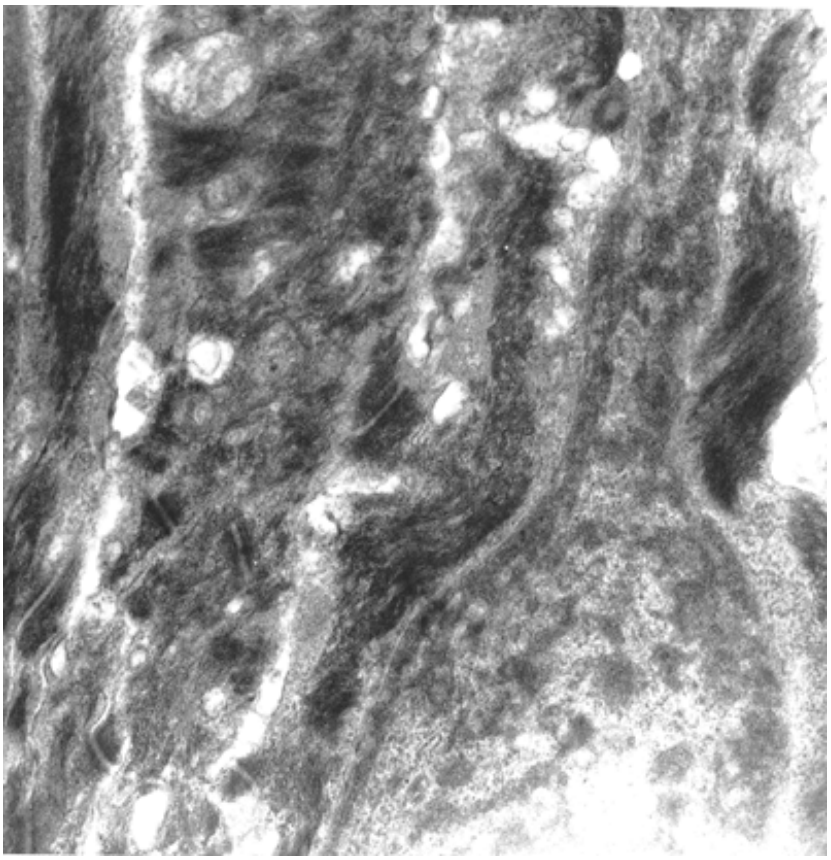

Figure 2.29 Detail of the basal layer of the matrix. Extensive condensati normal skin at this epidermal level (Ã—12,000).

Abundant desmosomes can be seen in the intermediate layers with high intermediate layer of the nail matrix is similar to the upper layers of the organelles, and their cytoplasm is nearly filled with tonofibrils. For this re three to four cellular lines to completely keratinized corneocytes.

Other Tissues of the Nail Unit

Dermis

The dermal component of the nail structures is a very specialized tissue, u closely associated with its vasculature and nerve supply. There is no sub

Dermis, epithelium, and nail plate in the nail bed present special histologi dermis is very thick with a dense collagen layer. These fibers are vertically

and inclined at an angle of 45 degrees in the zone adjacent to the hypony

Their mission is to attach the nail plate directly with the phalangeal perios firmly attached to each other, more so than the nail plate to the matrix, longitudinal ridges and furrows of the nail surface of the nail plate. The arrangement of papillary dermal papillae and epidermal rete ridges. This this arrangement is appreciated as a serrated interdigitation of the ventral be seen very well macroscopically just after avulsion of the nail plate, bu scanning electron microscope (Figures 2.34 and 2.35) (89).

The hyponychium is the area with greater abundance of nerve endings of corpuscles, as in the lateral nail folds (120). This histologic feature gives the finger.

Bone

The nail apparatus includes the subjacent bone. Although the bone has be postamputational repair following digit-tip amputation revealed an unexpe In this way, Zhao and Neufeld (123) have studied this relationship, obser distal levels, and, conversely, when the nail was surgically retained, bone

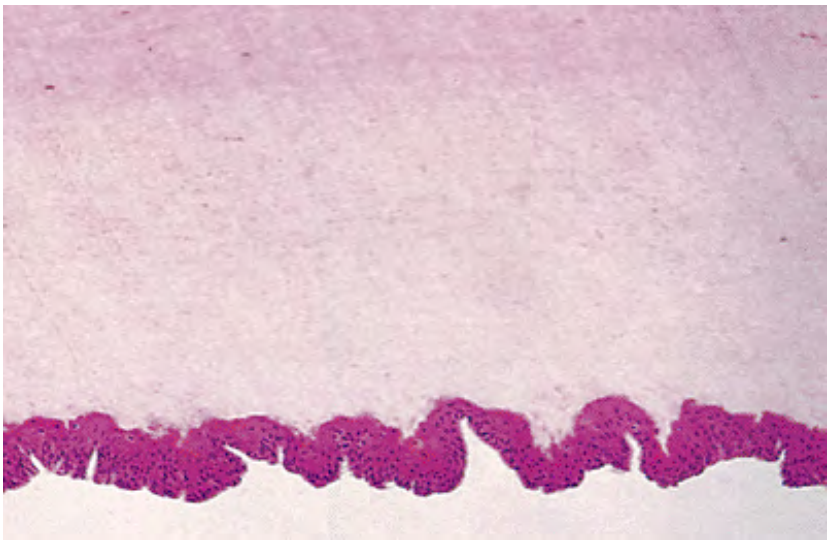

Figure 2.35 Avulsed nail plate. Observe the sinusoidal form of the nail b

Blood Supply

The nail has a rich vascularization that deserves separate mention. The ar from paired digital arteries. The most important studies have been publish et al. in 1991 (126), concluding that the main supply passes into the pul the digit. An accessory supply arises further back on the digit and does r three characteristic anatomic features: arched anastomotic arteries in the to supply the rete (127), and the great tortuosity of the arterial architec arteries possess inner longitudinal and outer circular coats of smooth mus diameter of 5 Âµm) to measure the distribution of P_{O2} in dermal papillae developed by Wang et al. (128).

The vasculature in the nail bed is unique in that it must supply a vascula bone. Studies with scanning electron microscopy revealed special vascular

and perionychium, the vascular villi followed the direction of nail growth. I wide-mesh

net of capillaries was evident. In the nail bed, the vessels were arranged the digit. In the root of the nail, many columnar vessels characterized by observed.

Figure 2.36 Vascular system of the nail bed. This zone has a rich vascu arched arteries of the deep dermis) (MF stain,Ã—47).

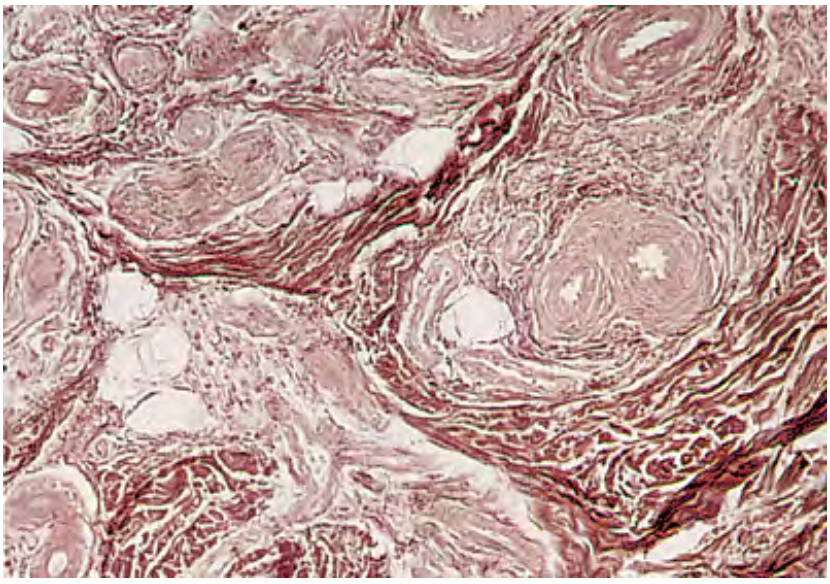

Figure 2.37 Detail of the rich vascular supply of the nail bed (reticulin s

The venous drainage is achieved by two veins, one on each side of the na network is easily seen in the proximal nail fold with a magnifying lens an microscope. It is essentially the same as the network of the skin, but the their length. Certain diseases (e.g., connective tissue disorders, macro syndrome) can modify its normal structure and a simple clinical examinati as an aid in diagnosis (130 ,131 ,132 ,133). A special vascular formation bodies. This vascular structure has the mission of regulating the peripher

Nail Growth

The rate of growth of the nail plate has been studied extensively. Normal to 4.4 mm per month (135 ,136). This growth, however, is not the same than toenails. Whereas a normal fingernail grows out completely in approx to do the same (83). Nails grow faster when regenerating after avulsion

Several physiological circumstances can cause variations in the nail growt the day, during pregnancy (137), in persons who bite their nails (43), a grow more slowly in females, during the night, in toes, in winter, after ag

Nail growth is also altered in several diseases (Table 2.6) (140 ,141 ,142 pityriasis rubra pilaris (94), etretinate treatment (141), and hyperthyroi paralysis (142), local ischemic conditions (135), cytostatic therapy (39 , nail syndrome (144). In the case of a sudden decrease in nail growth, fo appear afterward, depressed in the proximal line called Beau's line. Howe support the hypothesis that slow nail growth rate is a predisposing factor from healthy nail bed may also be related to the adherence of the overlyi as the suprabasal layer of the nail bed, containing keratins not produced properties associated with K1, K10, and Ha1. The presence of these overl layer and associated absence of K1 and K10. In diseases such as onycho granular layer forms alongside expression of K1 and K10. (99 ,100 ,101 ,

The rate of growth of the nail plate is determined by the turnover rate of incorporate tritiated thymidine in their nuclei; the cells appear to be inca nail does not grow (88). Previous reports of nail growth after death are, postmortem drying and shrinking of the soft tissues around the nail plate,

The question of where the nail plate is formed is still controversial (147) toward a complete formation by the matrix (148). Years later, Lewis (8) three different matrices on the basis of staining of the nail plate with a Lewis's hypothesis was supported by differential staining of the nail plate ,71 ,72), and by ultrastructural observation of keratohyalin granules in e extensively reviewed. Zaias and Alvarez (88) used radioautography to sh in normal conditions; Samman (149) and Norton (147) confirmed it by in

human toenails; and Caputo and Dadati (46) reported that, ultrastructura evidence of formation from three different matrices. To add one final bit t under normal conditions the nail plate is made exclusively by the matrix, nail to the undersurface of the nail plate. Finally, Kato (150) published a growth. In this case, the proximal nail fold promotes upward growth of the

Some recent authors believe that the nail bed epithelium produces a signi

bed in the generative portion of the nail (151). Interestingly, indirect imr
anti-type I and II hair keratin antibodies revealed a positive staining in a
However, exclusion of hair keratins hHa1, hHb5, hHb1, hHb6 and hHa4 fr
as the sole origin of the nail plate (152). It has previously been speculat
the nail bed epithelium to the underside of the nail plate. Although our s
positive nail bed cells in the lower nail plate, we believe that these cells
stained for either K5/17 or hHb5, show that the boundary between the na
and that the resulting narrow-spaced folds and ridges exhibit a distinctly
deviations from a vertical angle of section through the nail bed region ma
stem from the tip of an adjacent epithelial fold of the bed epithelium. Co
does not actively contribute to the formation of the nail plate. (Figure 2.3

An important controversy is why nails grow out instead of up. Kligman (1
groove forced the cells of the matrix to grow out. To confirm his theory l
vertical cylinder of hard keratin that had histologic characteristies of the r
matrix cells in embryonic nail was directed upward and distally.

Another important question is why the nail bed accompanies the nail plate
occurs between the plate and bed will grow forward with the plate. If the
move; therefore, the upper part of the bed must move out with the plate.
and Zaias (84), tried to study this phenomenon in an experimental way.
present: he believes that the proximal nail bed moves out, either by press
distal nail bed and hyponychium do not move. Similarly

controversial is the existence of a thin dorsal nail plate, which has been
the nail plate (156); a differential distribution of phospholipid, sulfhydryl,
observations (118). Moreover, the keratin pattern of the thin dorsal nail
hair keratins as a major constituent and the epithelial keratin pairs K5/K1
low amounts of K1/10 (152).

Figure 2.38 Schematic diagram of nail growth.

Handling and Processing of the Nail

The major problems of processing the nail unit are the difficulty of tissue specimen. These problems are the reason for the small number of histolc

The first important point is how to take a biopsy of the nail unit (153 ,154 The best way of studying a biopsy of the nail is to ascertain that it includ plate, bed, and subjacent dermis); these can be sectioned transversely. If through the nail plate and into the underlying tissue to obtain a specimen plate before taking the biopsy, special care has to be taken about nail av epithelium of the bed or matrix may become separated and the undersurfa histopathologic picture. The ideal biopsy technique for the nail is a longitu nail bed, matrix with overlying plate, and the proximal nail fold and cuticle apparatus or from the lateral edge (161 ,162), or it may be modified to ,164).

The second point is the orientation of the specimen for cutting. In all cas submission form as to the way the specimen was obtained, whether a par plate is included.

The third point is how to treat the specimen in the laboratory. If the nail cutting with a microtome unless some method of softening is used. A spe leave the plate softer (161). Alternatively, the specimen can be placed ir (162). Another helpful technique for softening the hard keratin of the nai

- Fix specimen in 10% formalin for 24 hours.

- Place specimens in the following solution until completely dekeratinized

    - Mercuric chloride

    4.0 g
    - Chromic acid

    0.5 g
    - Nitric acid, concentrated

    10.0 mL
    - Ethyl alcohol, 95%

    50.0 mL
    - Distilled water

    200.0 mL
- Wash in running water for three hours.
- Dehydrate, clear, and impregnate with paraffin, or process as desired

With this technique, the preservation of the cytologic characteristics of the good as with the previous one, but it is very helpful for softening the ha

Breast

Laura C. Collins

Stuart J. Schnitt

Introduction

Remarkable advances in breast imaging over the past decade have provided a variety of noninvasive means to assist in the evaluation of patients with breast disorders (1,2,3,4). Nevertheless, at the present time, histologic examination of tissue specimens remains the cornerstone for the diagnosis of breast diseases, and an understanding of normal breast histology is essential for accurate evaluation of such specimens. It should be noted, however, that what constitutes â€œnormalâ€• histology in the breast varies according to gender, age, menopausal status, phase of the menstrual cycle, pregnancy, and lactation, among other factors. Therefore, determination of whether a given breast specimen is normal or shows pathologic alterations must take these variables into consideration.

Embryology

Development of the human mammary gland begins during the fifth week of gestation, at which time thickenings of the ectoderm appear on the ventral surface of the fetus. These mammary ridges, also known as milk lines, extend from the axilla to the groin. Except for a

small area in the pectoral region, the bulk of these ridges normally regress as the fetus continues to develop. Failure of regression of other portions of the milk lines can result in the appearance in postnatal life of ectopic mammary tissue or accessory nipples anywhere along the milk lines; this phenomenon is most commonly encountered in the axilla, inframammary fold, and vulva (5,6,7).

The earliest stages of breast development are largely independent of sex steroid hormones (8). After the fifteenth week of gestation, the developing breast exhibits transient sensitivity to testosterone, which acts primarily on the mesenchyme. Under the influence of testosterone, the mesenchyme condenses around an epithelial stalk on the chest wall to form the breast bud, the site of mammary gland development. Solid epithelial columns then develop within the mesenchyme, and these ultimately give rise to the lobes or segments of the mammary gland. Portions of the fetal papillary dermis encase the developing epithelial cords and eventually give rise to the vascularized fibrous connective tissue that surrounds and invests the mammary ducts and lobules. The more collagen-rich

reticular dermis extends into the breast to form the suspensory ligaments of Cooper, which attach the breast parenchyma to the skin. Portions of the mesenchyme differentiate into fat within the collagenous stroma between the twentieth and thirty-second weeks of gestation. During the last eight weeks of gestation, the epithelial cords canalize and branch, forming lobuloalveolar structures as a result of mesenchymal paracrine effects. A depression in the epidermis, the mammary pit, forms at the convergence of the lactiferous ducts. The nipple forms by evagination of the mammary pit near the time of birth.

During the last few weeks of gestation the fetal mammary gland is responsive to maternal and placental steroid hormones, and, as a result, the epithelial cells in the acinar units exhibit secretory activity. At the time of birth, withdrawal of the maternal and placental sex steroids stimulates prolactin secretion, which in turn

stimulates colostrom secretion. At this time, both male and female neonates exhibit palpable enlargement of the breast bud. As the serum levels of maternal and placental sex steroid hormones and prolactin decline during the first month of life, secretory activity ends, and the gland regresses and becomes inactive. At this stage, and until puberty, the breast consists primarily of lactiferous ducts that exhibit some branching without evidence of progressive alveolar differentiation, although some rudimentary lobular structures may persist.

Another feature that may be seen in the fetal breast is extramedullary hematopoiesis, and this may persist in the periductal stroma until 4 months of age (9) (Figure 3.1).

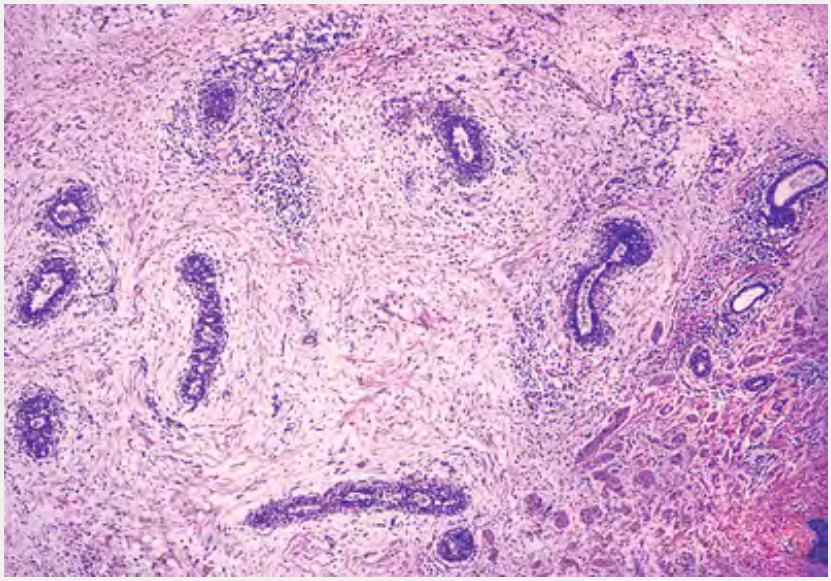

Figure 3.1 Breast tissue from an infant showing ducts embedded in a loose connective tissue stroma. The stromal mononuclear cells are hematopoietic elements, indicative of persistent extramedullary hematopoiesis. (Courtesy of Theonia Boyd, M.D, Children's Hospital, Boston, MA)

Adolescence

Adolescent breast development in the female begins with the onset of puberty and the cyclic secretion of estrogen and progesterone. However, a variety of other steroid and peptide hormones are also required for proper mammary gland development (8) (Table 3.1). The ducts elongate, branch, and develop a thickened epithelium due primarily to the influence of estrogen (10) (Figure 3.2). The process of ductal growth and branching is largely independent

of progesterone. There is an increase in the density of periductal connective tissue, also as a result of relative estrogen dominance. Deposition of stromal adipose tissue occurs, and it is this adipose tissue that is largely responsible for the enlargement and protrusion of the breast disk at this time. Cyclical exposure to progesterone following exposure to estrogen during ovulatory cycles promotes lobuloacinar growth, as well as connective tissue growth. Although the majority of breast development occurs during puberty, this process continues into the third decade, and terminal differentiation of the breast is only induced by pregnancy.

Table 3.1 Major Steroid and Peptide Hormonal Influences on the Breast (Adapted from Mccarty and Nath (8))

Hormone	Effects
Estrogen	Required for ductal growth and branching during adolescence Required for lobuloalveolar growth during pregnancy Required for induction of progesterone receptor Not necessary for maintenance of

	secretion or lactation
Progesterone	Required for lobuloalveolar differentiation and growth Probable mitogen in normal estrogenprimed breast Not necessary for ductal growth and branching
Testosterone	Stimulates breast mesenchyme during fetal development Causes mesenchymal destruction of mammary epithelium during critical period of testosterone sensitivity
Glucocorticoids	Required for maximal ductal growth Enhances lobuloalveolar growth during pregnancy
Insulin	Enhanced ductal-alveolar growth Enhances protein synthesis in mammary epithelium Required for secretory activity (with glucocorticoids and prolactin)
Prolactin	Stimulates epithelial growth after parturition Required for initiation and maintenance of lactation
Human placental lactogen	Able to substitute for prolactin in epithelial growth and differentiation

	Stimulates alveolar growth and lactogenesis in second half of pregnancy
Growth hormone	Required for ductal growth and branching during adolescence May contribute to lobuloacinar growth during pregnancy
Thyroid hormone	Increases epithelial response to prolactin May enhance lobuloacinar growth

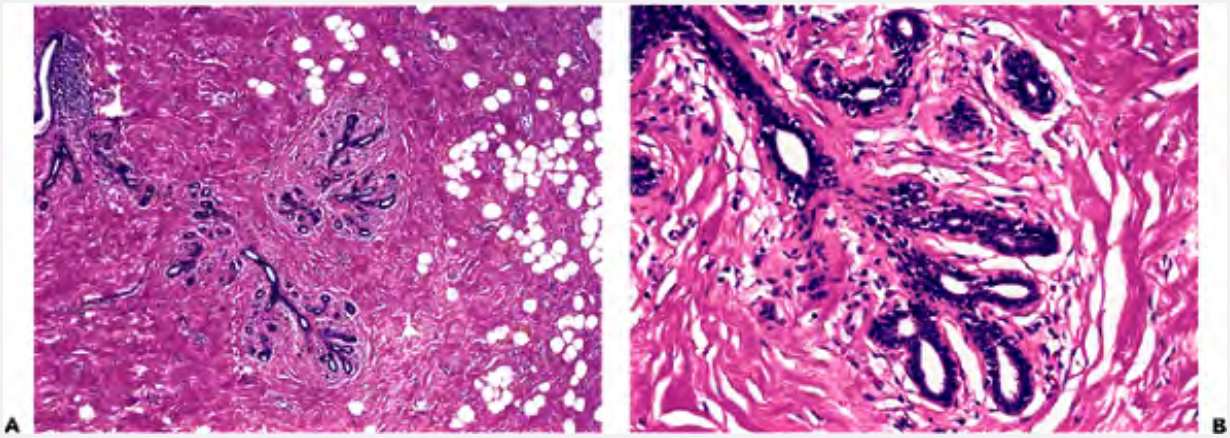

Figure 3.2 Adolescent breast tissue composed of branching ducts with rudimentary lobule development (type 1 lobules). The stroma consists a mixture of fibrous connective tissue and adipose tissue. A. Scanning magnification. B. High power.

The adolescent male breast is composed of fibroadipose tissue and ducts lined by low cuboidal cells.

The Adult Female Breast

The size of the breast is greatly influenced by the individual's body habitus since the breast is a major repository for fat; it can range in size from 30 g to more than 1000 g. The breast lies on the anterior chest wall over the pectoralis major muscle and typically extends from the second to the sixth rib in the vertical axis and from the sternal edge to the midaxillary line in the horizontal axis. Breast tissue also projects into the axilla as the tail of Spence. The breast extends laterally over the serratus anterior muscle and inferiorly over the external oblique muscle and the superior rectus sheath. The breast lies within a space in the superficial fascia, which is continuous with the cervical fascia superiorly and the superficial abdominal fascia of Cooper inferiorly. The only boundary of the breast that is anatomically well-defined is the deep surface where it abuts the pectoralis fascia. However, despite this macroscopic demarcation, microscopic foci of glandular tissue may extend into and even through the pectoral fascia and may traverse the other anatomic boundaries described above. The clinical significance of this observation is that even total mastectomy does not result in removal of all glandular breast tissue. Bundles of dense fibrous connective tissue, the suspensory ligaments of Cooper, extend from the skin to the pectoral fascia and provide support to the breast.

The adult female breast consists of a series of ducts, ductules, and lobular acinar units embedded within a stroma that is composed of varying amounts of fibrous and adipose tissue. The stroma comprises the major portion of the nonlactating adult breast, and the relative proportions of fibrous tissue and adipose tissue vary with age and among individuals (Figure 3.3).

The ductal-lobular system of the breast is arranged in the form of segments, or lobes. While these segments can be readily appreciated by injecting the ductal system with dyes or radiologic contrast agents (Figure 3.4), they are anatomically poorly defined, and no obvious boundaries can be appreciated between these segments during

surgery, upon gross inspection of mastectomy specimens, or on histologic examination. In addition, these segments show considerable individual variation with regard to their distribution, and the ramifications of individual segments may overlap. The segmental nature of some neoplastic processes in the breast, particularly ductal carcinoma in situ, is now widely appreciated, and surgical resection of the involved segment is an important therapeutic goal. Unfortunately, since it is not possible for the surgeon to define intra-operatively the boundaries of the involved segment, performing a â€œsegmentectomyâ€• to remove the entirety of a diseased segment is at this time more of a theoretical concept than a practically attainable goal.

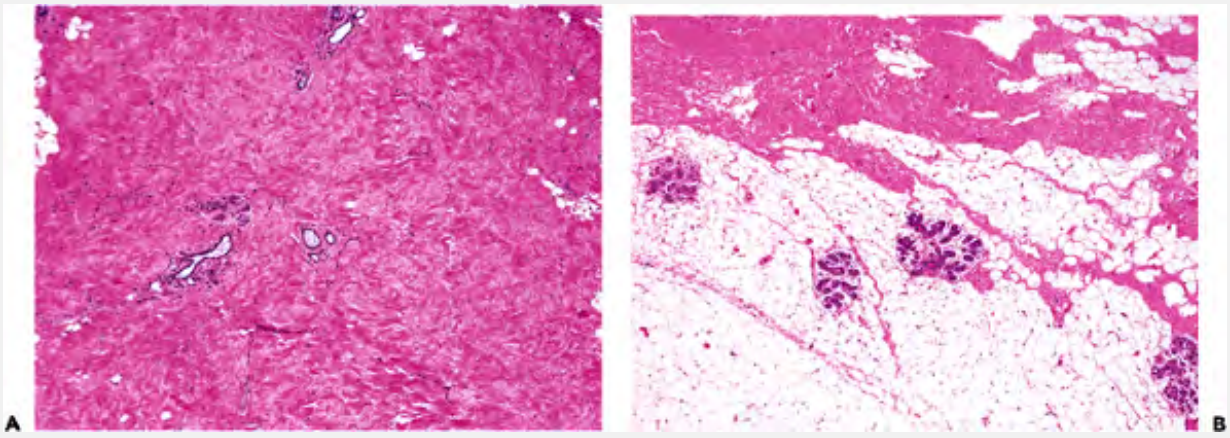

Figure 3.3 The stroma is the predominant component of the nonlactating breast and consists of varying amounts of collagen and adipose tissue. A. Low-power view of breast with dense, fibrotic stroma. B. Low-power view of breast with predominantly fatty stroma.

Each segment consists of a branching structure that has been likened to a flowering tree (11) (Figure 3.5). The lobules represent the

flowers, draining into ductules and ducts (twigs and branches), which, in turn, drain into the collecting ducts (trunk) that open onto the surface of the nipple. Just below the nipple, the ducts are expanded to form lactiferous sinuses. The sinuses terminate in cone-shaped ampullae just below the surface of the nipple.

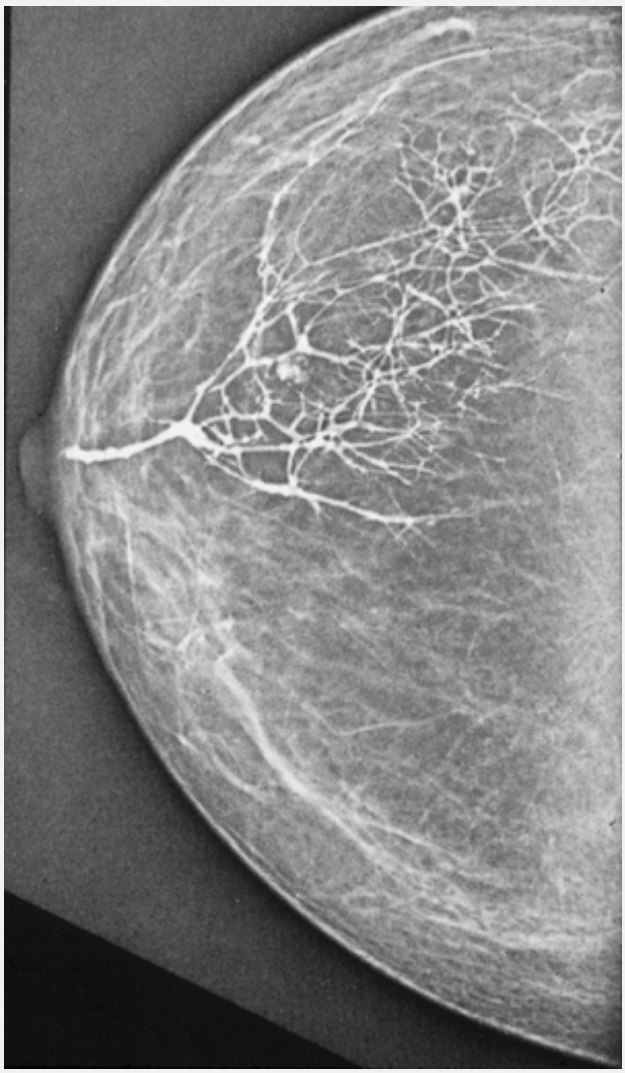

Figure 3.4 Ductogram (galactogram). Performed by injecting contrast material into an orifice of a lactiferous duct at the nipple, a ductogram demonstrates the complex ramifications of a single mammary ductal system (also known as a segment or

lobe).

The actual number of segments in the breast and their relationship to each other has long been a matter of debate. Most textbooks indicate that there are 15 to 20 ductal orifices on the nipple surface and suggest that this corresponds to the number of ductal systems, segments, or lobes in the breast (5,6,12,13). In contrast, a number of mammary duct injection studies have suggested that there are only between five and ten discrete breast ductal systems or segments in each breast. The discrepancy between the number of ductal orifices on the nipple and the actual number of breast segments or ductal systems may be explained by the fact that some of the orifices on the nipple represent openings of

sebaceous glands or other nonductal tubular structures that do not contribute to the ductal-lobular anatomy of the breast. Another possibility is that some lactiferous ducts bifurcate immediately prior to entering the nipple or end blindly (13). The issue of anastomoses between ductal systems is also unresolved. One recent study indicated that, while ductal systems may lie in close proximity to one another and even intertwine within a particular quadrant, they do not interconnect (13). However, anastamoses between ductal systems have been reported by others (14).

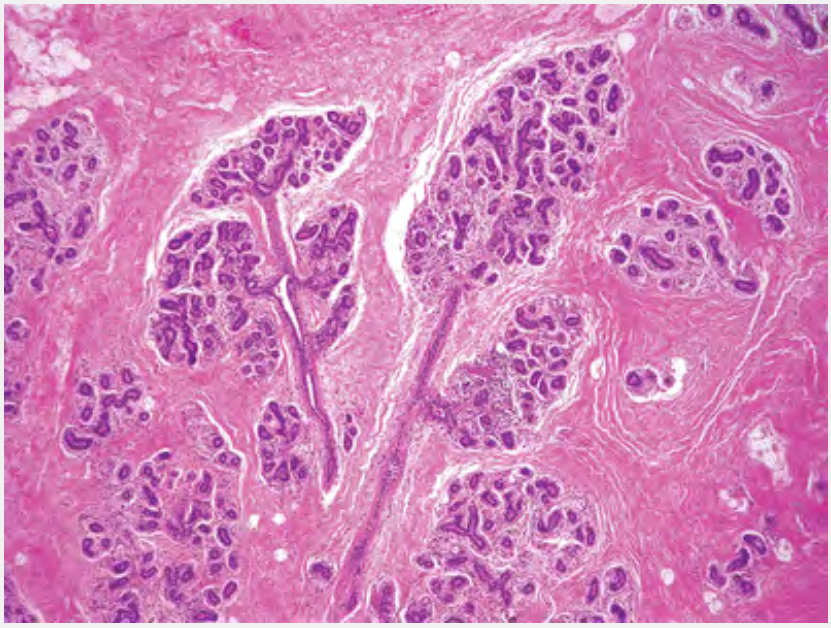

Figure 3.5 Microanatomy of normal adult female breast tissue showing extralobular ducts, terminal ducts, and lobules, the latter composed of groups of small glandular structures, the acini.

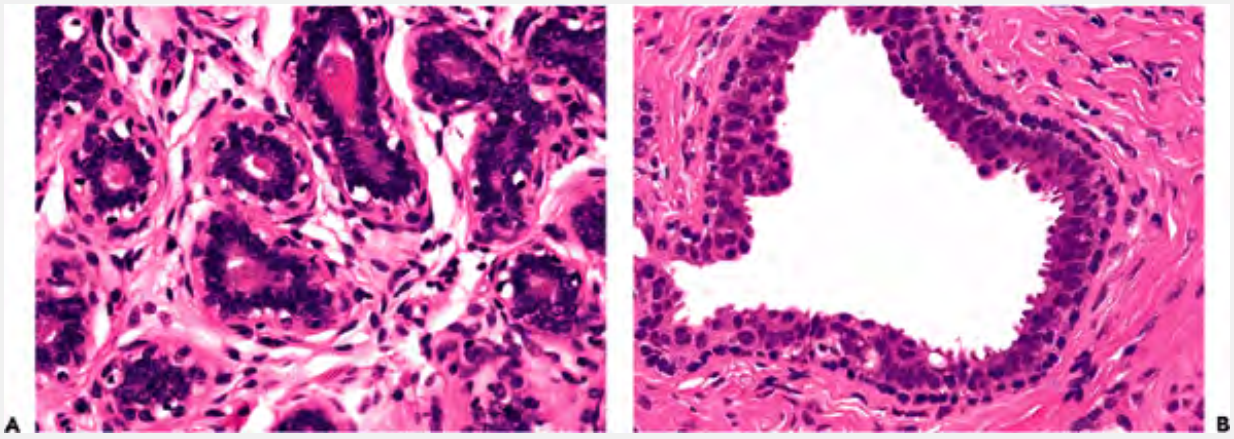

Figure 3.6 The mammary ductal-lobular system is lined by a dual cell population, an inner epithelial cell layer and an outer

layer of myoepithelial cells. A. High-power view of a lobule. The myoepithelial cells surrounding the acinar epithelial cells are variably conspicuous. B. High-power view of an extralobular duct, showing distinct epithelial and myoepithelial cell layers.

The epithelium throughout the ductal-lobular system is bilayered, consisting of an inner (luminal) epithelial cell layer and an outer (basal) myoepithelial cell layer. The importance of this double cell layer cannot be overemphasized because it is one of the main guides used to distinguish benign from malignant lesions (15). The luminal epithelial cells of the resting breast ducts and lobules are cuboidal to columnar in shape and typically have pale eosinophilic cytoplasm and relatively uniform oval nuclei. These epithelial cells express a variety of low-molecular weight cytokeratins, including cytokeratins 7, 8, 18, and 19 (16,17,18,19,20). The outer (or myoepithelial) cell layer, although always present, is variably distinctive (Figure 3.6). Myoepithelial cells range in appearance from barely discernible, flattened cells with compressed nuclei to prominent epithelioid cells with abundant clear cytoplasm. In some cases, the myoepithelial cells have a myoid appearance featuring a spindle cell shape and dense, eosinophilic cytoplasm, reminiscent of smooth muscle cells (Figure 3.7). Even when inconspicuous on

hematoxylin- and eosin-stained sections, myoepithelial cells can readily be demonstrated using immunohistochemical stains for a variety of markers, including S-100 protein, actins, calponin, smooth muscle myosin heavy chain, p63, and CD10, among others (21,22,23) (Figure 3.8). However, these markers vary in both sensitivity and specificity for myoepithelium. Myoepithelial cells also express high molecular weight cytokeratins 5/6, 14, and 17 (16,17,18,19,20,24). Recent work has documented the presence of a third cell type in normal breast tissue. These cells are dispersed individually and irregularly throughout the ductal-lobular system,

express the basal cytokeratin CK5, and are thought to be progenitor cells capable of differentiating into both glandular epithelial cells and myoepithelial cells (19). However, the presence of such progenitor cells has not yet been universally accepted (25).

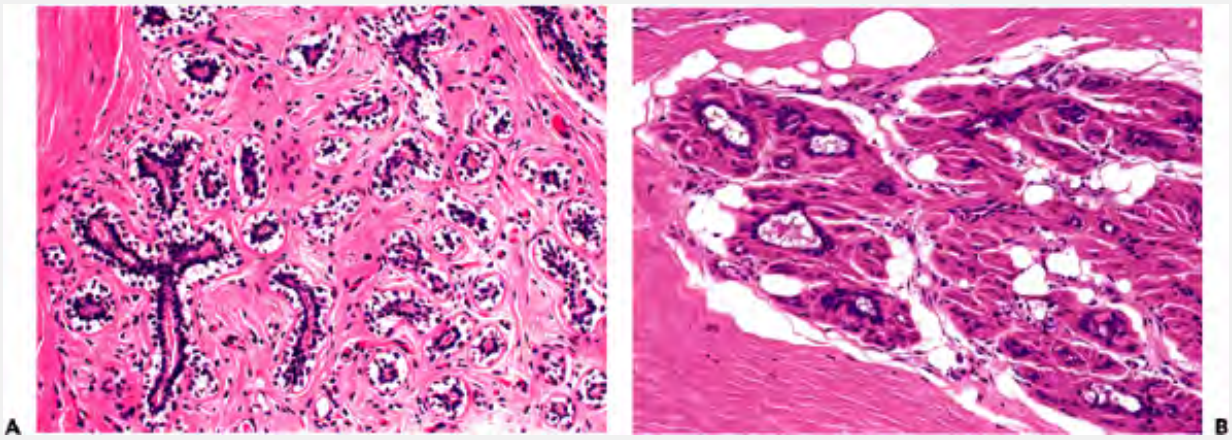

Figure 3.7 Myoepithelial cells can vary in their histologic appearance. A. Myoepithelial cells in this lobule show prominent cytoplasmic clearing. B. In this lobule, the myoepithelial cells show myoid features.

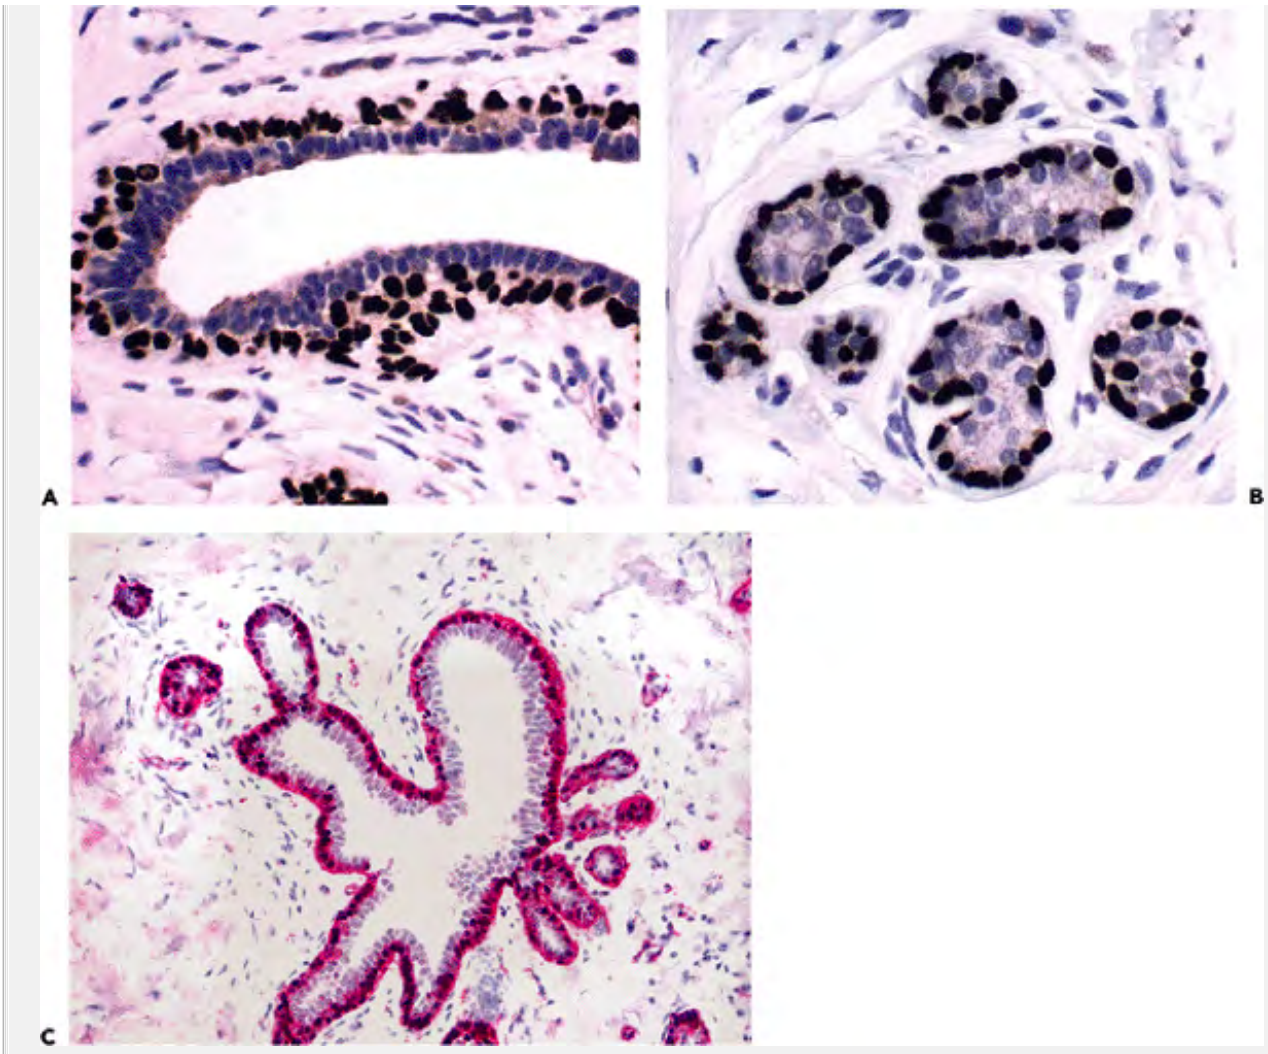

Figure 3.8 A. Extralobular duct and B. lobule immunostained for p63. The myoepithelial cells show strong nuclear reactivity, whereas the epithelial cell nuclei are negative. C. Double immunostain for smooth muscle actin (red cytoplasmic staining) and p63 (brown nuclear staining) highlight the myoepithelial cells around this mammary duct. Note the lack of staining of the epithelial cells for both p63 and smooth muscle actin.

A basal lamina consisting of type IV collagen and laminin surrounds the mammary ducts, ductules, and acini (17,26). This basal lamina is present outside of the myoepithelial cell layer and serves to

demarcate the breast ductal-lobular system from the surrounding stroma (Figure 3.9). Beyond the basal lamina, the extralobular ducts exhibit a zone of fibroblasts and capillaries. Elastic tissue is normally present in variable amounts around ducts and is generally more prominent in older than in younger women. Elastic fibers are not typically seen around the terminal ducts or acini.

The lobule, together with its terminal duct, has been called the terminal duct lobular unit (TDLU). This represents the structural and functional unit of the breast. During lactation, epithelial cells in both the terminal duct and lobule undergo secretory changes. Thus, the terminal ducts are responsible for both secretion and transport of the secretions

to the extra-lobular portion of the ductal system (12). Subgross anatomic studies have shown that most lesions originally termed â€œductalâ€• (e.g., cysts, ductal epithelial hyperplasia, and ductal carcinoma in situ) actually arise from the TDLU, which â€œunfoldsâ€• with coalescence of the acini to produce larger structures resembling ducts. The majority of pathologic changes in the breast, including in situ and invasive carcinomas, are generally considered to arise from the TDLU (11,27). Indeed, the only common lesion thought to arise from the large- or medium-sized duct rather than from the TDLU is the solitary intraductal papilloma (Figure 3.10).

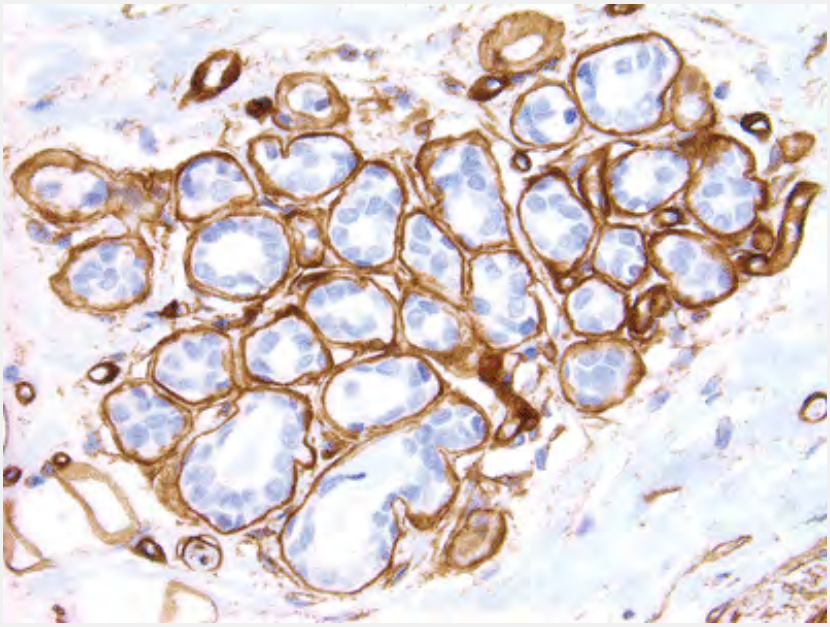

Figure 3.9 Immunostain for type IV collagen highlights the basal lamina around the acini of a lobule.

The normal lobule consists of a variable number of blind-ending terminal ductules, also called acini, each with its typical double cell layer. The lobular acini are invested by a loose, fibrovascular intralobular stroma with varying numbers of lymphocytes, plasma cells, macrophages, and mast cells. This specialized intralobular stroma is sharply demarcated from the surrounding denser, more highly collagenized, paucicellular interlobular stroma and stromal adipose tissue (Figure 3.11). One feature of note that is sometimes encountered in the extralobular stroma is the presence of multinucleated giant cells (28). Their significance is unknown; and, while they may present a disturbing appearance, they should not be mistaken for the malignant cells of an invasive carcinoma (Figure 3.12).

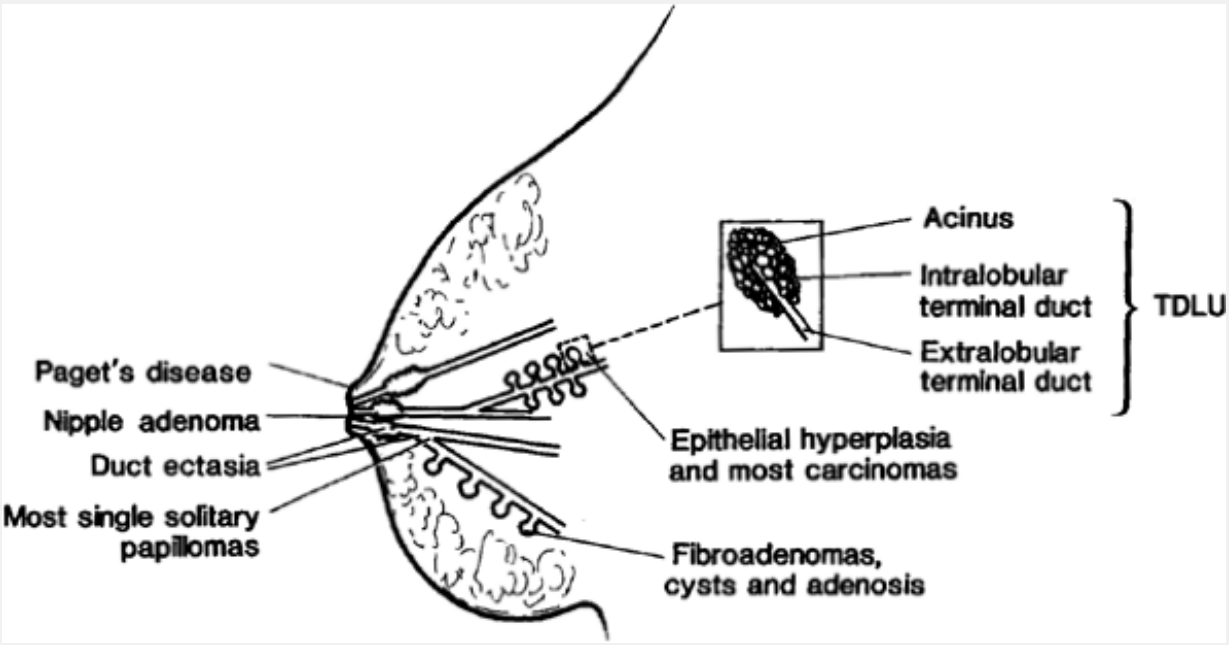

Figure 3.10 A schematic representation of the breast, indicating the sites of origin of pathologic lesions. (Reprinted from Schnitt SJ, Millis RR, Hanby AM, Oberman HA. The breast. Mills SE, Carter D, Greeson JK, Oberman HA, Reuter VE, Stoler MH eds. *Sternberg's Diagnostic Surgical Pathology*. 4th ed. Philadelphia: Lippincott Williams & Wilkins; 2004; 323â€“398.)

The size of mammary lobules and number of acini per lobule are extremely variable. Russo et al. (29,30,31) have described four lobule types. Type 1 lobules are the most rudimentary and are most prevalent in prepubertal and nulliparous women, comprising 65 to 80% of the lobules in this group (Figure 3.2). These lobules are comprised primarily of ducts with sprouting alveolar buds. Type 1 lobules gradually evolve to more mature structures (type 2 and type 3 lobules) through the development of additional alveolar buds. The number of alveolar buds per lobule increases from approximately 11 in type 1 lobules to 47 and 80 in type 2 and 3 lobules, respectively.

In the parous, premenopausal woman, type 3 lobules are most prevalent, comprising 70 to 90% of the lobular elements. Type 4 lobules are those seen during pregnancy and lactation. Of interest, Russo et al. (31) have reported that type 1 lobules predominate in the breasts of women with breast cancer, regardless of pregnancy history. They have also provided experimental evidence suggesting that type 1 and 2 lobules are more susceptible to malignant transformation than are type 3 lobules upon exposure to chemical carcinogens (32). It should be noted, however, that type 1, 2, and 3 lobules commonly co-exist in the same breast and that the utility of distinguishing among them in clinical practice remains to be defined.

The lobules exhibit morphologic changes during the menstrual cycle, and these are seen in both the epithelial

and stromal components (33,34,35,36). These changes are summarized in Table 3.2. While the changes that occur during the menstrual cycle are variable among lobules in the same breast, even among immediately adjacent lobules, a dominant morphologic pattern is typically present in each phase. However, these menstrual cycleâ€“related changes are subtle when compared with the dramatic alterations seen during pregnancy and lactation and when compared with the menstrual cycle-related changes seen in the endometrium.

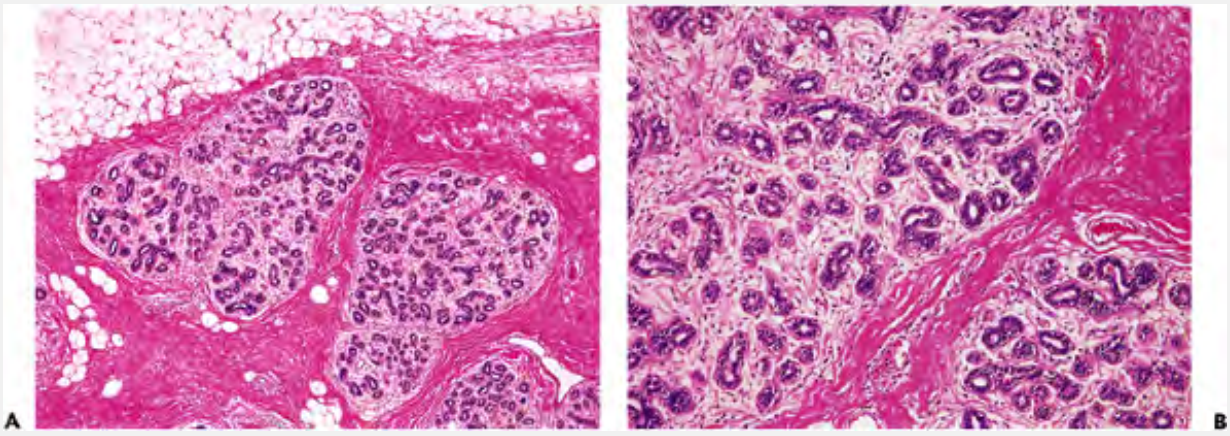

Figure 3.11 Intralobular and extralobular stroma. A. Low-power view of several lobules that are invested by loose, intralobular stroma. The interlobular stroma is composed primarily of dense collagen with admixed adipose tissue. B. Higher power view contrasts loose intralobular stroma with more collagenized interlobular stroma.

Occasionally, the TDLU epithelial cells show prominent clear cell change in the cytoplasm. This may be seen in both premenopausal and postmenopausal women and appears to be unrelated to pregnancy or exogenous hormone use (37).

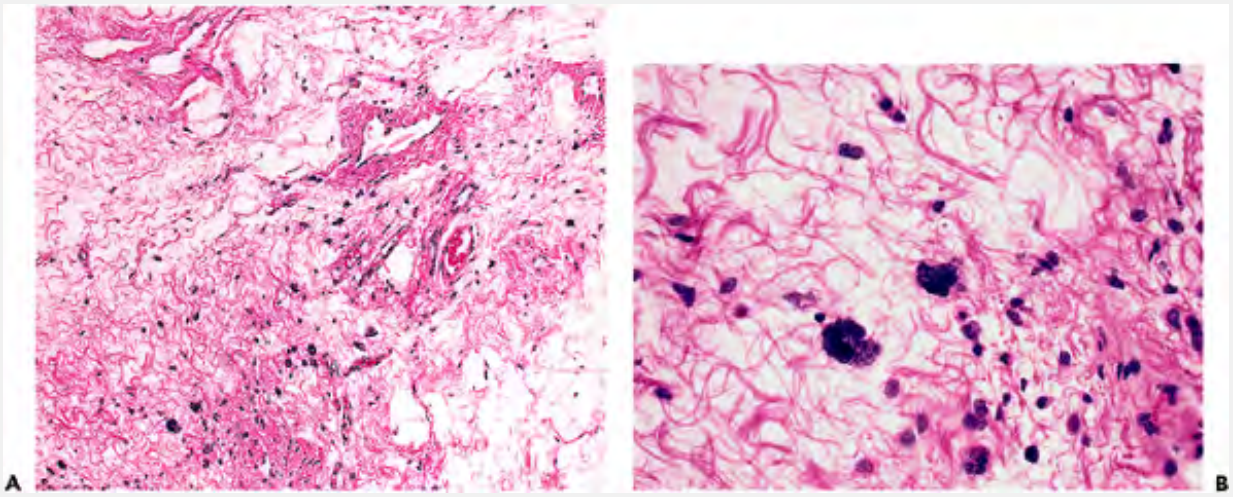

Figure 3.12 Multinucleated stromal giant cells. A. Low-power view showing multinucleated giant cells scattered in the stroma. B. High power illustrates cytologic detail. These cells have a mesenchymal phenotype. Despite their worrisome histologic appearance, they have no known clinical significance.

The nipple-areola complex is a circular area of skin that exhibits increased pigmentation and contains numerous sensory nerve endings. The nipple is placed centrally and is elevated above the surrounding areola. The tip of the nipple contains 15 to 20 orifices. However, as discussed earlier, the number of such openings may not correlate directly with the number of breast segments. In the nonlactating breast, these duct openings typically possess keratin plugs. The areola surface exhibits numerous small, rounded elevations, the tubercles of Montgomery.

Table 3.2 Histologic Changes in Lobules During the Menstrual Cycle (Adapted from Mccarty and Nath (8))

Menstrual Cycle Phase	Epithelium	Acinar Lumina	Intralobular Stroma
Early follicular	*Cells*: single cell type (small, polygonal cells with pale eosinophilic cells); myoepithelial cells inconspicuous *Orientation*: poor *Secretion*: none *Mitoses/apoptosis*: rare	Largely closed and inapparent	Dense, cellular, with plump fibroblasts
Late follicular	*Cells*: three cell types, including luminal basophilic cells, intermediate pale cells (as seen in early follicular phase), and myoepithelial cells with clear cytoplasm *Orientation*: radial around lumen *Secretion*: none *Mitoses/apoptosis*: rare	Well defined	Less cellular and more collagenized than in early luteal phase
Early	*Cells*: three cell	Open,	Loose

luteal	types, including luminal basophilic cells with minimal apical snouting, intermediate pale cells, and myoepithelial cells with prominent cytoplasmic vacuolization and ballooning *Orientation*: radial around lumen *Secretion*: slight *Mitoses/apoptosis*: rare	enlarged compared to follicular phase, with slight secretion	
Late luteal	*Cells*: three cell types, including luminal basophilic cells with prominent apical snouting, intermediate pale cells and myoepithelial cells with prominent cytoplasmic vacuolization *Orientation*: radial around lumen *Secretion*: active apocrine secretion from luminal cells	Open, with secretion	Loose, edematous, congested blood vessels

	Mitoses/apoptosis: frequent (peak of mitotic activity)		
Menstrual	*Cells*: two cell types, including luminal basophilic cells with scant cytoplasm and less apical snouting than in late luteal phase, and myoepithelial cells with extensive cytoplasmic vacuolization *Orientation*: radial around lumen *Secretion*: resorbing *Mitoses/apoptosis*: rare	Distended with secretion	Dense, cellular

Both the nipple and areola are covered by keratinizing, stratified squamous epithelium, and this extends for a short distance into the terminal portions of the lactiferous ducts. The epidermis of the nipple-areola complex may contain occasional clear cells that are cytologically benign and that must not be confused with Paget's cells (38,39) (Figure 3.13). Some of these cells represent clear keratinocytes, whereas others are thought to be derived from epidermally located mammary ductal epithelium (39).

The proximal ramifications of the mammary ductal system that are present in the dermis of the nipple typically have a pleated or

serrated contour (Figure 3.14). These ducts are surrounded by a stroma rich in circular and longitudinal smooth muscle bundles, collagen, and elastic fibers (Figure 3.15). Occasionally, lobules may be seen in the nipple (40). Simple mammary ducts are also present throughout the dermis of the areola, even at its periphery, and these may extend to within less than 1 mm of the basal layer of the epidermis (41).

While the nipple-areola complex lacks pilosebaceous units and hairs except at the periphery of the areola, the dermis contains numerous sebaceous glands. Some of

these glands open directly onto the surface of the nipple and areola, whereas others drain into a lactiferous duct or share a common ostium with a lactiferous duct. The tubercles of Montgomery represent a unit consisting of a sebaceous apparatus and an associated lactiferous duct (42) (Figure 3.16). During pregnancy, these tubercles become increasingly prominent. Apocrine sweat glands may also be seen in the dermis of the nipple and areola.

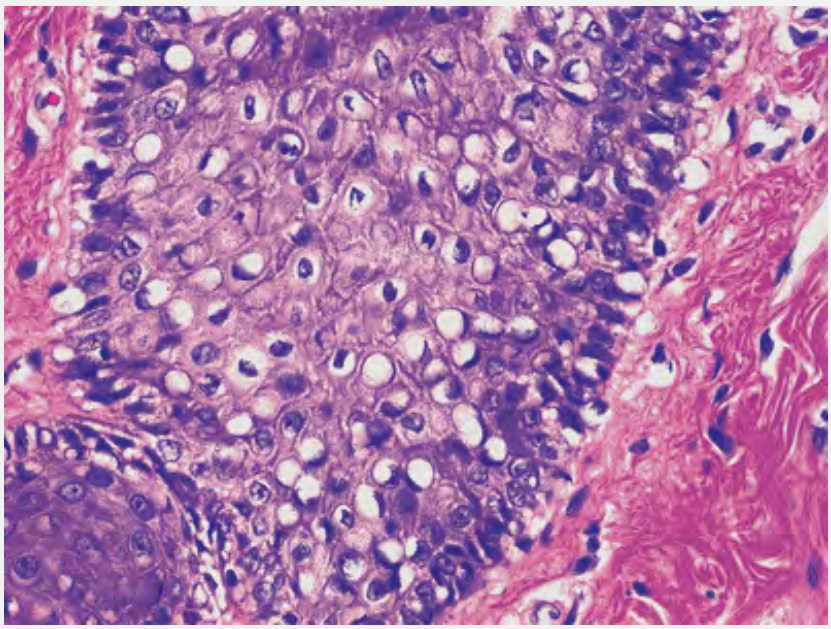

Figure 3.13 Clear cells in nipple epidermis. In some cells, the clearing is extreme, with formation of large intracytoplasmic vacuoles. These cells should not be mistaken for the cells of Paget's disease.

Another finding that may occasionally be encountered within the breast parenchyma is the presence of intramammary lymph nodes (43,44). These lymph nodes may be identified as an incidental finding in breast tissue removed because of another abnormality, or they may be seen as densities on mammograms (45).

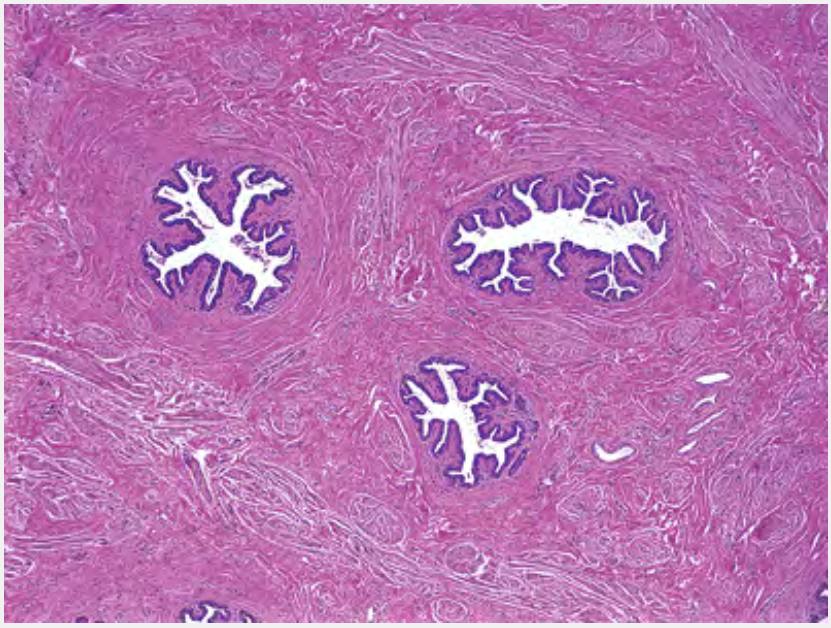

Figure 3.14 Cross section through the nipple. The irregular, pleated or serrated contour of the nipple ducts is evident.

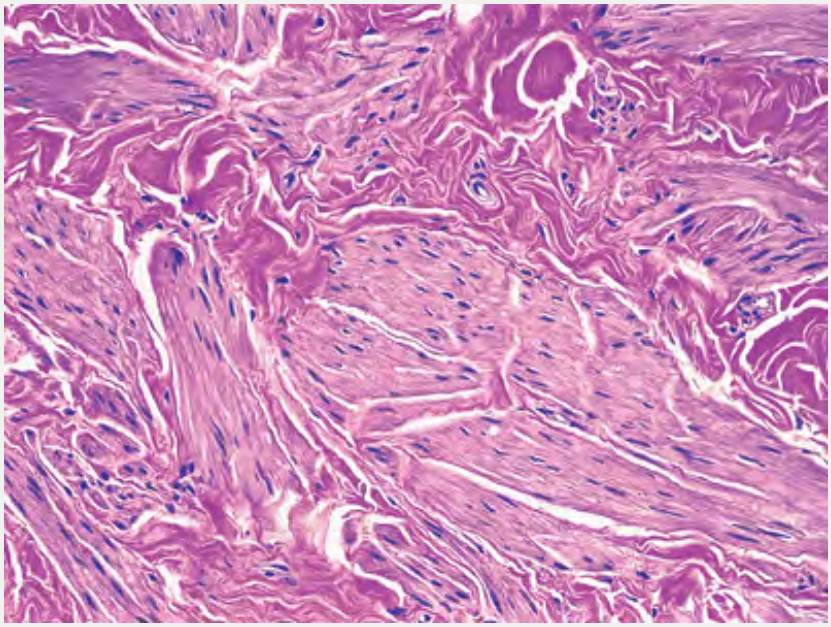

Figure 3.15 High-power view of nipple dermis/stroma, demonstrating prominent bundles of smooth muscle fibers.

Pregnancy and Lactation

It is not until pregnancy that full development of the breast occurs in humans. During pregnancy, epithelial cell proliferation resumes. There is a dramatic increase in the number of lobules, as well as in the number of acinar units within each lobule secondary to epithelial cell proliferation and lobuloalveolar differentiation under the influence of estrogen, progesterone, prolactin, and growth hormone; growth is further enhanced by adrenal glucocorticoids and insulin. This lobular development and expansion occurs at the expense of both the intralobular and extralobular stroma. By the end of the first trimester, there is grossly evident breast enlargement, superficial venous dilatation, and increased pigmentation of the areola.

During the second and third trimesters, lobular growth continues, and the acinar units begin to appear monolayered. The myoepithelial

cells in the acini are difficult to discern at this time due to the increase in size and volume of the epithelial cells, but they remain clearly evident in the extralobular ducts. The cytoplasm of the epithelial cells becomes vacuolated, and secretion accumulates in the greatly expanded lobules. After parturition, the lactating breast is characterized by distension of the lobular acini as a result of accumulated abundant secretory material and prominent epithelial cell cytoplasmic vacuolization. Many of the epithelial cells have a bulbous or hobnail appearance and protrude into the acinar lumina (Figure 3.17). Myoepithelial cells remain attenuated and inconspicuous. The florid changes seen in pregnancy and lactation can be alarming to the inexperienced observer; areas of infarction, which occasionally occur in the pregnant breast, may compound the problem (46).

When lactation ceases, the lobules involute and return to their normal resting appearance. Involution usually proceeds

unevenly and takes several months. Involuting lobules are irregular in contour and are frequently infiltrated by lymphocytes and plasma cells (47,48). Occasionally, an isolated lobule showing secretory changes may be seen in the breasts of women who are not pregnant. Although this is often called a residual lactating lobule, it may occur in the nulliparous woman as well.

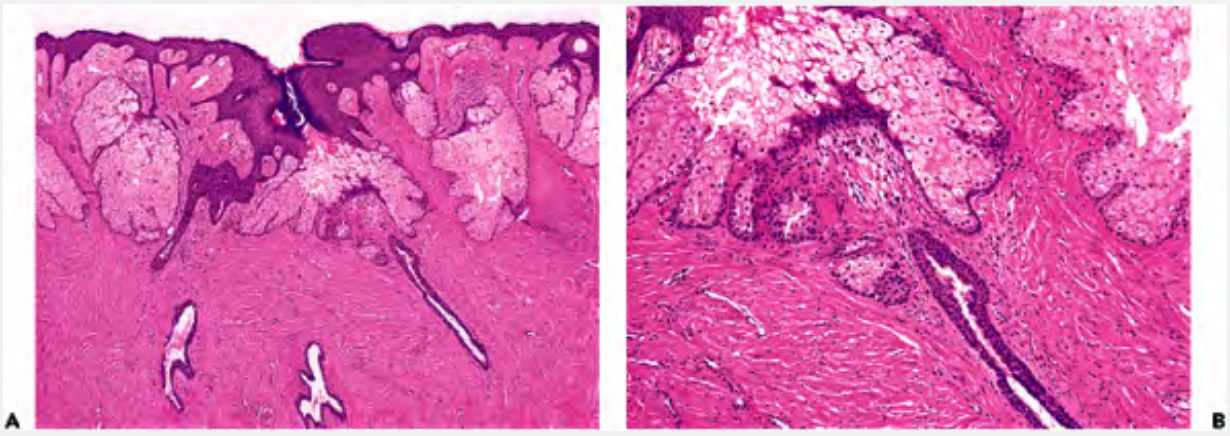

Figure 3.16 Montgomery's areolar tubercle. A. Low power view. B. Higher power view. These tubercles are units composed of a lactiferous duct and associated sebaceous gland.

Menopause

During the postmenopausal period, with the reduction of estrogen and progesterone levels, there is involution and atrophy of the mammary TDLUs, with reduction in the size and complexity of the acini, and there is loss of the specialized intralobular stroma (49,50). Ducts may become variably ectatic. The postmenopausal breast is characterized by a marked reduction in glandular tissue and collagenous stroma, often with a concomitant increase in stromal adipose tissue. The end stage of menopausal involution is typified by remnants of the TDLUs, typically composed of ducts with atrophic acini, surrounded by hyalinized connective tissue or embedded within adipose tissue with little or no surrounding stroma (Figure 3.18).

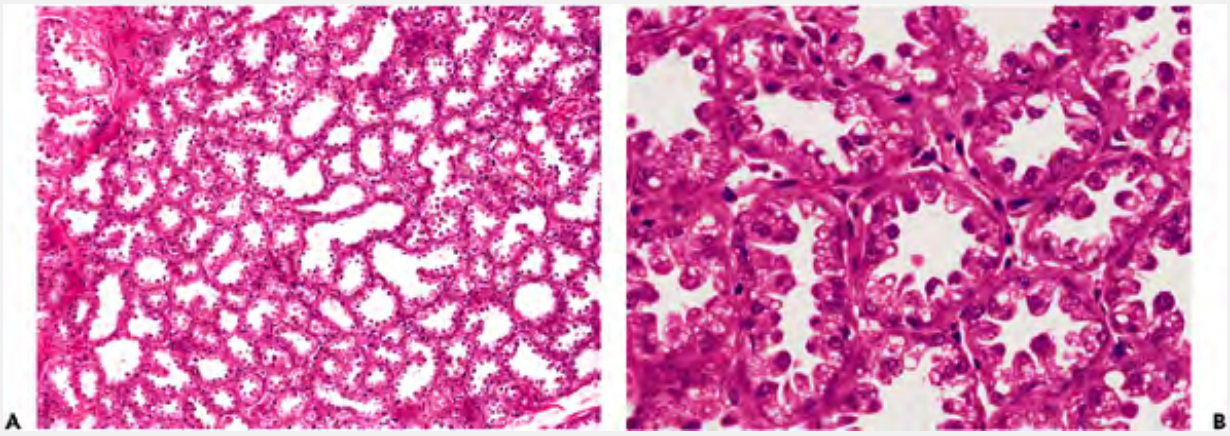

Figure 3.17 Lactating breast tissue. A. There are numerous acini in this lobule, and these are enlarged and dilated. There is minimal intervening stroma. B. Higher power view illustrates prominent epithelial cell enlargement, cytoplasmic vacuolization, and protrusion of cells into the acinar lumen. Some of the cells have a hobnail appearance. Myoepithelial cells are inconspicuous.

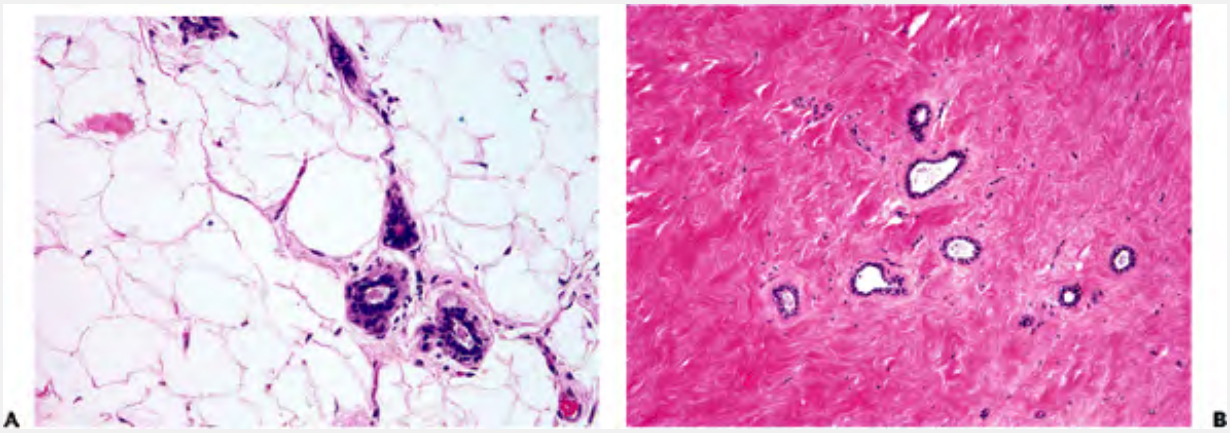

Figure 3.18 Postmenopausal breast tissue. A. This sample consists primarily of fatty stroma with a few atrophic ductules. B. In this specimen, a few residual, atrophic lobular acini are evident in a fibrotic stroma, which has replaced the normal, loose

intralobular stroma.

Blood Supply

The principal arterial supply to the breast is provided by the internal mammary and lateral thoracic arteries. Perforating branches of the internal mammary artery provide the blood supply to approximately 60% of the breast, mainly the

medial and central portions. Approximately 30% of the breast, mainly the upper and outer portions, receives blood from the lateral thoracic artery. Branches of the thoracoacromial, intercostal, subscapular, and thoracodorsal arteries make minor contributions to the mammary blood supply (7).

Venous drainage of the breast, as in other locations, shows considerable individual variation but largely follows the arterial system. There is a superficial venous complex that runs transversely from lateral to medial in the subcutaneous tissue. These vessels then drain into the internal thoracic vein. Deep venous drainage of the breast is via three routes: the perforating branches of the internal thoracic vein, branches of the axillary vein, and tributaries of the intercostal veins, which drain posteriorly into the vertebral veins and the vertebral plexus (5,51).

Lymphatic Drainage

Lymphatic drainage of the breast occurs through four routes: cutaneous, axillary, internal thoracic, and posterior intercostal lymphatics. The cutaneous lymphatic drainage system consists of both a superficial plexus of channels that lie within the dermis overlying the breast and a deeper network of lymphatic channels that runs with the mammary ducts in the subareolar area. Most of these cutaneous channels drain to the ipsilateral axilla. Cutaneous

lymphatics from the inferior aspect of the breast may drain to the epigastric plexus and ultimately to the lymphatic channels of the liver and intra-abdominal lymph nodes.

There are three lymphatic drainage pathways in the mammary parenchyma. The most important drainage basin for lymphatic flow from the breast is the axilla, and the axillary lymph nodes receive the vast majority of the lymph drained. The internal thoracic lymphatic route carries less than 10% of the lymphatic flow from the breast and ultimately terminates in the internal mammary lymph nodes (7). Drainage eventually empties into the great veins via the thoracic duct, the lower cervical nodes, or the jugular-subclavian confluence. The third and least important route of mammary lymphatic drainage are the posterior intercostal lymphatics, which drain into the posterior intercostal lymph nodes. An understanding of the lymphatic drainage of the breast is of particular importance in the current era of sentinel lymph node biopsy since this explains the occasional finding of sentinel lymph nodes outside of the axilla (5,7,8).

The Adult Male Breast

The adult male breast, like the female breast, is composed of glandular epithelial elements embedded in a stroma that is composed of varying amounts of collagen and adipose tissue. However, in contrast to the adult female breast, the epithelial elements of the male breast normally consist of branching ducts without lobule formation.

Biologic Markers, Immunophenotype, and Molecular Biology

Estrogen Receptor and Progesterone

Receptor

It is now known that there are at least two different estrogen receptors (ER), ERÎ± and ERÎ²; ERÎ± has been far more extensively studied. Using immunohistochemistry, ERÎ± expression can be demonstrated in the nuclei of both ductal and lobular epithelial cells, with a higher proportion in

lobules than in ducts. However, even in the lobules, only a small proportion of the cells show ERÎ± immunoreactivity. Most often, ERÎ±-positive cells in the lobules are distributed singly, admixed with and surrounded by ERÎ±-negative cells (52) (Figure 3.19). Furthermore, there is considerable heterogeneity in staining for ERÎ± among lobules in the same breast. Of interest, in breast tissue from premenopausal women, there is generally an inverse relationship between expression of ERÎ± and markers of cell proliferation. In particular, most ERÎ±-positive cells do not show expression of the proliferation related antigen Ki-67, and Ki-67-positive cells are typically ERÎ±-negative. The proportion of ERÎ±-positive cells gradually increases with age but remains relatively stable after the menopause. The incidence of lobules showing contiguous patches of ERÎ±-positive cells also increases with age and with involutional changes (52). In addition, the proportion of ERÎ±-positive proliferating cells increases with age (53). In premenopausal women, ERÎ± expression varies with the phase of the menstrual cycle, being higher in the follicular than in the luteal phase (54). Myoepithelial cells do not show ERÎ± immunoreactivity.

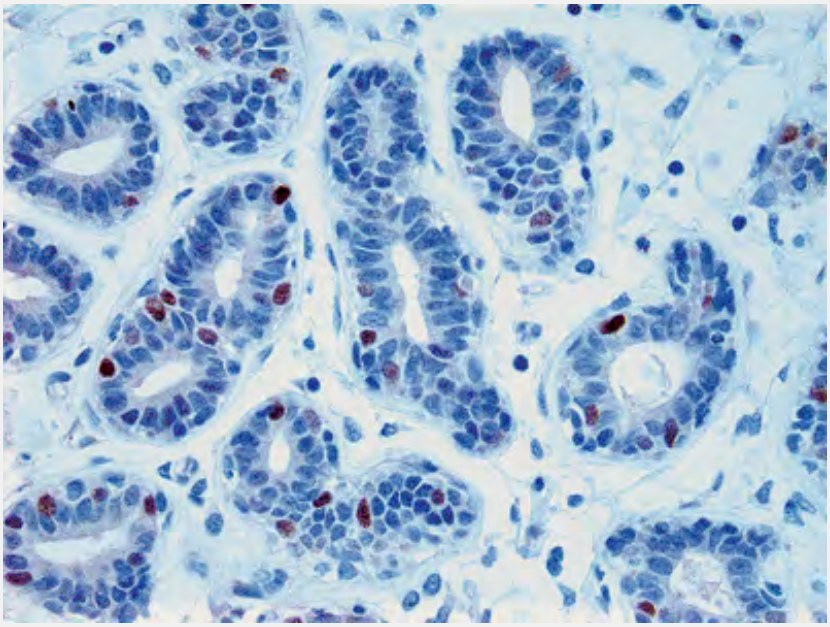

Figure 3.19 Immunostain for estrogen receptor-Î± (ERÎ±) in a normal lobule. A minority of epithelial cells show nuclear staining.

Recent studies have indicated that a second form of ER, ERÎ², is also expressed in normal breast tissue. Expression of ERÎ² has been observed not only in epithelial cells of ducts and lobules, but also in myoepithelial cells, endothelial cells, and stromal cells (54,55). The expression of this form of ER does not seem to vary with the phase of the menstrual cycle. It has been speculated that the relative levels of ERÎ² and ERÎ± may be important in determining the risk of breast cancer development, and that higher levels of ERÎ² relative to ERÎ± are protective against neoplastic progression in the breast (55). However, additional studies are needed to more clearly elucidate the role of ERÎ² in normal breast physiology and in breast cancer pathogenesis.

Expression of progesterone receptor (PR) has not been as extensively studied in normal breast tissue as has ER. Like ERÎ±, PR is expressed

in the nuclei of ductal and lobular epithelium. However, in contrast to ERÎ± expression, PR expression does not seem to vary with the menstrual cycle phase (54).

Other Biomarkers and Immunophenotypic Features

Expression of a wide variety of biomarkers has been studied in benign breast tissue (56) and a comprehensive review of these is beyond the scope of this chapter. However, a few of these merit brief mention. Rarely, normal breast epithelium may show HER2 protein overexpression, *p53* protein accumulation, or *p53* mutations, but, the clinical significance of these findings is uncertain.

The anti-apoptotic protein bcl-2 is consistently expressed by normal breast epithelial cells (57). The S-100 protein is strongly expressed by normal myoepithelial cells and variably expressed by mammary epithelial cells (58). Epithelial cells also show variable expression for casein (59), Î±-lactalbumin (60), gross cystic disease fluid protein-15 (61), and c-kit (CD117) (62), among other proteins. As noted earlier, cytokeratins 7, 8, 18, and 19 (16,17,18,19,20) are typically expressed by epithelial cells, whereas myoepithelial cells express cytokeratins 5/6, 14, and 17 (16,17,18,19,20,24).

Molecular Markers

The ability to evaluate DNA, RNA, and protein using the modern tools of molecular biology, particularly when guided by such techniques as laser capture microdissection (63), will greatly enhance our understanding of breast tumorigenesis and may even serve to redefine what constitutes â€œnormal.â€• For example, a number of studies have shown that histologically normal TDLUs can exhibit an abnormal genotype, characterized by loss of heterozygosity (64) or allelic imbalance (65,66) at various chromosomal loci. At this time, however, the significance of these genetic alterations in histologically

normal breast tissue remains to be determined. Studies of normal breast tissue using these techniques will also help define the presence and nature of progenitor cells or stem cells and their role in breast development and carcinogenesis (19,67), as well as patterns of gene and protein expression that distinguish normal from abnormal breast tissue and cells (68,69,70,71).

Conclusion

The histologic features of the normal breast are dynamic and vary with age and hormonal milieu, among other factors. An understanding of normal breast histology is essential to permit the reliable distinction between physiologic changes and pathologic alterations.

Bone

Andrew E. Rosenberg

Sanford I. Roth

Introduction

Bone tissue along with cartilage, fibrous tissue, fat, blood vessels, nerves, and hematopoietic elements form individual bones. In humans, there are 206 separate bones, which together with their articulations form the skeleton. Anatomically, the skeleton can be divided into the *axial* skeleton, which includes the skull, vertebral column, ribs, sternum, and hyoid, and the *peripheral* (or *appendicular*) skeleton, which consists of the upper and lower limbs and the pelvis (Figure 4.1). The *acral* skeleton refers to the bones of the hands and feet.

Bone, whether referring to an organ or a type of connective tissue, is composed of a unique biphasic blend of organic and inorganic elements. The quality, quantity, and architectural arrangement of these components determine its ultimate form and function and confer important biological properties. The contributions of bone to mineral homeostasis are vital to life, and its structural characteristics are essential to locomotion and organ protection. Additionally, bones form the framework of our bodies, thereby giving it size and shape and provide a nurturing storehouse for the hematopoietic elements.

Boneâ€”the Organ: Gross and Microscopic Anatomy

Bones are rigid (but not brittle), lightweight, usually cylindrical structures, that have a relatively high tensile strength. Tan-white and smooth-surfaced, they are the hardest and strongest structures of the body, being as strong as cast iron but one-third of the weight as a result of their unique structure. Bones are reinforced, asymmetric, hollow structures designed to provide a maximum strength-to-weight ratio (Figure 4.2).

Individual bones are classified according to their size and shape. There are bones that are flat (bilaminar plates), those that are cuboid, and the most common group are bones that are tubular, both long and short (Figure 4.1). Tubular bones are further subdivided anatomically along their long axis into the epiphysis (extends from the base of the articular surface to the region of the growth plate), the metaphysis (extends from the region of the growth plate to where the diameter of the bone becomes significantly narrow), and the diaphysis or shaft (extends from the base of one metaphysis to the base of the opposing metaphysis) (Figure 4.3). In immature or growing bones, the metaphysis is

separated from the epiphysis by a cartilaginous growth plate, or physis (1). Apophyses, such as the greater and lesser trochanters of the femur, are protuberances that form at large tendoligamentous insertion sites. The medical and forensic determination of skeletal age and growth utilizes the amount and localization of bone ossification, the formulation and size of the secondary ossification centers, and the degree and amount of remodeling (see below).

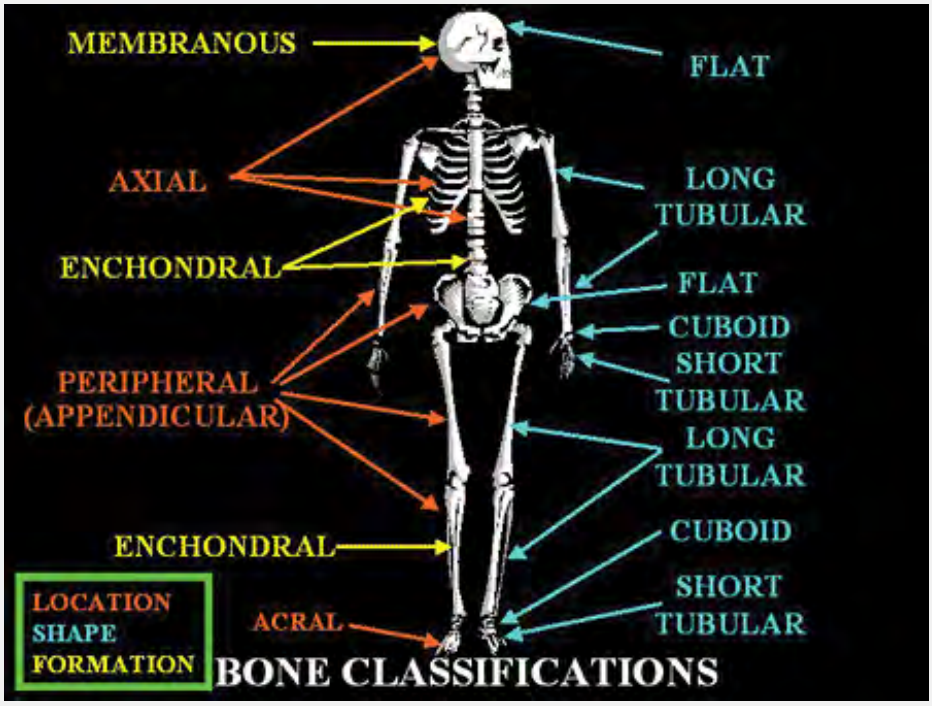

Figure 4.1 Diagram of the skeleton illustrating the different shapes and sizes of bones, as well as their method of formation.

Despite their differences in size and shape, all bones are of similar composition and generally have a periosteum, cortex, and medullary canal that contains variable amounts of cortical (compact) and cancellous bone, fatty and hematopoietic marrow (Figure 4.2), blood vessels, and nerves. For any given bone, the quantity and arrangement of cortical or cancellous bone is directly related to the biomechanical requirements (Wolff's law). For instance, bones exposed to the largest torsional forces are usually long bones, and they are composed roughly of 80% cortical bone and 20% cancellous bone. In contrast, bones that predominately transmit weight-bearing forces, such as the vertebral bodies, consist of 80% cancellous bone and 20% cortical bone.

Figure 4.2 Gross (*left*) and macerated (c*enter*) longitudinally cut specimen and the accompanying x-ray (right) of a proximal femur, including the head, neck, and upper diaphysis sectioned in the frontal plane. The cortex defines the outer limits of the bone and is thickest along the medial surface (*left*) of the neck and diaphysis, where load bearing is greatest. The medullary cavity is filled with bony trabeculae and red hematopoietic and yellow fatty marrow. The trabeculae are aligned along the lines of stress; this is especially prominent in the medial portion. The horizontal line at the base of the head on the x-ray represents the accrual of bone that occurred during closure of the epiphyseal growth plate.

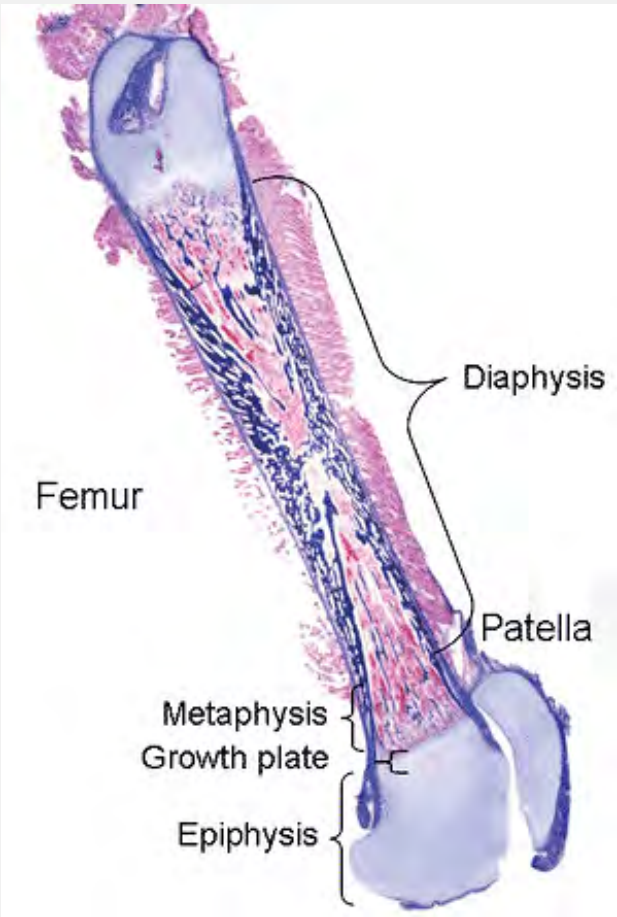

Figure 4.3 Whole mount of an immature femur and patella. The long bone is composed of the proximal and distal epiphyses, metaphyses and growth plates, and the intervening diaphysis.

Woven and Lamellar Bone

Histologically, bone tissue, regardless of whether it is cortical or cancellous, normal or part of a pathologic process, is categorized into woven and lamellar types based on the organization of its type I collagen fibers. In woven bone, the collagen fibers are arranged in an irregular feltwork (Figure 4.4), while in lamellar bone they are deposited in parallel arrays (Figure 4.5).

Woven bone is fabricated during periods of rapid bone growth; it composes the developing bony skeleton during embryogenesis and portions of bones in the growing infant and adolescent. It may also be the predominant type of bone that is formed in a variety of reactive (fracture-callus, infection-involucrum) and neoplastic (Codman's triangle, matrix of bone forming neoplasms) conditions. Woven bone is hypercellular, and the osteocytes and their lacunae

are large and appear to be distributed in a haphazard fashion as the long axes of the cells parallel the feltlike direction of the neighboring collagen fibers (Figure 4.4). The mineral content of woven bone is higher than that of lamellar bone, and more than 50% of it is deposited outside of the collagen fibers. Overall, this structural organization enables woven bone to resist forces equally in all directions and facilitates rapid formation, mineralization, and resorption. These factors explain why woven bone is weaker, less rigid, and more flexibile than lamellar bone.

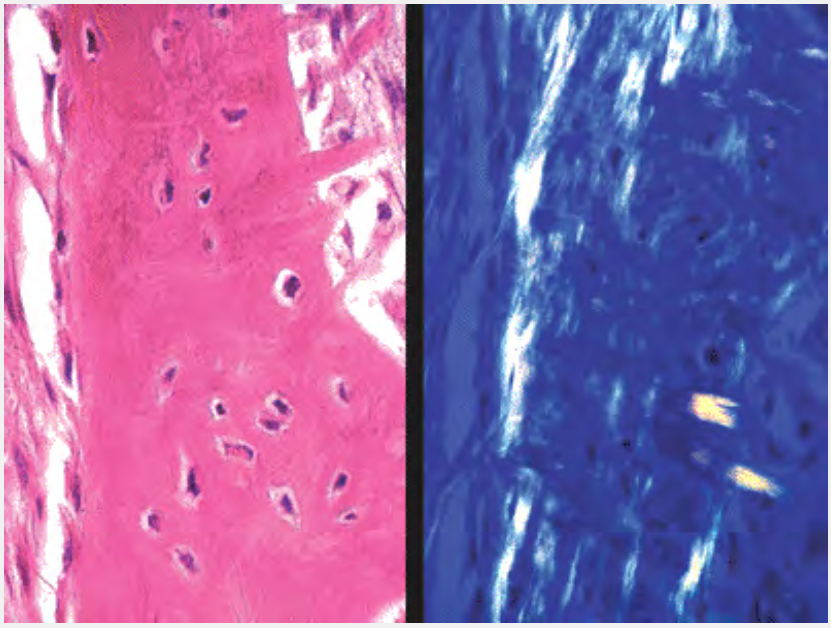

Figure 4.4 Woven bone seen on hematoxylin- and eosin-stained

slide (*left*) and with polarized light (*right*). The collagen fibers are oriented in all planes. There are many osteocytes, and their long axes follow the direction of the neighboring collagen fibers.

Normally, the entire mature skeleton is composed solely of lamellar bone. Lamellar bone, in contrast to woven bone, is synthesized more slowly, is less cellular, and the osteocytes and their lacunae are smaller and distributed in a more organized fashion along the more regular collagen lamellae (Figure 4.5). Additionally, the process of mineralization of lamellar bone differs from that of woven bone in that it occurs more slowly and continues long after the organic matrix is initially deposited. Furthermore, the mineral deposits are localized almost exclusively within the collagen fibers and are first deposited within the spaces, or â€œhole regions,â€• between the ends of adjacent collagen fibers (2,3). Subsequently, the mineral content increases as a result of enlargement and increase in the number of the apatite crystals. Microradiographs of undemineralized sections reveal varying densities, with the oldest bone being most heavily mineralized (Figure 4.6). Since the mineral and collagen fibers are well-organized and intimately bound to one another, lamellar bone has greater rigidity and tensile strength and less elasticity than woven bone.

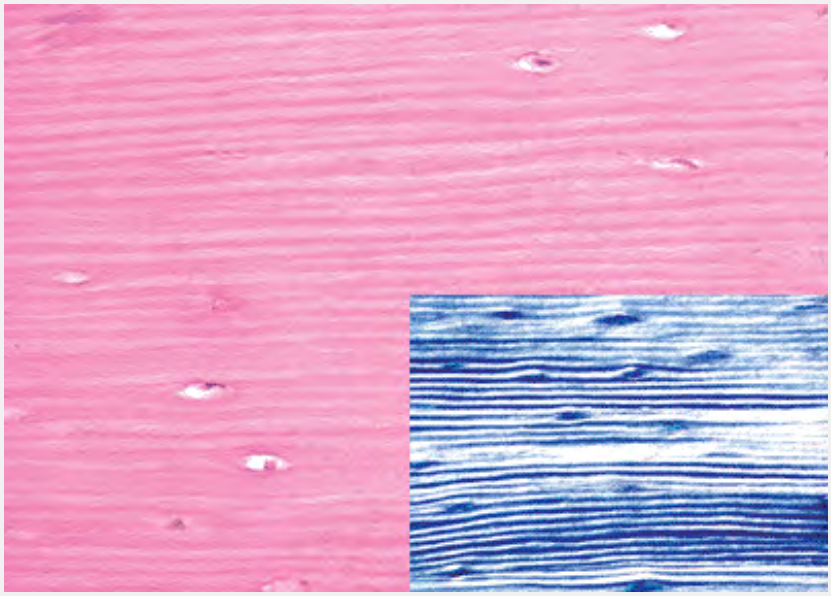

Figure 4.5 Lamellar bone as seen on hematoxylin- and eosin-stained slide and with polarization (inset). The collagen fibers are arranged in parallel arrays. There are comparatively fewer osteocytes, and they oriented in the same direction as the collagen fibers.

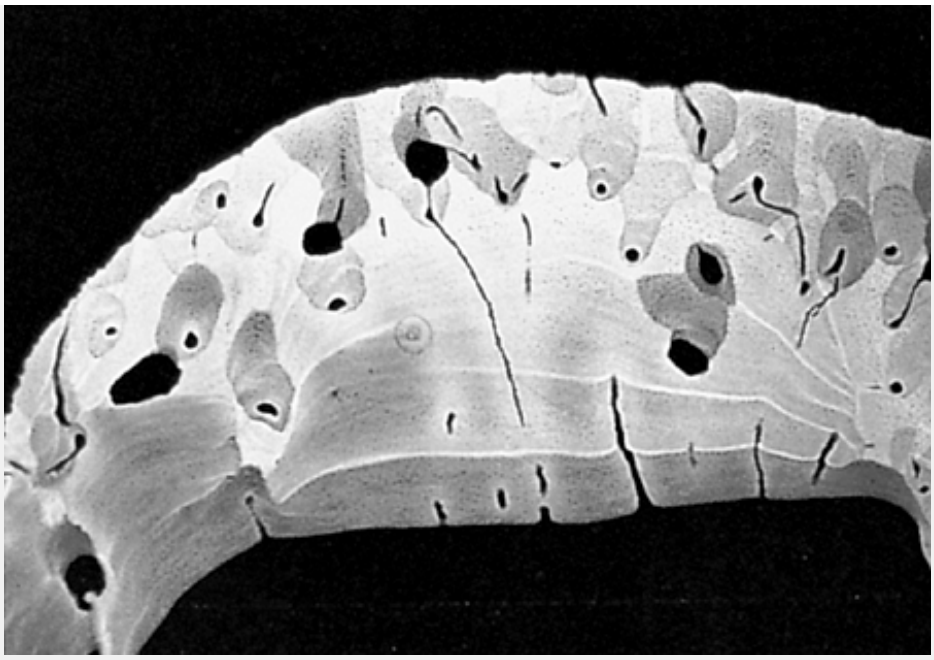

Figure 4.6 Microradiograph of the cortex of a 2-month old female. There are various degrees of mineralization, with the radiolucent being the most recently deposited and the radiodense portions representing the oldest.

Both lamellar and woven bone are made by osteoblasts in discrete quantities or units, which are fastened to one another by cement or reversal lines. Cement lines are thin and intensely basophilic on conventional histologic slides, and comparatively little is known about them. Recent studies, however, have shown that they are collagen poor, have less mineral, an increased calcium-to-phosphorus ratio compared to hydroxyapatite, and are richer in sulfur than is the surrounding bone matrix (4,5). Some investigators have suggested that cement lines represent a residuum of mineralized â€œground substanceâ€• that is secreted during the initial reversal phase in the formation of new bone (6).

Cortical (Compact) Bone

Cortical bone, also known as dense compact bone, is hard and tan-white (Figures 4.2, 4.7). Its thickness depends on its location and mechanical requirements, being thickest in

areas exposed to large torsional and weight-bearing forces, such as the middiaphysis of the femur or tibia, and thinnest where the transmission of weight-bearing forces is paramount, as seen adjacent to articular surfaces and in vertebral bodies (Figure 4.2).

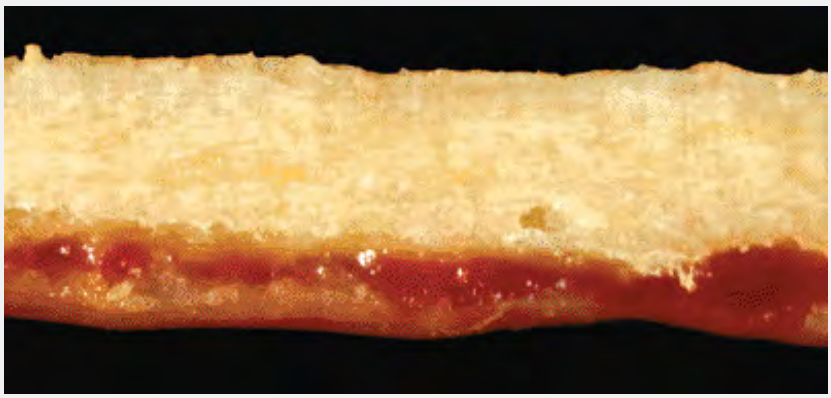

Figure 4.7 Longitudinal section through cortical bone. The cortex is tan-white and solid. The round hole within it represents the pathway of the nutrient artery.

During the early stages of growth and development, cortical bone is constructed entirely of woven bone. Over time, it is gradually remodeled until it is composed of pure lamellar bone in the mature skeleton. Adult cortical bone is composed of three different architectural patterns of lamellar bone: circumferential, concentric, and interstitial (Figure 4.8). The circumferential lamellae form outer and inner envelopes to the cortex and consist of several subperiosteal and endosteal layers that are oriented parallel to the long axis of the bone. They are the first cortical lamellae to be

deposited, and in young individuals comprise almost the entire cortex. As mechanical stresses on the bone increase, many of the circumferential lamellae (except for several lamellae just beneath the periostum and along the endosteum) are replaced by the concentric lamellae of the haversian systems (Figures 4.8,4.9,4.10,4.11,4.12).

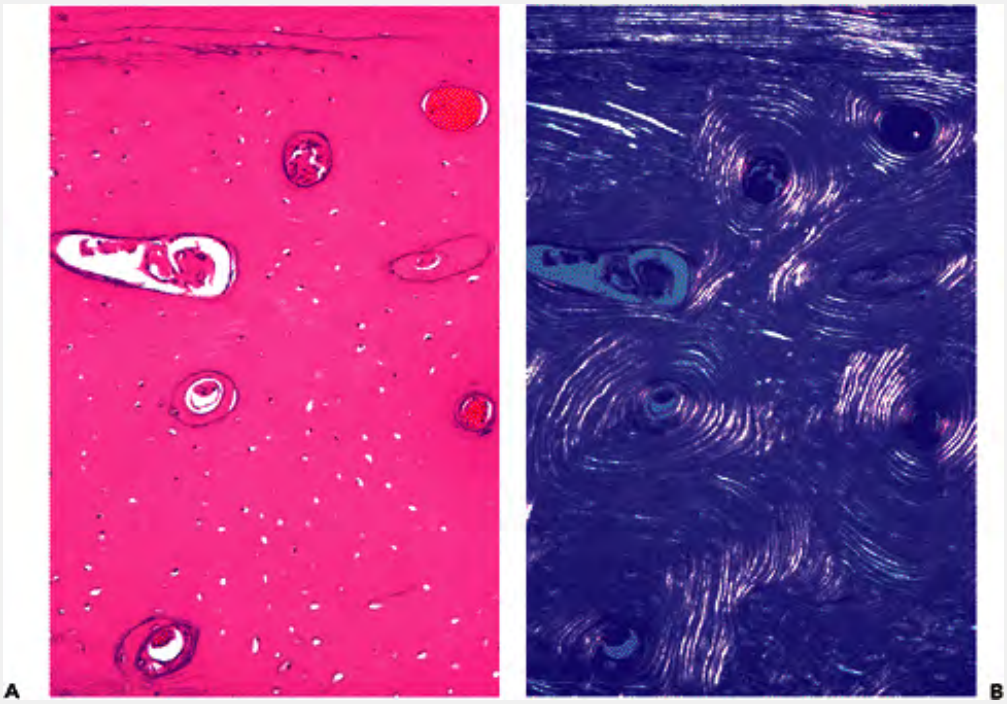

Figure 4.8 Cross sections of cortex with circumferential, concentric, and interstitial lamellae. The circumferential lamellae are beneath the periosteum, the concentric lamellae surround the haversian canals containing blood vessels, and the interstitial lamellae fills the intervening spaces (A, H&E; B, polarized light).

Haversian systems, or osteons, are created by osteoclastic resorption of the circumferential lamellae that usually begins on the endosteal surface of the cortex, and less

frequently on the periosteal surface. As the bone resorption

proceeds, it penetrates into the cortex and forms a canal (Volkmann's canal) perpendicular or at an angle to the long axis of the bone (Figures 4.10, 4.11). The numerous osteoclasts located in the head of the canal form the â€œcutting cone,â€• and the canal they generate is filled with vessels, nerves, and mesenchymal cells (including stem cells) enmeshed in a loose connective tissue stroma. Within a short distance, the osteoclastic activity becomes concentrated on one side of the canal; and, as a consequence, the direction of the cutting cone becomes aligned with the long axis of the bone. The burrowing osteoclasts elongate the canal, and in their wake newly formed osteoblasts deposit lamellae of bone in a targetlike, or concentric, fashion. The collagen fibers in any one lamella are oriented parallel to each other; however, their pitch is slightly different from those in adjacent lamellae, and this enhances the

biomechanical strength of the cortex. In due course, the accrual of concentric lamellae reduces the diameter of the haversian canal so that in the end it is small and contains nutritional blood vessels and nerve twigs (Figure 4.8).

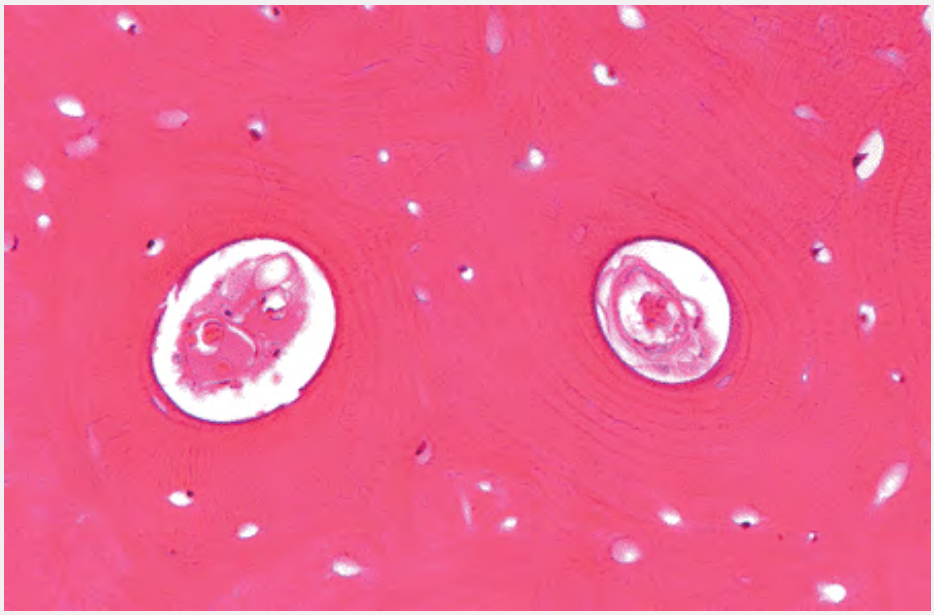

Figure 4.9 Two adjacent mature haversian systems containing the central canal, blood vessels, and surrounding concentric lamellae. Empty lacunae are seen in areas of the interstitial lamellae.

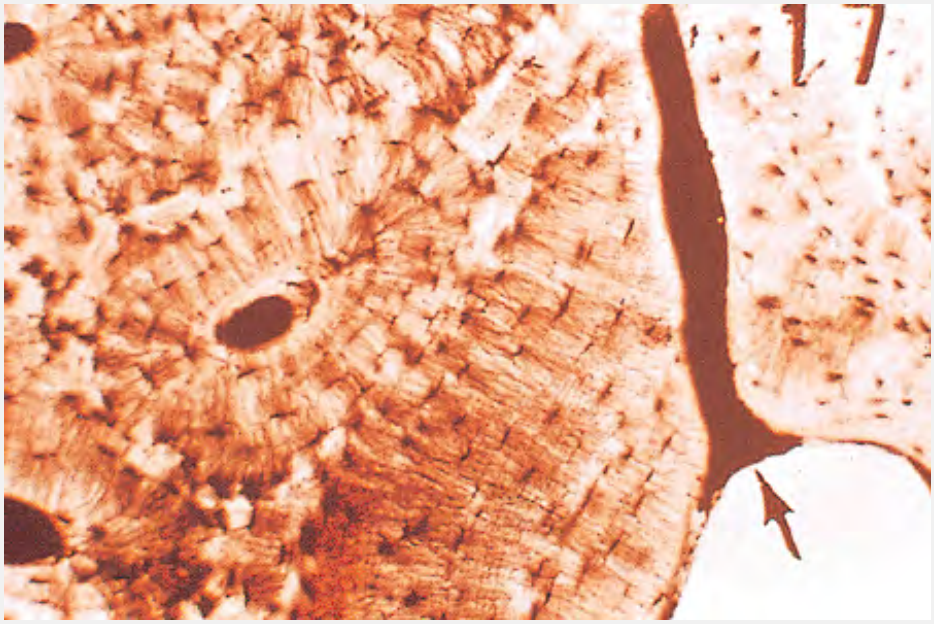

Figure 4.10 Ground, unstained section of mineralized, compact, cortical bone. The arrow points to a Volkmann's canal arising from the endosteum. Canaliculi connect cells in adjacent circumferential lamellae. (This slide was prepared by Glimcher MJ, Roth SI, Schiller AL, as part of a course in Pathophysiology of Bone for the Harvard Medical School, Boston, MA.)

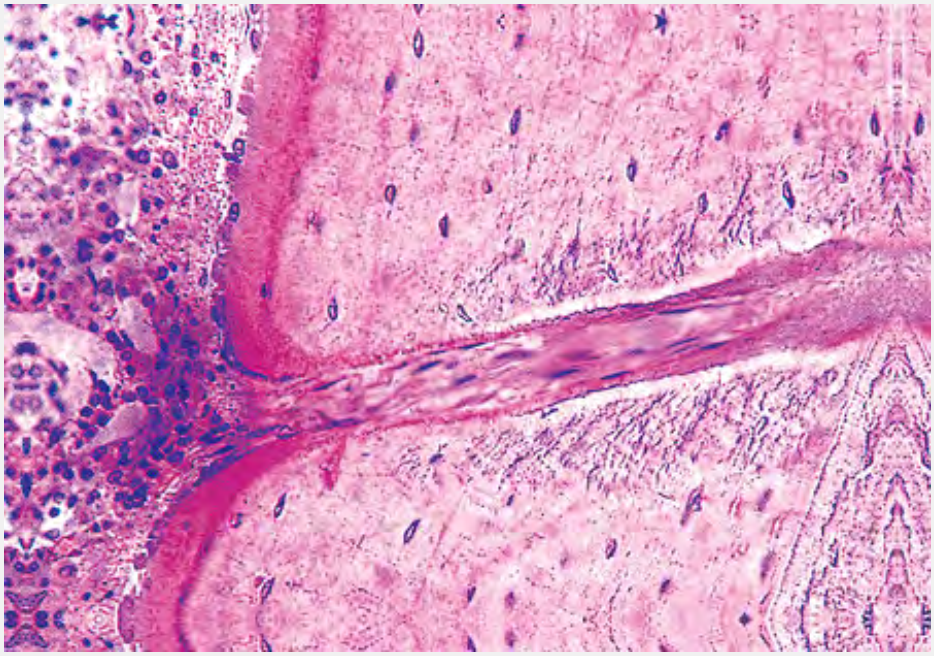

Figure 4.11 A forming Volkmann's canal coursing through the cortex of the bone. The canal is angled with respect to the bone lamellae and is filled with connective tissue. Osteoid and osteoblasts, indicating new bone formation, are present around the endosteal opening of the canal, but none are seen in the canal. The cortex shows circumferential lamellar bone with regularly placed osteocytes. (Undemineralized bone section.)

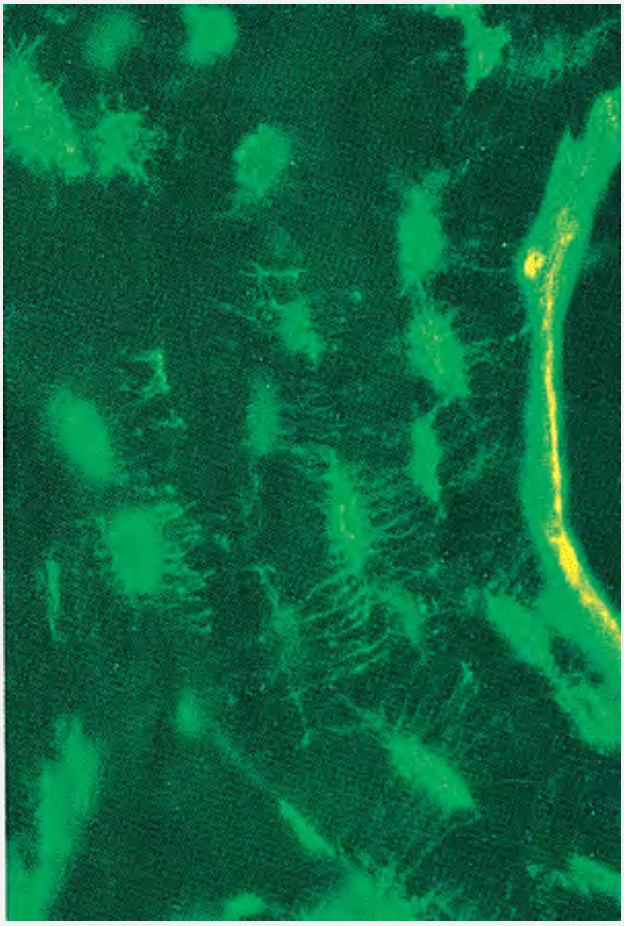

Figure 4.12 An undemineralized section of cortical bone, stained in vivo, with tetracycline. A layer of tetracycline appears at the mineralization front of the haversian system where new bone is being formed. The osteocyte lacunae and the canaliculi of their connecting dendritic processes are visible as bright green areas. (Unstained, fluorescent light.)

Individual haversian systems are relatively self-contained metabolic units because nutritional support of their cells, especially the bone cells, depends upon the process of diffusion from their central vessels. Consequently, osteocyte viability is not sustainable beyond a certain distance from the vessels, which imposes a biologic limit on

the maximal number of lamellae contained within any haversian system. Also, the integrated network of osteocytes is generally limited to the osteon within which it develops, as osteocytic cytoplasmic processes generally contact only those that dwell in the same system, with cement lines defining the physical boundaries of every haversian system (Figures 4.10, 4.12).

Mature haversian canals are long and cylindrical, range from 25 to 125 Âµm in diameter (average 50 Âµm), and are widest nearest the medullary cavity. They form an intricate, branching, spiraling, and interconnecting network that courses thoughout the cortex. The number of haversian systems in a particular bone is variable and is determined by age, the amount of mechanical stress and weight that the bone is subjected to over time, and other biological and genetic factors (6,7).

Between the haversian systems are the interstitial lamellae, which are somewhat irregular, geometric-shaped units of lamellar bone (Figure 4.9). They fill the spaces between active haversian systems and help â€œglue,â€• or anneal, them to one another, which is important in maintaining cortical integrity. The osteocytes confined to the interstitial lamellae may lose their access to nutritional sources and consequently undergo necrosis, leaving behind empty lacunae.

The endosteum is the loose areolar connective tissue that immediately abuts the osteoblasts along the inner surface of the cortex and along the medullary surfaces of the trabeculae.

Cancellous (Trabecular, or Spongy) Bone

Cancellous bone, also known as trabecular or spongy bone, is tan-white and fenestrated. It is composed of interconnecting plates and struts of trabecular bone and is located within the medullary cavity (Figure 4.2). In the adult, it is the fourth type of lamellar bone, and the lamellae are oriented parallel to the long axis of the bone (Figure

4.13). In developing bone, it is composed of significant amounts of woven bone; and, when initially formed, it contains a central core of calcified cartilage (primary spongiosa). Cancellous bone is deposited in relation to lines of mechanical stress (Wolff's law) to provide added support and distribute large weight-bearing forces along a variety of different pathways (Figure 4.2). Accordingly, cancellous bone is most abundant in the weight-bearing ends of bones, such as the epiphyses and vertebral bodies, and is present in only small amounts in the middiaphysis of tubular bones. Small trabeculae are avascular, while larger ones may contain haversian systems, including concentric lamellae. The surfaces of mature trabeculae are typically lined by endosteum composed of quiescent osteoblasts or surface-lining cells (Figure 4.14). In three dimensions, the trabeculae are usually interconnecting plates (Figure 4.15). The global surface area of cancellous bone is very large, which facilitates remodeling and the ability of the skeleton to rapidly respond to the metabolic demands of the body. The mature trabeculae are heavily mineralized with a thin (1â€“3 Âµm) layer of osteoid beneath the inactive flattened osteoblasts.

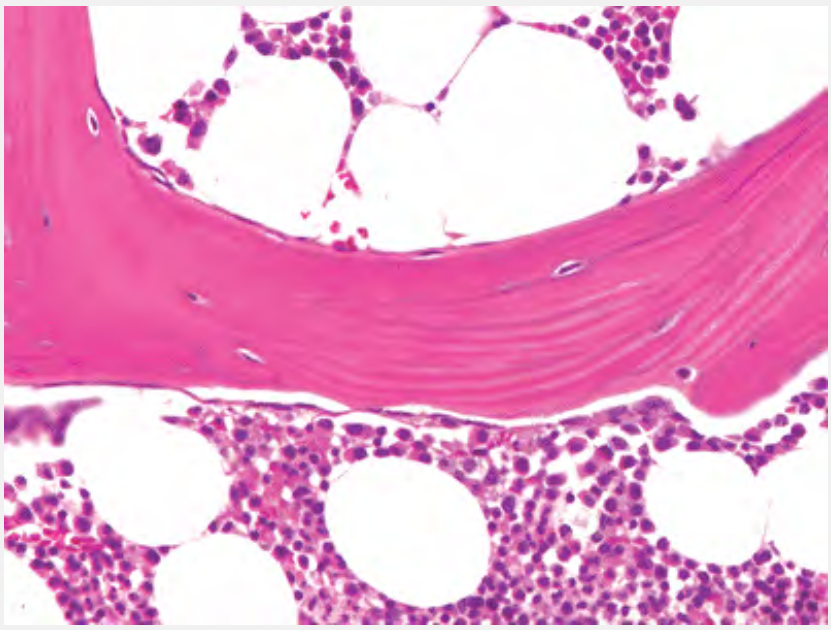

Figure 4.13 A mature trabeculum composed of lamellar bone. The lamellae are oriented in the same direction as the trabeculum.

Periosteum

The periosteum consists of a thin layer of tan-white connective tissue that covers the outer surface of all cortices. In children it is relatively loosely attached, whereas in adults it is firmly anchored to the bone. The periosteum is composed of an outer fibrous layer and an inner cellular (cambium)

layer (Figure 4.16). The fibrous layer contains fibroblasts and broad collagen fibers that are continuous with those of the joint capsule, tendons, and muscle fascia. At tendoligamentous insertion sites, the collagen fibers of the tendoligamentous structure pierce the periosteum and become anchored in the bone (Sharpey's fibers). Spindle-shaped fibroblasts and osteoprogenitor cells occupy the cambium layer, which is generally the most cellular during growth and development. The number of osteoprogenitor cells present depends on the age of the individual and the amount of bone cell activity in any particular region; they are especially numerous during periods of active bone formation.

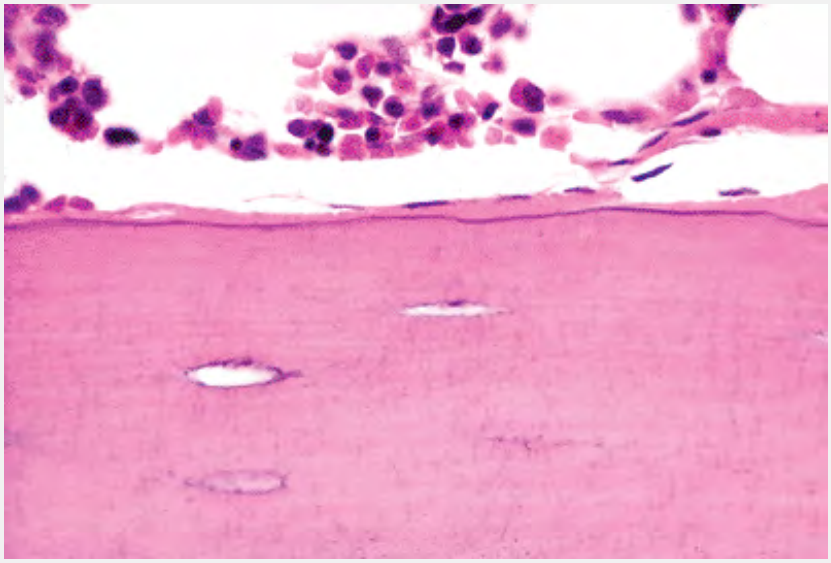

Figure 4.14 Quiescent osteoblasts lining a trabecular surface.

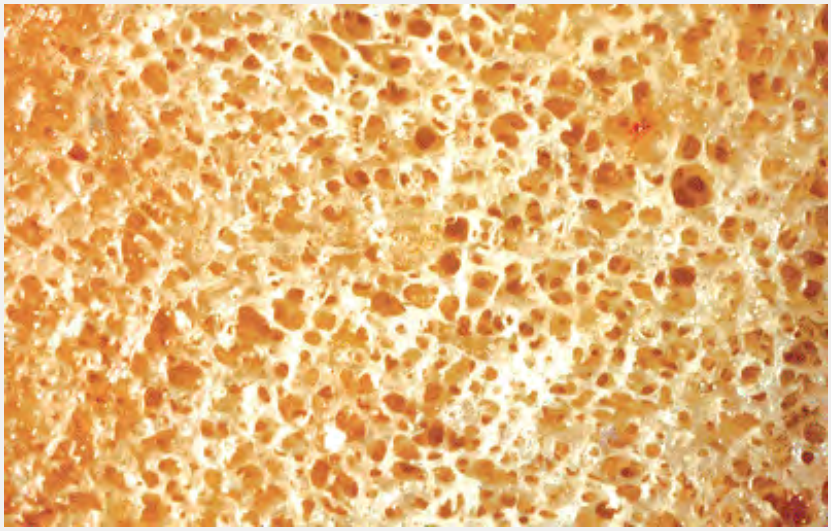

Figure 4.15 Gross photograph of a macerated portion of cancellous bone. The trabeculae are interconnecting plates.

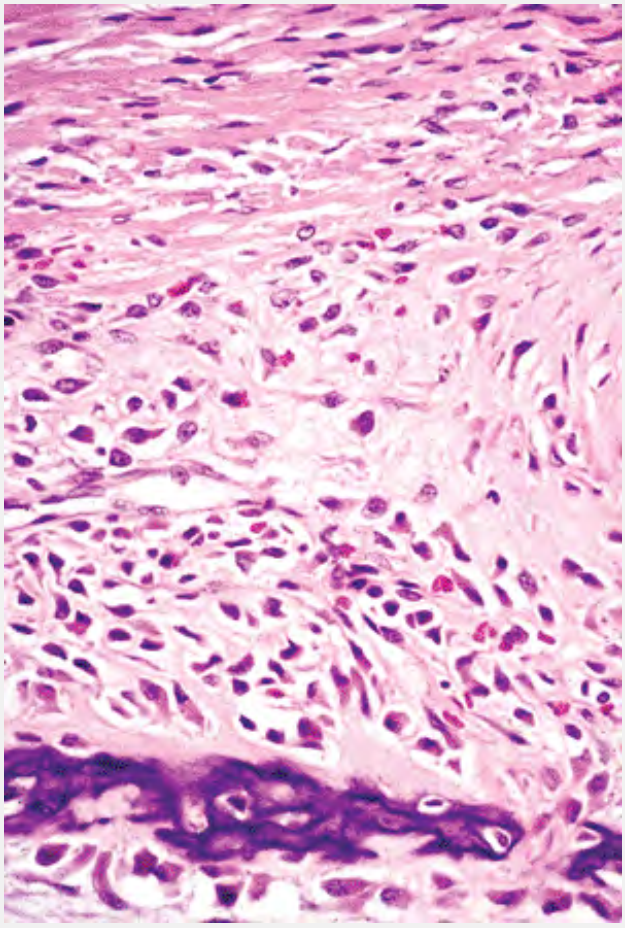

Figure 4.16 The outer fibrous layer of a fetal periosteum consists of thick bundles of horizontally oriented collagen fibers. The inner cellular cambium layer contains spindle-shaped, osteoprogenitor cells. The maturing osteoblasts steadily become more polyhedral and acquire increasing amounts of amphophilic cytoplasm. A portion of intramembraneous woven bone is seen forming the new cortex.

Vascular Supply and Innervation

Bones are vascular organs and require a vascular supply for viability. Bones receive their blood supply from three main sources: (a) large

nutrient arteries (one to two per bone), (b) metaphyseal and epiphyseal vessels, and (c) periosteal vessels. Nutrient arteries enter long bones in the diaphysis, traverse the cortex through foramina, and divide into ascending and descending branches within the medullary cavity. Smaller branch arteries, arterioles, capillaries, venules, and veins (Figure 4.17) course throughout the medullary cavity, nourish the fatty and hematopoietic marrow, and extend into haversian canals, where they supply the inner two-thirds of the cortex. At the ends of growing bones, they terminate as small arteries that give rise to capillary loops at the bases of epiphyseal growth plates. The epiphyseal and metaphyseal vessels access bone through small apertures and provide blood flow to regions of the epiphysis and metaphysis in the mature skeleton and to the secondary centers of ossification during active enchondral ossification. The periosteal vessels are small and are believed to nourish the outer third of the cortex. The venous drainage system bone is composed of medullary sinusoids that empty into a central venous sinus, which merges with nutrient veins.

Bones are innervated largely by nonmylineated nerves that are derived from the autonomic nervous system, and their function is to control blood flow. Larger nerve branches are usually associated with arterial vessels (Figure 4.17),

whereas small groups of fibers can be found adjacent to vessels in haversian systems. Nerves supplying the periosteum contain sensory elements and are the source of the sensation of bone pain.

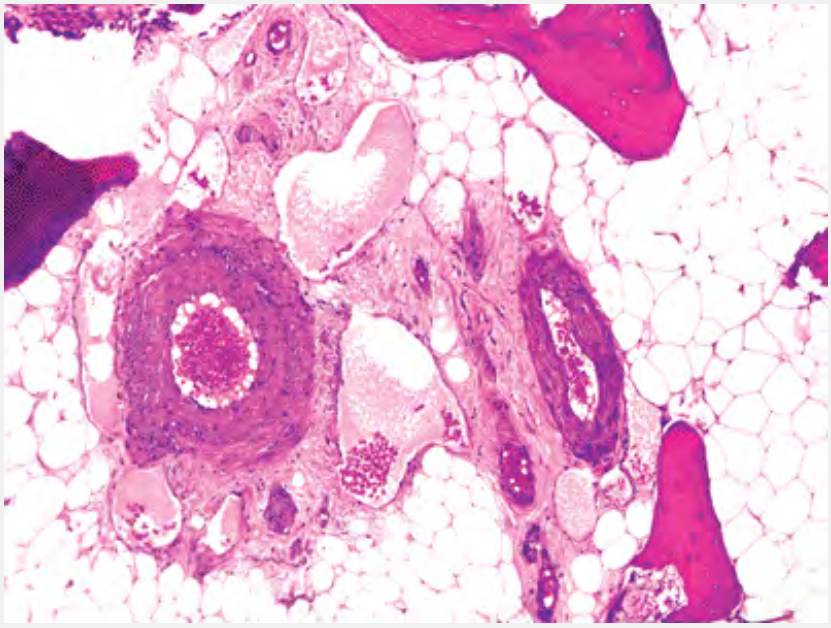

Figure 4.17 Small arteries, surrounded by dilated capillaries and nerves in an area of fatty marrow.

Boneâ€”the Tissue: Organic and Inorganic Components

The special biphasic amalgamation of organic and inorganic materials found in bone distinguishes it from all other tissues in the body. The organic component consists of proteins and bone cells, and the inorganic element is a specialized, calcium-poor form of apatite, resembling hydroxyapatite [$Ca_{10}(PO_4)_6(OH)_2$] in which the hydroxyl residues are replaced by phosphate and carbonate ions. The integration of the mineral phase with the organic matrix (primarily collagen) provides bone with hardness, strength, and limited elasticity (2).

Organic Components

Proteins

The organic component accounts for approximately 35% of the wet weight of bone; and, of this, collagen is responsible for 90%. Collagen is the primary structural protein of bone, and the overwhelming majority (90%) is type I (8); type V collagen is present in much smaller amounts, and there are only trace quantities of collagens III, XI, and XIII (9). Type III collagen may be increased in pathologic conditions (10). The numerous large type I collagen molecules are produced by osteoblasts; aside from their contribution to structural support, they also anchor many of the other constituents (11).

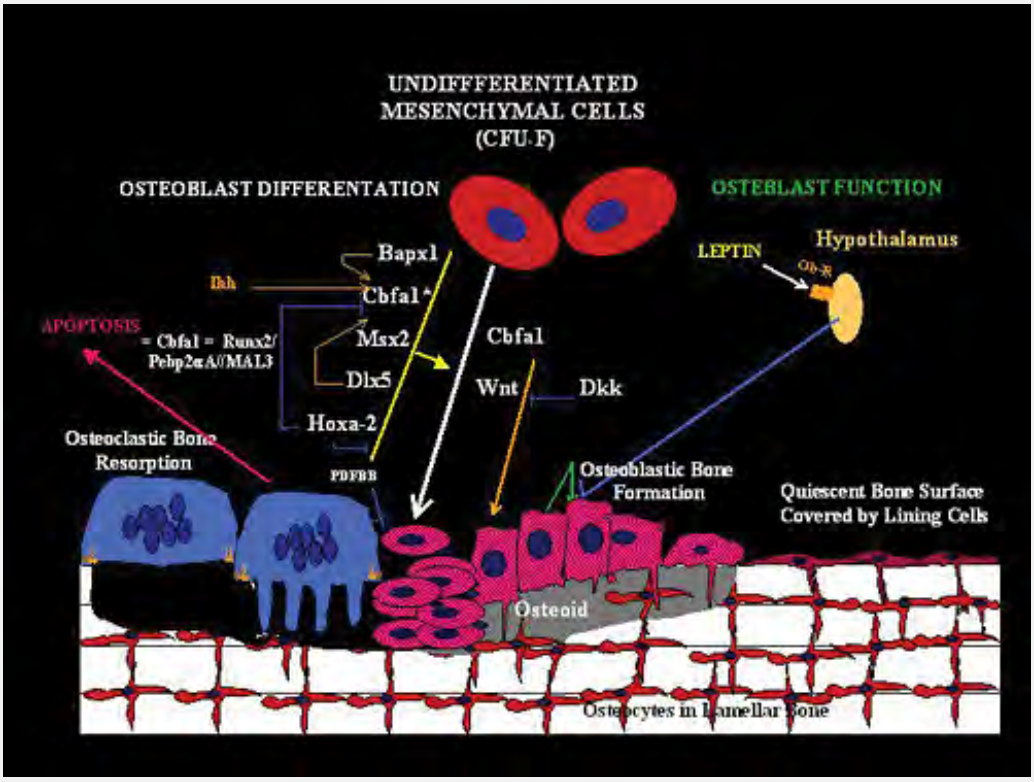

Figure 4.18 Diagram of osteoblast formation and metabolism. (*Bagpipe,* the vertebrate homologue of the *Drosophila* gene; *Bapx1,* a member of the NK2 class of homeobox genes; *Cbfa1,*

core binding factor Î±1; *F-CFU,* colony-forming unit fibroblasts; *Dlx5,* homeodomain transcription factor; *Dkk,* Wnt antagonist Dickkopf2; *HOX2a,* homeobox gene; *Ihh,* Indian hedgehog gene; *MSx2,* homeodomain protein; *Ob-R,* leptin receptor; *PDFBB,* prostate-derived factor BB; *BMP,* a member of the bone morphogenic protein; *RUNX2/Pebp2aA//MAL3,* runt homology domain protein; *Wnt,* secreted glycoproteins that function as ligands for members of the Frizzled family of seven transmembrane-domain receptors.)

The noncollagenous proteins are grouped according to their function as adhesion proteins, calcium-binding proteins, mineralization proteins, enzymes, cytokines, growth factors, and receptors. These proteins mediate all aspects of bone cell activity and are extremely important to the biological success of bone as a tissue. Many of these substances are synthesized and secreted by osteoblasts, and others are derived and concentrated from the serum. The most abundant of the osteoblast-produced noncollagenous proteins is osteocalcin, which functions as a regulator of mineralization. Osteocalcin is made solely by osteoblasts, and its quantification in serum has made it an important clinical marker of bone formation (11).

Osteoprogenitor Cells

Osteoprogenitor cells are derived from tissue-bound mesenchymal stem cells that have developed into fibroblastic colony-forming units (F-CFU) (12,13,14,15,16). They are located in the periosteum, the haversian system, and the Volkmann's and medullary canal. Osteoprogenitor cells are primitive determined mesenchymal cells that have the capacity to produce only osteoblasts. The process of osteoblast differentiation and maturation is complex and involves a variety of different factors (Figure 4.18). By light microscopy, osteoprogenitor cells appear as generic spindle cells and do

not have any distinguishing morphologic features; therefore, they cannot be identified with certainty in ordinary histologic sections (Figure 4.16). Because bone can be formed in skin, soft tissue, muscle, and viscera, in both experimental and pathologic conditions, osteoprogenitor cells or induceable stem cells are likely present in these sites as well.

Osteoblasts

Osteoblasts are vital to bone tissue and are the cells responsible for the production, transport, and arrangement of most of the components of the organic matrix (osteoid). Additionally, they initiate and regulate matrix mineralization and use autocrine and paracrine mechanisms to control the activity of neighboring osteoblasts, osteocytes, and osteoclasts (3,12,14,17). Immunohistochemical and biochemical studies reveal the presence of alkaline phosphatase, osteopontin, and osteocalcin within their cytoplasm, constitutively expressed RANKL (see section entitled Osteoclasts), and receptors for parathyroid hormone (PTH), prostoglandins, vitamin D_3, estrogens, and cytokines, including colony-stimulating factor 1 (CFS-1), on their cell membranes (8,18,19,20,21).

Osteoblasts cover all bone surfaces, where their lifespan may range from months to many years. Their metabolic state is closely related to their morpholgy; they are spindle-shaped when quiescent and large and polyhedral when rapidly producing bone. Metabolically active osteoblasts vary in size from 10 to 80 Âµm (average 20â€“30 Âµm) and have abundant amphophilic to basophilic cytoplasm that is in intimate contact with the bone (Figures 4.19, 4.20). Multiple cytoplasmic processes extend from the cells into and through the bone, contacting adjacent osteoblasts and osteocytes via nexus (gap) junctions. The nucleus is polarized away from the matrix surface and often has a conspicuous nucleolus and a prominent perinuclear halo that represents a well-developed Golgi apparatus. The cells flatten

and elongate as their synthetic activity diminishes and remain lining the resting bone surfaces (Figures 4.14, 4.20).

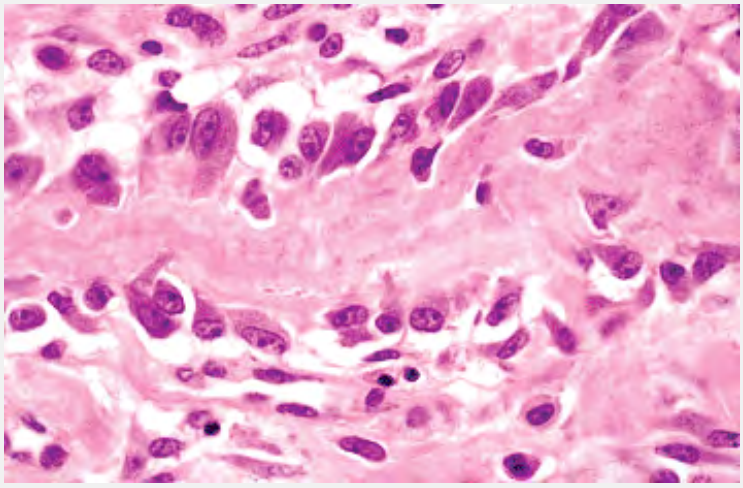

Figure 4.19 Metabolically active osteoblasts lining a trabeculum of woven bone. Some osteoblasts are in various stages of being surrounded by matrix and becoming osteocytes.

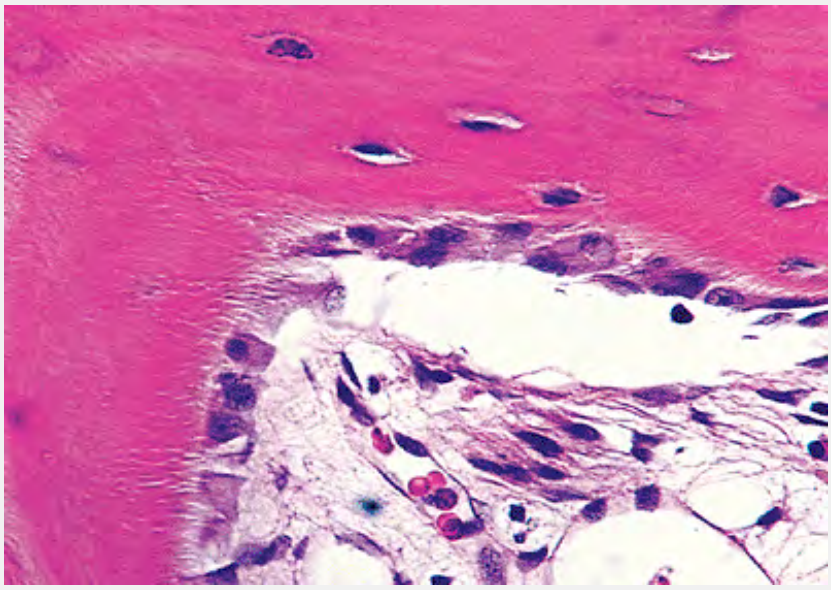

Figure 4.20 Metabolically active osteoblasts forming lamellar bone. The thin layer of osteoid cannot be identified in this demineralized sections. At the right of the micrograph, the osteoblasts are becoming inactive, flattening, and being incorporated into the bone as osteocytes. The osteocytes of the lamellar bone are spindle-shaped. The dendrites are identifiable extending from the osteoblast bodies into the bone where they are seen as clear streaks perpendicular to the bone surface represent the canaliculi containing the dendrites of the osteocytes and osteoblasts.

Ultrastructurally, the cytoplasm of productive osteoblasts contains extensive, granular endoplasmic reticulum, a large prominent Golgi apparatus, and numerous mitochondria and lysosomes (8,9,14,22). In contrast, the cytoplasm of inactive osteoblasts resembles that of quiescent fibroblasts (14).

Osteocytes

Osteoblasts enveloped by matrix become osteocytes, and their half-life is estimated to be as long as 25 years (23). The cell body, nucleus, and surrounding scant cytoplasm reside within a lacunar space. The nuclei are comparatively small and are not always visible in every plane of section; therefore, in most slides of bone tissue, random lacunae appear empty. Osteocytes have numerous long and delicate cytoplasmic processes (dentrites), similar to the neuritic processes (axons) of neurons (Figures 4.12, 4.21). These cell processes traverse the matrix through small tunnels termed *canaliculi* and provide a very large surface area of contact between the osteocyte and the matrix and extracellular fluid that bathes each cell (22). Osteocyte cell processes connect to those of neighboring osteocytes and to surface osteoblasts via gap junctions. Gap junctions facilitate the transfer of small molecules and biologically generated electrical potentials from cell to cell. In this manner,

osteocytes communicate with one another and form a complex and integrated network throughout bone tissue.

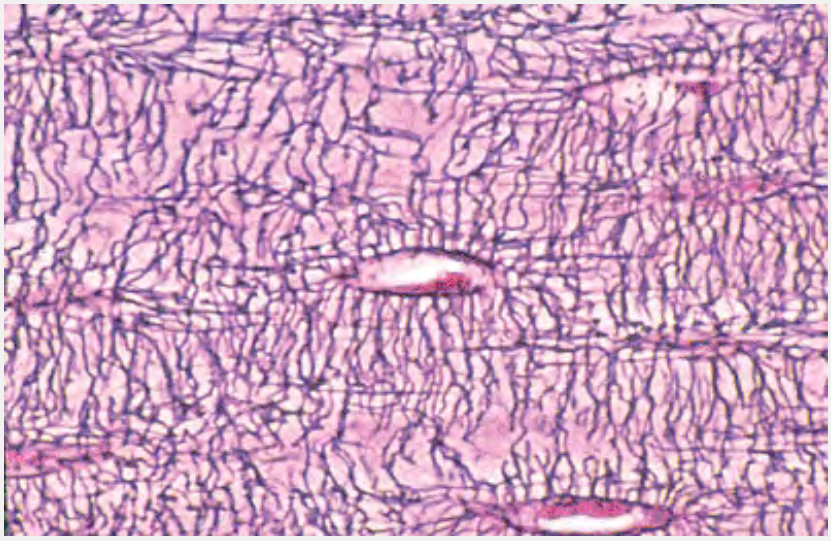

Figure 4.21 Osteocytes within lacunar space. Numerous cell processes course through the matrix and contact those of neighboring osteocytes.

The number, size, shape, and position of osteocytes varies according to the type of bone they inhabit. In woven bone, they are numerous, large, and plump (Figure 4.4). Their arrangement appears disorganized because their long axes parallel the direction of the neighboring collagen fibers, which in sections of woven bone appears random. In lamellar bone, osteocytes are comparatively fewer in number, smaller, more spindle-shaped, and appear in sections to be more regularly organized because the cells are oriented in the same direction as the surrounding lamellae (Figure 4.5).

The repertoire of biological activity possessed by osteocytes helps them maintain bone tissue and allows bone to be responsive to the mechanical and metabolic demands of the body. For instance,

osteocytes are mechanosensory cells that translate mechanical forces into biological activity (23,24). The detection of physical forces stimulates osteocytes to produce and release intercellular messengers that target precursor cells, osteoblasts, and osteoclasts (23). These cells, in turn, respond by remodeling the bone regionally and allowing it to change its mass and structure according to demands of the external physical environment (Wolff's law) (25,26). The widespread distribution of osteocytes and their cell processes is fundamental to another important role of theirs, namely, mineral homeostasis (27). Osteocytes generate and respond to microfluxes in ion concentrations and mediate the exchange of calcium and other ions between the bone matrix and extracellular fluid. In certain conditions, they may even be able to rapidly release calcium and phosphorus from the mineralized matrix by a process termed *osteocytic osteolysis,* which manifests histologically as enlarged lacunar spaces (28). All in all, their aggregrate activity likely influences the systemic metabolism of calcium and phosphous (27).

Osteoclasts

Osteoclasts are terminally differentiated, multinucleated cells responsible for bone resorption. They are mobile effector cells that have a lifespan of only several weeks. By the time they are recognizable by light microscopy, they are mature and biologically active and can be found residing within resorption pits (Howship's lacunae) produced by their digestion of mineralized bone matrix (Figure 4.22).

Osteoclasts are 40 to 100 Âµm in diameter and are polarized with one portion of the cell membrane intimately attached to the bone and the remainder exposed to the extracellular fluid in its microenvironment. The segment of cell membrane that actually adheres or seals to bone is laden with $\hat{I}\pm_V\hat{I}^2_3$ integrins. The integrins bind to specific extracellular bone matrix proteins (vitronectin, osteopontin, and bone sialoprotein) previously deposited by

osteoblasts, and in this manner the osteoclast can anchor to the bone surface. A network of interconnecting actin filaments that produces a clear area in the cytoplasm links the sealing zone of the osteoclast cell membrane to the nuclei (14,29). On average, osteoclasts have 4 to 20 nuclei (8), though the number may range from 2 to as many as 100. In normal circumstances, however, the amount is usually not greater than 12. The nuclei and adjacent prominent Golgi apppartus tend to congregate away from the bone-resorbing surface, and are surrounded by abundant amphophilic cytoplasm.

The cytoplasm in the vicinity of the resorbing surface is rich in tartrate-resistant acid phosphatase, carbonic anhydrase, and membrane-bound lysosomes. The adjacent cell membrane, which also directly apposes the bone-resorbing surface, has numerous fingerlike extensions that effectively increase its surface area and form the so-called brush border.

The lysosomes fuse with the brush border and release their contents into the resorption pit, which begins the actual process of bone digestion. Metabolic activation of osteoclasts is initiated by anchorage, and this process generates

a stimulatory signal that is transmitted to the nuclei by the actin network. The nuclei, now activated, orchestrate the complex and transitory cytoplasmic and cell membrane modifications required for bone digestion. Importantly, mineralized bone or cartilage is more efficiently resorbed by osteoclasts than is nonmineralized bone or cartilage. Focal, or partial, demineralization of collagen fibers appears to be one of the first steps in matrix resorption and is followed by catabolism of noncollagenous proteins and, lastly, the degradation of collagen fibers themselves. Once osteoclast activity ceases and the cell moves to another targeted site, macrophages meander into the base of the resorption pit and phagocytize the organic remnants.

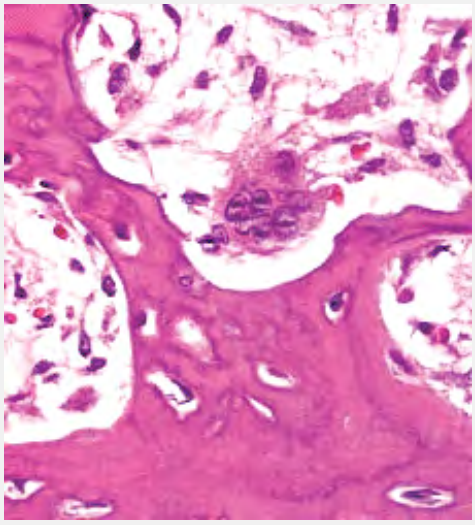

Figure 4.22 Osteoclast located within a resorption pit on a trabeculum (Howship's lacunae).

Osteoclasts are derived from mononuclear, hematopoietic progenitor cells of the granulocytic-macrophage colony-forming (GM-CFU) and macrophage colony-forming units (M-CFU) (16,29,30,31,32,33,34,35,36,37,38,39,40,41,42) (Figure 4.23). The mononuclear preosteoclasts undergo primary fusion to form multinucleated osteoclasts, which are capable of acquiring and shedding nuclei throughout their short lifespans (40). A variety of cytokines and growth factors are critical to their development, maturation, and activity and include interleukin (IL)-1, IL-3, IL-6, IL-11, tumor necrosis factor (TNF), granulocyte-macrophage colony-stimulating factor (GM-CSF), and macrophage colony-stimulating factor (M-CSF) (43). These factors work by either stimulating osteoclast progenitor cells or participating in a paracrine system in which osteoblasts and marrow stromal cells play a central role.

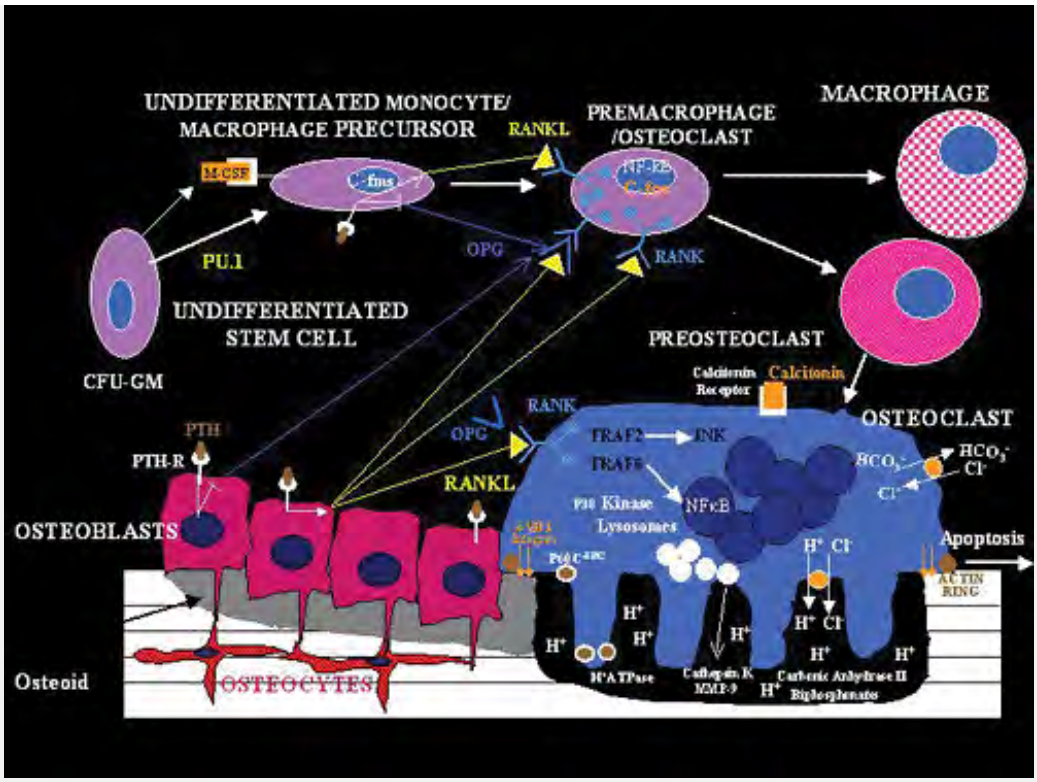

Figure 4.23 Diagram of the formation of osteoclasts and their relationship to osteoblasts and undifferentiated mesenchymal cells. necrosis factor receptorâ€“associated factor 6.

This system is essential to bone metabolism, and its mediators include the molecules RANK (receptor activator for nuclear factor ÎºÎ²), RANK ligand (RANKL), and osteoprotegerin (OPG) (43). RANK is a member of the TNF family of receptors expressed mainly on cells of macrophage/monocytic lineage, such as preosteoclasts. When this receptor binds its specific ligand (RANKL) through cell-to-cell contact, a series of signal cascades are activated and osteoclastogenesis is initiated. RANKL is produced by and expressed on the cell membranes of osteoblasts and marrow stromal cells. It's expression may be influenced by other osteotropic factors, and its major role in bone metabolism is stimulation of

osteoclast formation, differentiation, activation, and survival. The actions of RANKL can be blocked by another member of the TNF family of receptors, osteoprotegerin, which is a soluble protein produced by a number of tissues, including bone, hematopoietic marrow cells, and immune cells. Osteoprotegerin inhibits osteoclastogenesis by acting as a decoy receptor that binds to RANKL, thus preventing the interaction of RANK with RANKL. The interplay between bone cells and these molecules permits osteoblasts and stromal cells to control osteoclast development. This ensures the tight coupling of bone formation and resorption vital to the success of the skeletal system and provides a mechanism for a wide variety of biologic mediators (hormones, cytokines, growth factors) to influence the homeostasis of bone tissue.

Inorganic Component

Mineral

The primary mature inorganic mineral of bone is a calcium deficient

varient of hydroxyapatite [$Ca_{10}(PO_4)_6(OH)_2$], in which the hydroxyl groups have been largely replaced by phosphate and carbonate groups (44). There is minimal water in the mature crystals (44). It is the body's major reservoir for calcium and phosphate and contains more than 99% of the body's calcium and 85% of the body's phosphorus (1,9,44). Also harbored within the bone crystals are 95% of the body's sodium, 50% of the body's magnesium, and trace amounts of other essential minerals (1,9,44).

The process of mineralization varies according to the type of tissue. In cartilage and possibly woven bone, it begins with the production of numerous small vesicles (matrix vesicles) derived from chondroblasts and osteoblasts (1,2,45). The matrix vesicles are 2 to 4 Âµm in diameter and are the sites where mineral is first observed. Although there is some uncertainty regarding the initial structure and composition of the mineral, crystals of hydroxyapatite, as well as amorphous calcium phosphate and brushite have been identified (2,3,12,18,45,46,47,48). The primary crystals serve as a nidus for the deposition of larger aggregates, which are then deposited in and around the collagen fibers.

In lamellar bone, matrix vesicles are not present, and the process of mineralization is controlled by osteoblasts. The regulatory steps are complex and incompletely understood, though numerous proteins, growth factors, and cytokines are involved (2,3,12). Mineralization begins with the deposition of mineral in the spaces (â€œholesâ€•) between the ends of adjacent collagen molecules. It is still unclear whether the first deposits are hydroxyapatite, amorphous calcium phosphate, or a nonapatite crystalline calcium phosphate (octocalcium phosphate, [$Ca_8(HPO_4)_2PO_4)_4 . 5H_2O$]) (44). Regardless of their initial form, the aggregates grow and form crystalline bone apatite. Initially, the crystals are situated within the collagen fibrils, but eventually they also develop outside the fibrils and fibers (44). The shapes of the mature crystals are are not known with certainty. High resolution transmission electron microscopy shows that they have the features of thin plates, whereas, studies with small-angle x-

ray scattering suggest that they are needlelike (44). Once the crystals are deposited in bone, they remain there for days to years, only to be dissolved at a future time during bone resorption, when the calcium and phosphorous are released into the extracellular fluid and become available for other biological activities.

Mineralization of osseous organic matrix takes approximately two weeks, therefore, the surfaces of bone are covered by a layer of unmineralized bone, called osteoid (Figures 4.11, 4.19, 4.20). The width of this layer is dependent on the relative rate of bone formation. In inactive regions, the bone is nearly fully mineralized and is covered by a thin osteoid seam (1â€“5 Âµm in thickness), whereas, in foci of rapid bone deposition, the osteoid layer may be more than several times thicker. The actual zone of mineralization can be detected by the systemic administration of the antibiotic tetracycline, which binds to the bone at the mineralization front and can be visualized with flourescent microscopy (Figure 4.12).

Bone Formation, Growth, and Remodeling

From the time that skeleton formation begins in the embryo until the stage that adult stature is attained, the bones of the body undergo a marked increase in size, refinement of their shape, and enhancement of their contour. Bone is a rigid structure that cannot grow interstitially and only enlarges by the apposition of new bone on its surface. Appositional growth alone is adequate for portions of the skeleton that enlarge slowly during maturation, such as the skull, and the diameter of long bones; however, it is insufficient for bones that must increase in size at a more rapid rate, such as the length of long and short tubular bones of the extremities, the vertebrae, and the ribs. Cartilage, in contrast, exhibits both appositional and interstitial growth; that is, it increases its volume and enlarges in all dimensions by adding new cells and elaborating freshly synthesized extracellular matrix. Consequently, the growth in length of tubular

bones in embryos and prepubertal children occurs as growing cartilage is replaced by bone, with the majority of the increase in bone length derived from the cartilage primordium represented in the anlage and growth plate (physis). In the case of callus, bone formation occurs both intramembranously in the fibrous callus and by enchondral cartilage replacement.

The genetic code for skeletal morphogenesis is encrypted in the homeobox genes. Homeobox genes contain the DNA library of a repository of transcriptional regulators essential for growth and differentiation. The expression of homeobox genes occurs in a specific order and temporal sequence; and, regarding the skeletal system, their activation results in the

generation of localized cellular condensations of primitive mesenchyme at the sites of future bones. The mesenchymal condensations are the earliest precursors of individual bones and are critical to the formation of the skeleton. They begin to develop just prior to day 40 of gestation and, depending upon their anatomic location, are derived from cells that migrate from the cranial neural crest (craniofacial skeleton), paraxial mesoderm (axial skeleton), or the lateral plate mesoderm (appendicular skeleton) (49). Shortly after being formed, usually by the seventh week of gestation, the mesenchymal cells in the condensations begin to alter their genetic expression and assume the morphology of matrix-forming cells. Those cells that mature into chondrocytes form a cartilage model or anlage of the future bone, which is fundamental to the process of enchondral ossification, whereas those that develop directly into osteoblasts produce bone via the mechanism of intramembranous ossification. The mature bone tissue formed from either enchondral or intramembranous ossification are grossly and histologically indistinguishable.

Enchondral Ossification

Initially, the newly formed cartilage anlage is avascular and has the crude shape of the adult bone (Figure 4.24). The mesenchyme surrounding the anlage forms the perichondrium (Figure 4.25), which is the precursor to the periosteum that develops once ossification begins (see below). This process is initiated in each bone at a specific time, and this temporal sequence is the same in all humans.

Growth of the anlage occurs both interstitially and appositionally as a result of the proliferation of chondrocytes and the accumulation of secreted extracellular matrix (Figures 4.25,4.26,4.27). The matrix is composed of proteoglycans and type II collagen with smaller amounts of collagen types IX, X, XI, and XIII (2). As this process continues, three events occur at very nearly the same time in every bone (50):

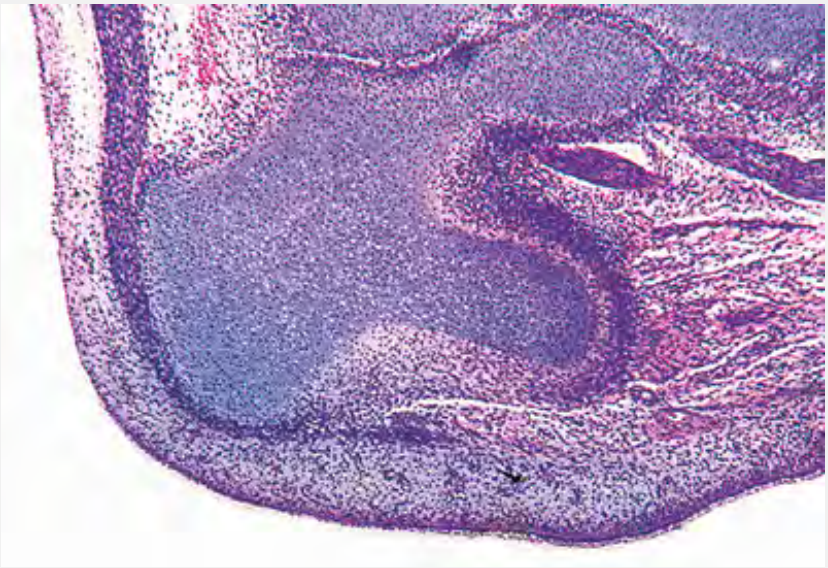

Figure 4.24 Cartilage anlage of the os calcis (calcaneus). The cartilage model is the approximate shape of the adult bone. The attachment site of the Achilles tendon and the tibial-calcaneal joint are present.

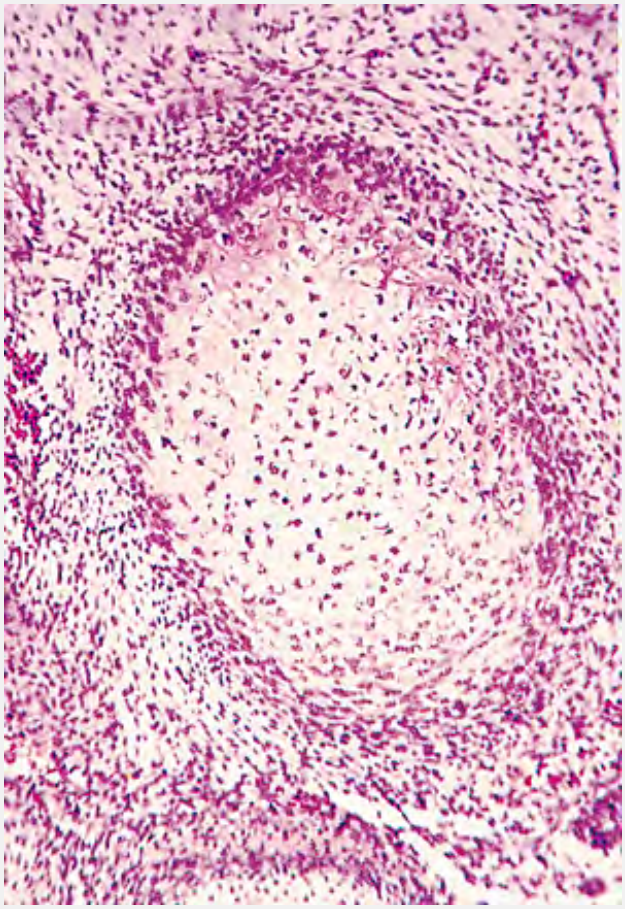

Figure 4.25 Cross section of the cartilage anlage of the embryonic femur. The chondrocytes are regular with little hypertrophy. The perichondrium is composed of undifferentiated spindle cells with little intervening stroma, surrounded by a loose mesenchymal tissue.

- The mesenchymal stems cells of the perichondrium, located around the midportion of the cartilaginous shaft, produce a layer of osteoblasts that deposit a collar of woven mineralized bone on the surface of the anlage. This heralds the transformation of the perichondrium into periosteum. The periosteum, osteoblasts, and the thin

surface layer of bone form the primary center of ossification and delineate the middle region of the diaphysis (Figures 4.28,4.29,4.30,4.31).

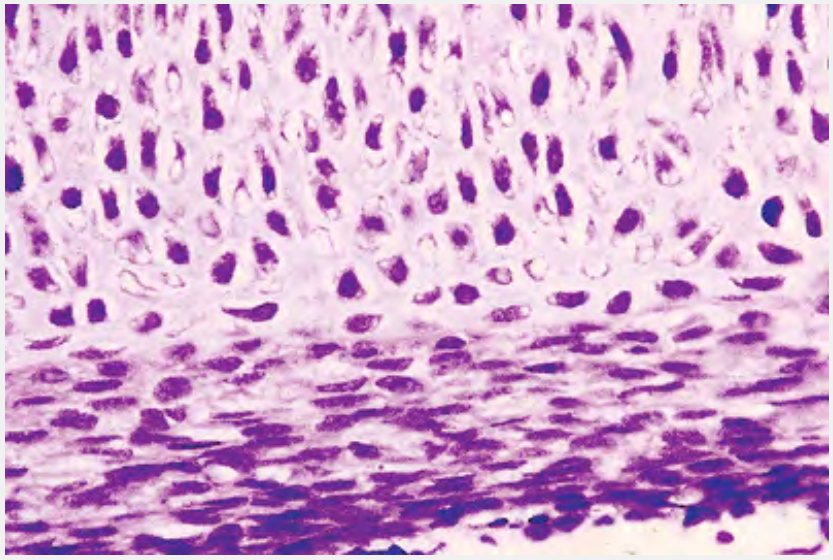

Figure 4.26 Cartilage anlage of femur in an embryo. The perichondrium is in intimate contact with the cartilage.

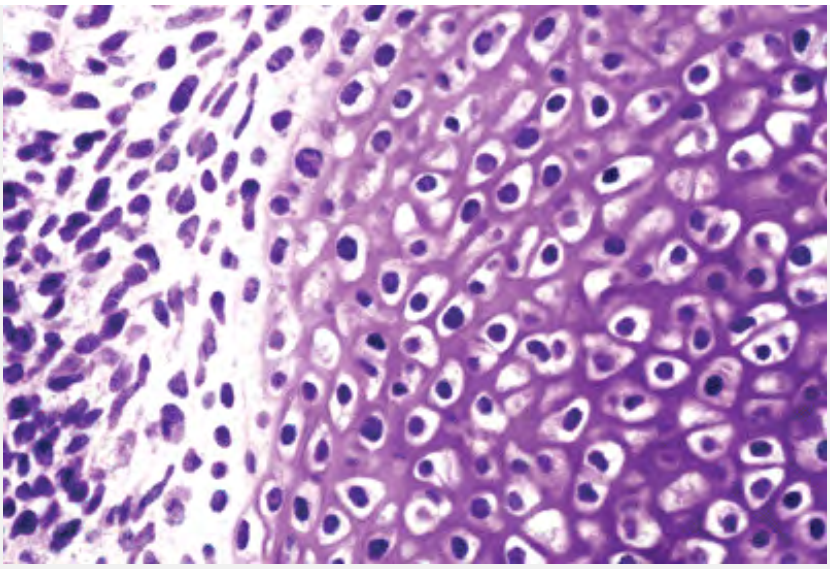

Figure 4.27 Cells of mesechymal condensation surrounding an area in which they have differentiated into hyalin cartilage anlage. The chondrocytes show early hypertrophy.

- The chondrocytes in the center of the anlage shaft become encased by the periosteal shell of bone and begin to hypertrophy and swell (Figures 4.27,4.28,4.29,4.30,4.31). The cell enlargement is accompanied by an increase in intracellular glycogen and in the perichondrocyte depostion of type X collagen, and soon thereafter the chondrocytes undergo apoptotic necrosis (51,52,53,54). Concurrently, the surrounding matrix mineralizes, largely via matrix vesicles, although some crystallization may occur within collagen fibers.

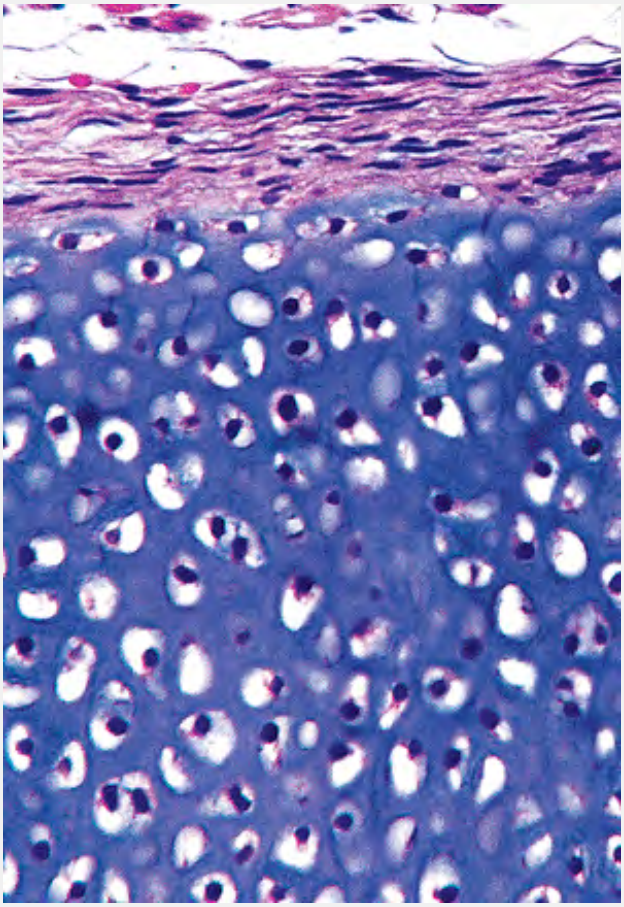

Figure 4.28 The early periosteum about the diaphysis of a cartilage anlage, showing the perichondrium surrounding the hypertrophied chondrocytes.

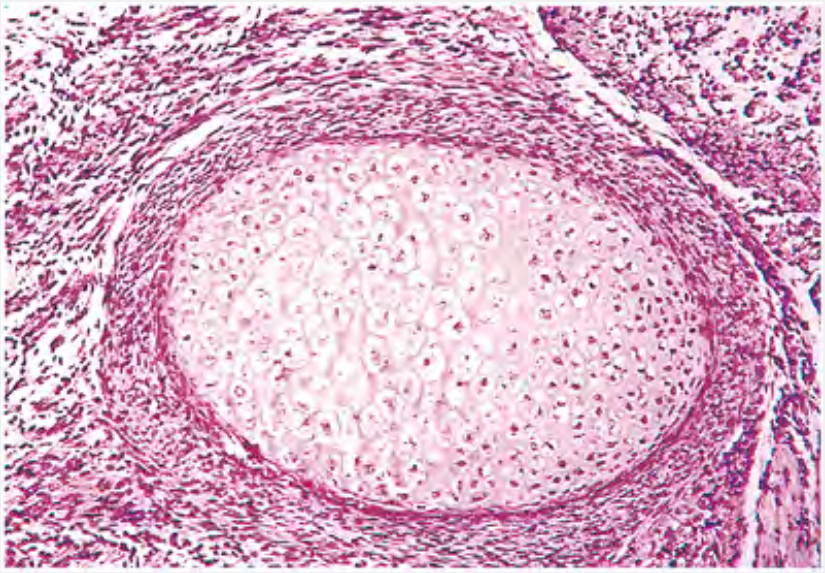

Figure 4.29 Cross section of the diaphysis of an embryonic femur. The thin, collarlike primary center of ossification is between the hypertrophying chondrocytes and the periosteal cells.

- A capillary network originating from periosteal vessels forms and, with the aid of osteoclastic (chondroclastic) resorption, penetrates the woven bone of the primary center of ossification (Figure 4.32) into the mineralized cartilage. The capillaries are the precursor to the future nutrient vessels and are accompanied by pericytes and other primitive mesenchymal cells, including osteoprogenitor and osteoclast progenitor cells.

As the cartilaginous core of the bone undergoes continued resorption, osteoblasts derived from perivascular stem cells deposit layers of osteoid on the residual longitudinally oriented

struts of mineralized cartilage. These trabeculae, composed of a central cartilaginous core covered by a rim of bone, are the first (or

primary) trabeculae formed, and together they form the primary spongiosa. The spaces that develop as a consequence of the cartilage resorption then coalesce and form the medullary cavity, which is initially filled with loose connective tissue. Eventually, it becomes occupied by varying amounts of adipose tissue and hematopoietic elements. This complex process begins within the center of the shaft and progresses toward both ends of the bone. When complete with primary trabeculae and an adjacent secondary center of ossification (see below), this is recognized as the fully developed growth plate (the physis) (Figures 4.33,4.34,4.35,4.36).

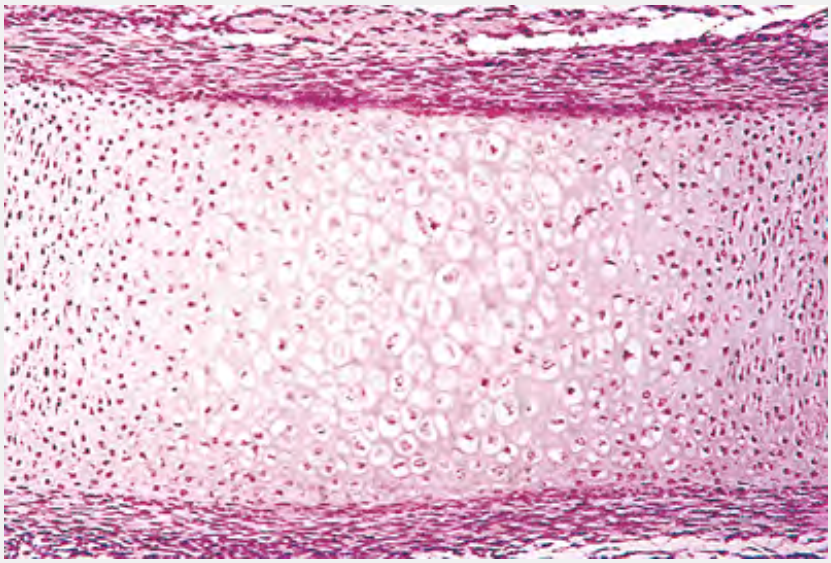

Figure 4.30 Longitudinal section of the primary center of ossification in an embryonic femur. The cellular layer of the periosteum is producing osteoblasts, which have formed a layer of pink osteoid. The outer spindle cells of the periosteum are oriented longitudinally along the femoral shaft. The underlying chondrocytes show hypertrophy.

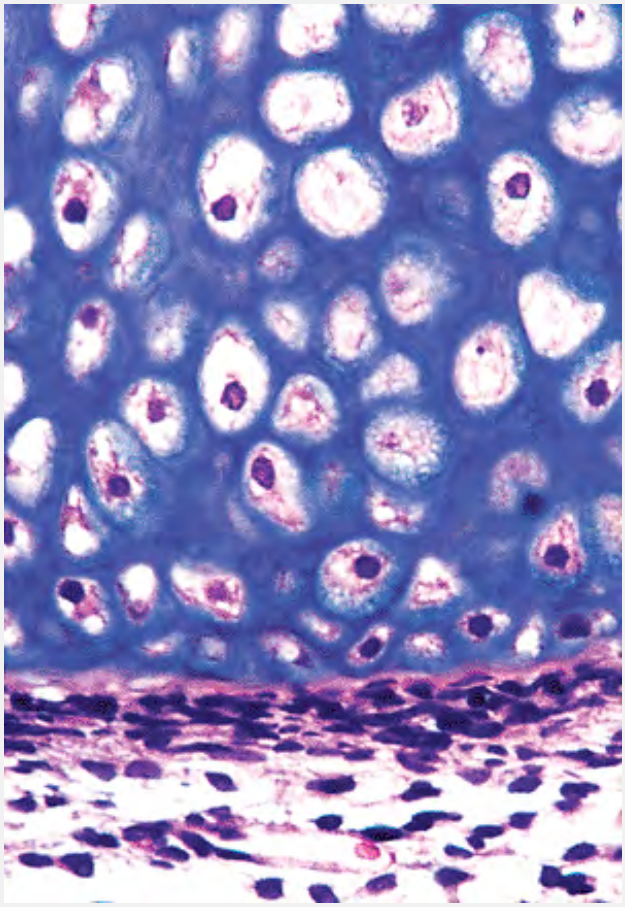

Figure 4.31 Primary center of ossification. A thin pink layer of osteoid, containing flattened osteocytes, separates the hypertrophied chondrocytes from the periosteal osteoblasts.

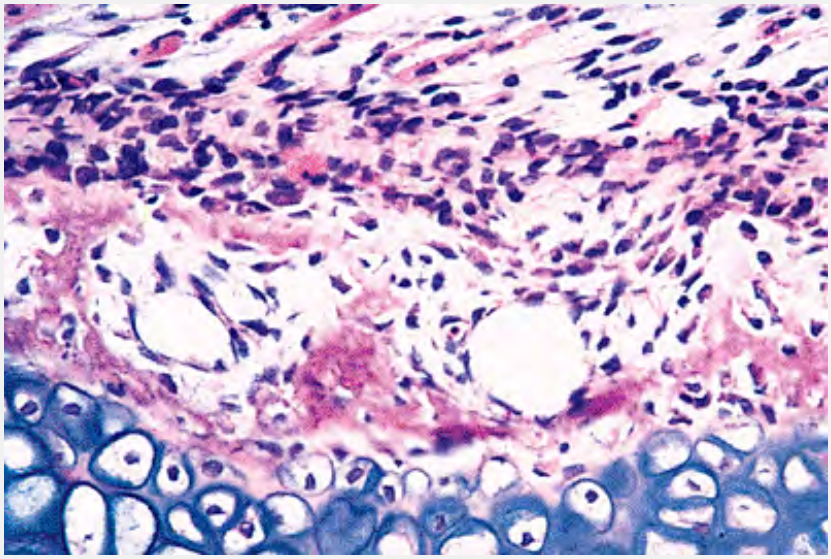

Figure 4.32 Primary center of ossification with capillary proliferation indicating the early formation of the nutrient artery. Between these capillaries, new trabecular membranous woven bone is being formed: in the cambium layer of the periosteum. The outer fibrous layer of the periosteum is more cellular than in the adult.

The fully developed growth plate is structured and has been divided into five merging regions that correspond to different stages of chondrocyte maturation (Figures 4.34, 4.36). As the chondrocytes pass through the different stages, they do not literally move within the matrix but mature in the position they occupy when first formed. Important regulators of this sequence of chondrocyte growth and maturation are the *Indian hedgehog* gene and parathyroid hormoneâ€“related protein (PTHrP) (54,55,56). The zones include: (a) a region of resting or reserve chondrocytes located nearest the ends of the bone; (b) a region of proliferating chondrocytes that become arranged in spiral columns; (c) a region of chondrocyte hypertrophy; (d) a region of chondrocyte apoptotic necrosis and matrix mineralization; and (e) a region of cartilage resorption by

osteoclasts (chondroclasts) that tunnel into the mineralized matrix and leave behind residual longitudinal struts of cartilage that parallel the long axis of the bone. The orientation of the struts is determined by the preexisting columnar arrangement of the chondrocytes in the proliferative and hypertrophied zones (Figures 4.34, 4.36). These cartilaginous struts act as scaffolding for newly deposited woven bone. These struts of mineralized cartilage covered by newly formed woven bone are the primary trabeculae (Figures 4.36,4.37,4.38). The rate of growth differs for each physeal plate and is greatest in the growth plate of the distal femur,

followed by that of the proximal tibia. In diseases in which mineralization of the cartilage is impaired (rickets), removal of the cartilage is handicapped, and the zone of hypertrophy becomes massively and irregularly thickened. While most tubular long bones have two epiphyseal growth plates, other bones (such as the ribs and some of the phalanges, carpals, tarsals, metacarpals, and metatarsals) have only a single physis. The growth plates, located at the diaphyseal-epiphyseal junctions of the bones, are delineated peripherally by a circumferential, thin collar of membrane bone that is a continuation of the primary center of ossification and is called the ring of Ranvier (Figures 4.34, 4.35) (57).

Figure 4.33 Gross photograph of the femoral heads of 3.5-year-old male. The secondary centers of ossification in the femoral heads are separated from the primary centers by the epiphyseal growth plates (the physes). The secondary center of ossification of the apophysis of the greater trochanter has not as yet formed. The metaphyses and diaphyses resemble their adult shapes.

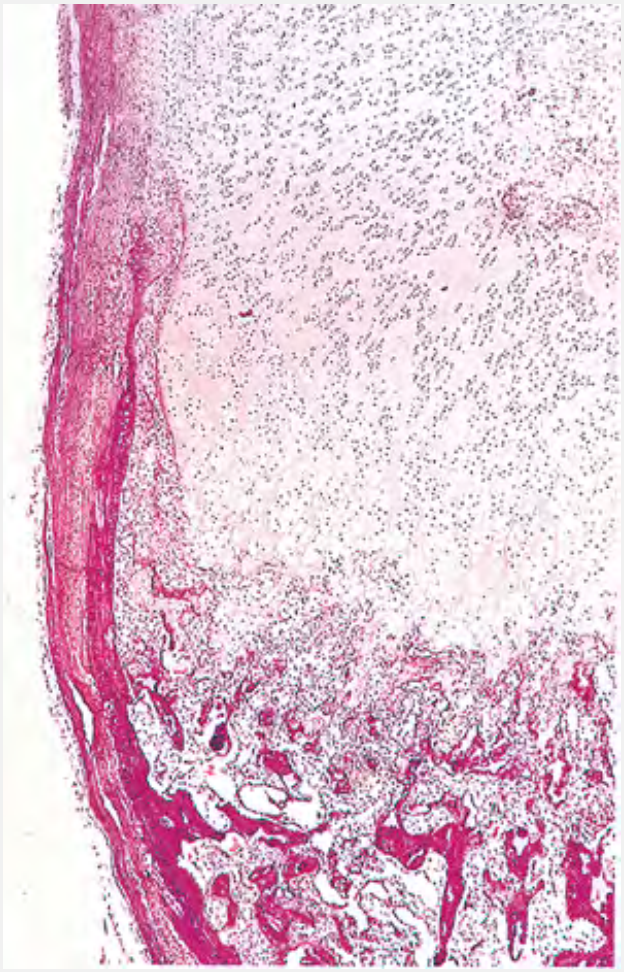

Figure 4.34 Photomicrograph of the epiphyseal growth plate of the costochondral junction from a 2-month-old male. The growth plate is surrounded by the ring of Ranvier. No secondary center is present. Primary trabeculae with central cartilaginous cores are seen in the metaphysis and upper diaphysis.

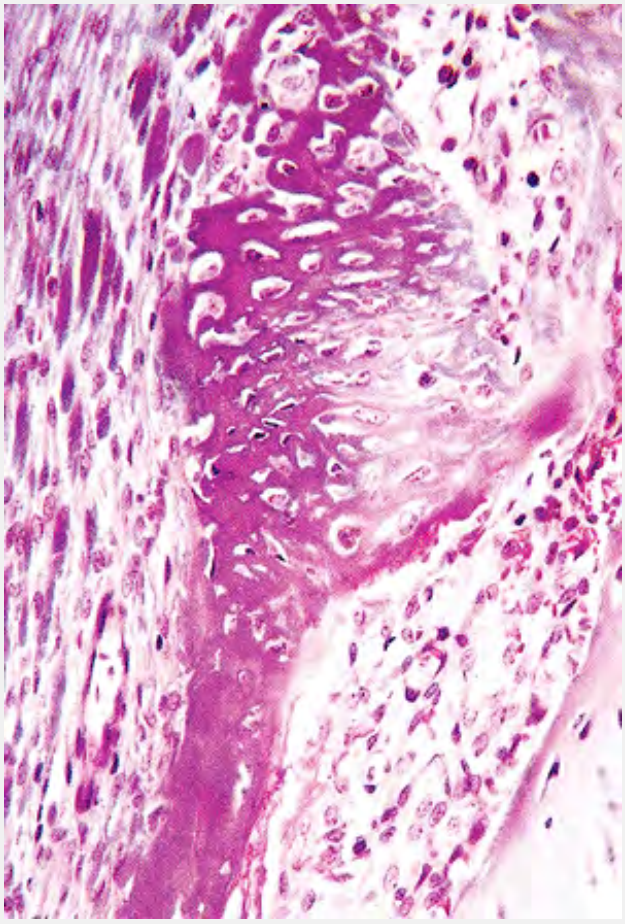

Figure 4.35 Ring of Ranvier, composed of bone that forms by the process of intramembranous ossification beneath the periosteum on the left and delineates the peripheral portion of the epiphyseal growth plate near the metaphysis.

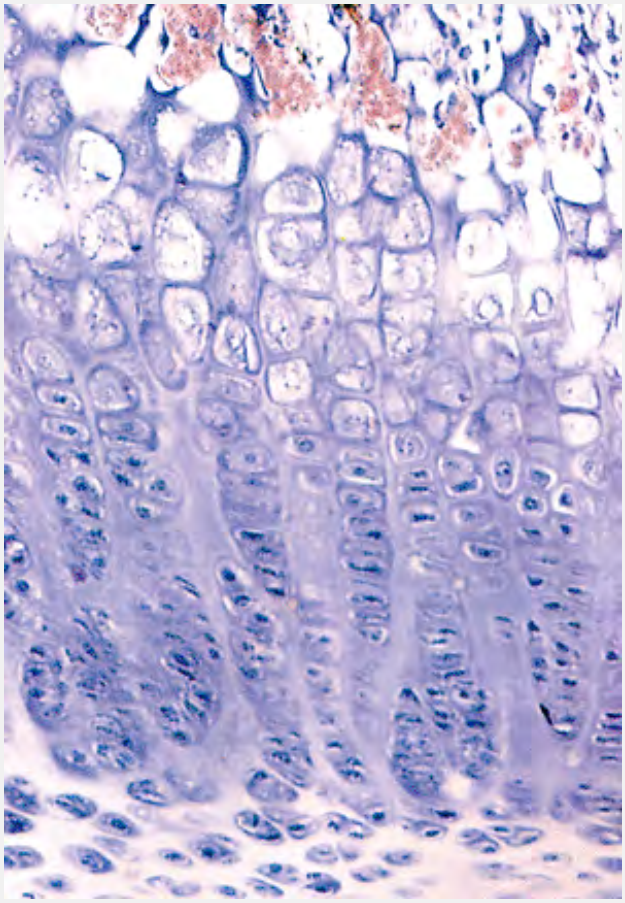

Figure 4.36 Photomicrograph of a maturing epiphyseal growth plate, showing the reserve zone (*top*), the proliferating zone, the hypertrophied zone, and zone of mineralization of the cartilage. The primary trabeculae are oriented vertically and are supporting the base of the growth plate.

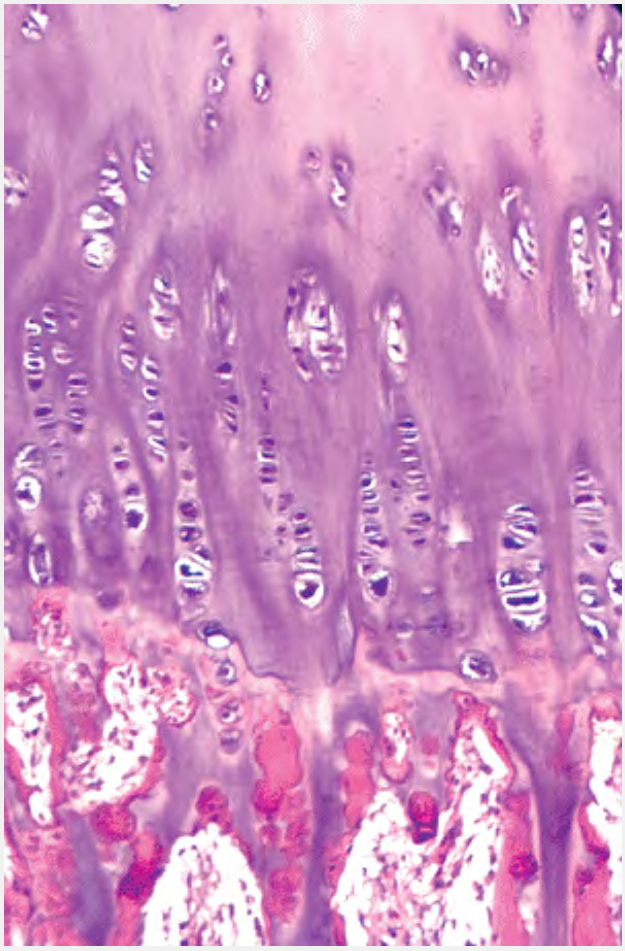

Figure 4.37 Junction between the mineralized cartilage columns and the primary trabeculae with the mineralized cartilage cores covered by a layer of woven bone.

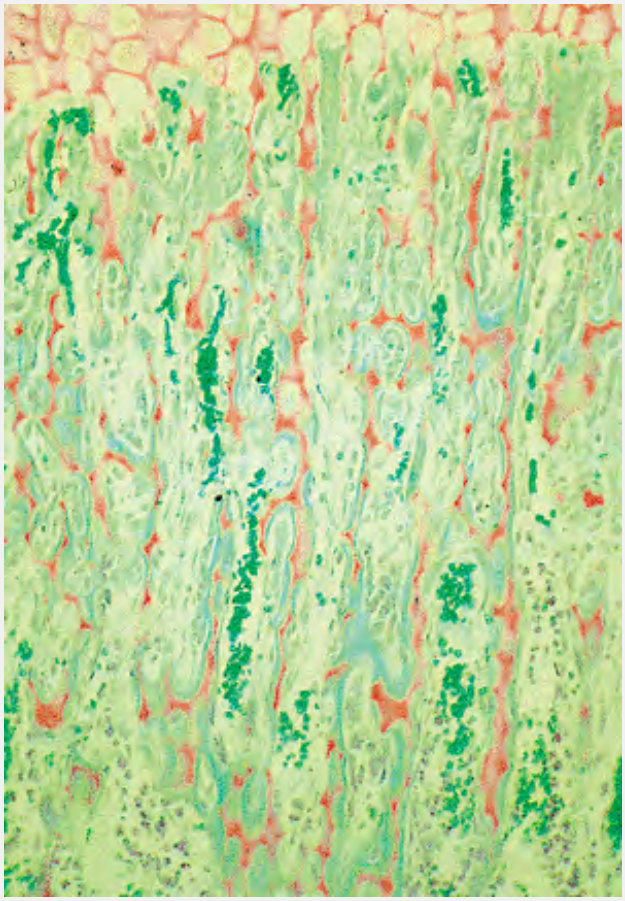

Figure 4.38 Longitudinal section of the epiphyseal growth plate, showing the zone of mineralization of the cartilage (orange) and the cartilage struts are being covered by a thin layer of osteoid (blue-green). Capillaries with numerous erythrocytes (green) are present between the primary bone trabeculae. (Goldner's stain.) (This slide was prepared by Glimcher MJ, Roth SI, Schiller AL, as part of a course in the Pathophysiology of Bone for the Harvard Medical School, Boston, MA.)

Concurrent with continued appositional and interstitial growth of epiphyseal and growth plate cartilage are dramatic changes in the cortex. As the bone increases in diameter, subperiosteal bone is deposited while the bone along the endosteum is resorbed so that

the cortical thickness remains proportionally uniform and the medullary cavity enlarges. The bone that first forms the cortex is woven in nature; but, within the first several years of life, the fabricated bone is lamellar. Variation in the rate of formation and resorption changes the shape of the bone. This is most pronounced in a region just distal to the base of the growth plate, known as the â€œcut backâ€• zone. The cut back zone is rich in subperiosteal osteoclasts, which reduce the diameter of the bone to that of the diaphysis, and this results in â€œfunnelizationâ€• of the bone. At the same time, the cortical thickness is maintained or increases by appositional new bone formation on the endosteal surface of the cortex. During growth and development, the diameter of the diaphysis continues to enlarge and in specific sites becomes asymmetric. This process is dynamic and not only determines the eventual diameter of the bone but controls the thickness and contour of the cortex. The increase in diaphyseal diameter is the result of periosteal osteoblastic bone formation. The thickness of the cortex is maintained by endosteal osteoclastic bone resorption. Conditions altering the balance of bone formation and resorption may cause abnormally thickened or significantly thinned (osteoporotic) cortices.

In most long bones, a similar process subsequently develops in the middle of the epiphysis, and this region is the secondary center of ossification (Figures 4.33, 4.39). A few long bones have a similar growth center in the apophyses. The maturation and replacement of the cartilage anlage in a secondary center is identical to that which occurs in the diaphysis except that the maturation proceeds from the center centrifugally, toward the periphery. This means that the growing area of the secondary center is, at first, a sphere. Eventually, the enlarging primary and secondary centers of ossification approach one another, entrapping a cylindrical segment of residual cartlage anlage and delineating the final form of the physis.

Continued growth of the primary and secondary centers of ossification results in the mergence of their reserve zones. At this

time, a plate of bone demarcating the

secondary center from the forming growth plate is deposited. From then on, the centrifugal growth of the epiphysis is hemispheric. The cartilage located at the base of the true articular cartilage is responsible for progressive epiphyseal enlargement, and it has the architectural organization of a physis. Variation in the subarticular growth results in concordant shapes of the ends of the adjacent bones about the joint spaces. The epiphysis receives its nutrition primarily from blood vessels within the bone and its adjacent periosteum, whereas, the true articular cartilage is nourished by synovial fluid.

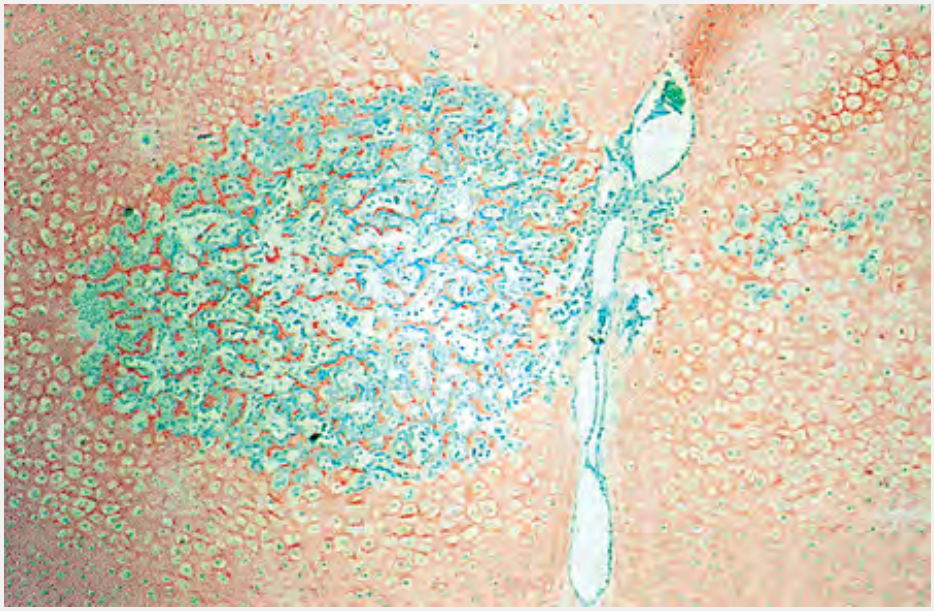

Figure 4.39 Photomicrograph of the secondary center of ossification of the femoral head. The nutrient vessels from the ligamentum teres are seen. Osteoid (green) is seen on the cartilage trabeculae (orange) in the spherical center. (Goldner's stain.)

In the apophyseal cartilage, located on the surface of the bone, a secondary-like center of ossification appears and is responsible for the development of apophyseal bone of the iliac crests, the greater and lesser trochanters of the femur (Figure 4.34), and the tibial tuberosities, to name a few.

Once enchondral ossification is well underway at the growth plate, modeling of the newly formed bone begins. The primary spongiosa undergoes complete osteoclastic resorption, and secondary trabeculae composed solely of lamellar bone are deposited. The expanding medullary cavity becomes largely free of spicules of cancellous bone in much of the diaphysis and fills with adipose tissue and the hematopoietic marrow. Subperiosteal bone deposition and endosteal resorption of the cortex maintains a proper, tubular shape, and mechanical forces exerted by weight bearing and muscle attachments alter the rate of these processes in specific regions, which help sculpt the contour of the bone.

Several hormones, including parathyroid hormone, growth hormone, somatomedins, thyroid hormone, androgens, estrogens, and adrenal cortical hormones, are essential regulators of bone growth. At puberty, low doses of androgens and estrogens cause an increase in cell division in the proliferative zone of the growth plate and the secondary center of ossification. This is accompanied by an increase in the rate of cartilage maturation, mineralization, osteoclastic removal, and formation of primary trabeculae. In toto, these effects produce the so-called growth spurt seen at puberty. As estrogen and androgen levels increase and growth hormone and somatomedin levels fall off, chondrocyte proliferation decreases while maturation and bone formation proceed. This leads to a diminution or thinning of the growth plate, and eventually all of the cartilage of the growth plate undergoes complete enchondral ossification, leaving little or no evidence of its previous existence. At this time, the growth plate is considered closed, and all additional bone growth is appositional (Figure 4.40) (1,14). Cessation of growth of the secondary centers of ossification occurs in a similar fashion. However, a remnant of

mineralized growth cartilage, which is the tide mark cartilage, persists at the base of the articular surface. It is demarcated from the true articular cartilage by a thin undulating layer of more densely mineralized matrix, known as the tidemark (Figure 4.41). The biologic potential of the tidemark cartilage persists as increases in hormones, such as growth hormone in the setting of acromegaly, can reactivate the process of enchondral ossification and produce additional growth in the adult. In normal circumstances, however, the vestige of the growth cartilage remains dormant and functions as an anchor of the true articular cartilage to the subchondral bone plate.

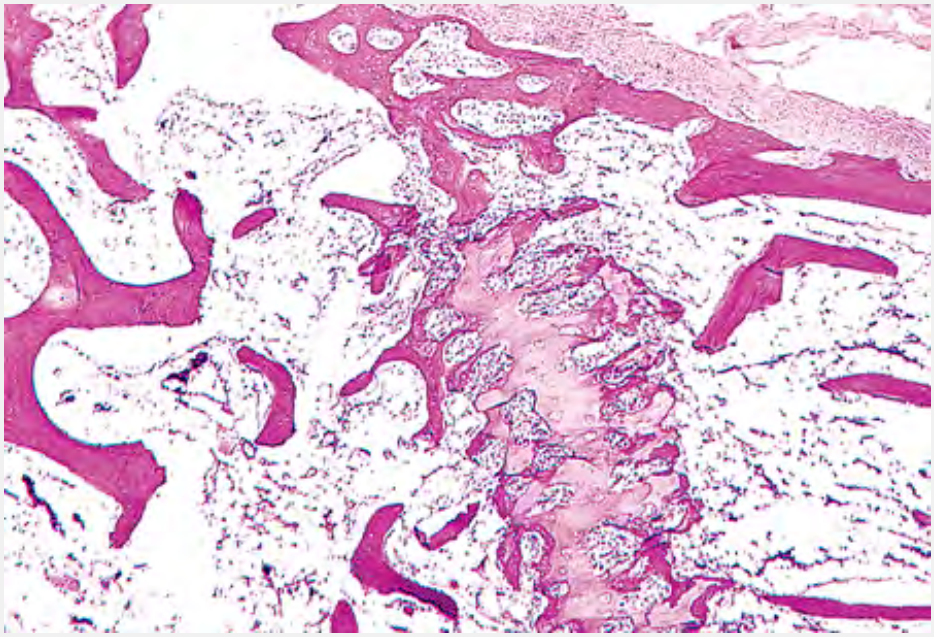

Figure 4.40 Closing epiphyseal growth plate in a 16-year-old boy. The periphery of the plate has been bridged by bone connecting the diaphysis and the secondary center of ossification. Cellular proliferation in the physis has ceased while the maturation process continues. The secondary center of ossification is at the top of the micrograph above the remnant of the physis.

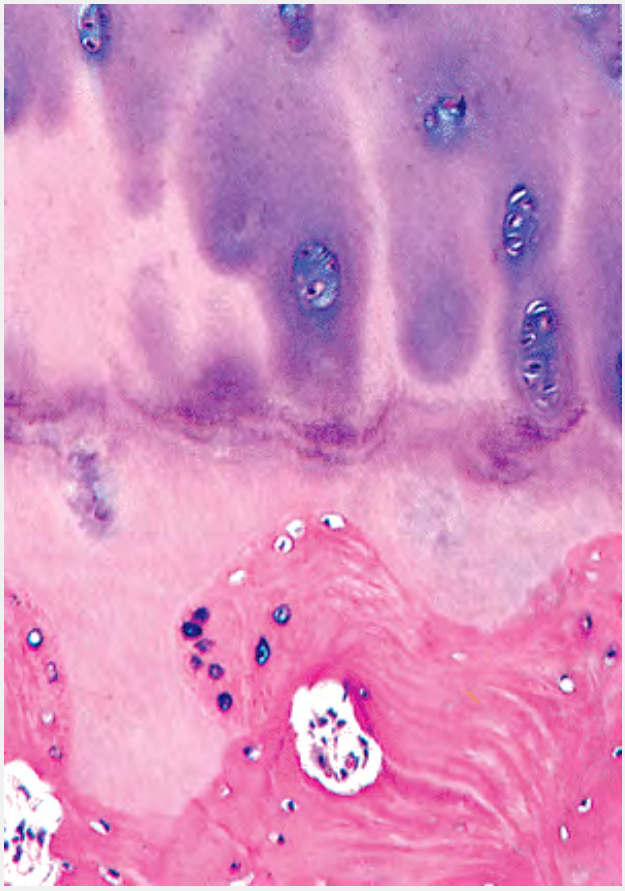

Figure 4.41 Section of base of articular cartilage in the region of the tidemark. The tidemark separates the articular nonmineralized cartilage (above) from the mineralized cartilage remnant of the physis and the lamellar bone of the subchondral plate (below).

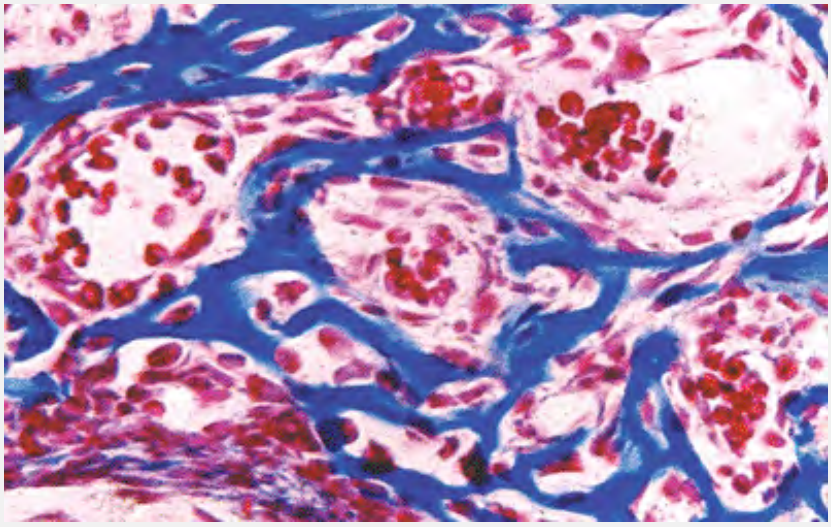

Figure 4.42 Intramembranous bone from a fetal skull. The osteoblasts are large along the randomly formed trabeculae. The osteocytes and their lacunae are large, round, and irregularly spaced in the trabeculae. (Trichrome stain.)

Intramembranous Ossification

Intramembranous ossification, or bone growth, refers to the process of bone formation in which the tissue occupying the site of the future bone or bone tissue is a fibrouslike membrane. The membrane is rich in osteoprogenitor cells and in normal situations forms the mesenchymal condensations in the developing embryo, the periosteum in the fetus, child, and adult, and the thin layer of fibrous tissue adjacent to all active bone-forming sites. The osteoprogenitor cells within the membrane produce offspring that differentiate into mature osteoblasts that directly deposit bone matrix (Figures 4.19, 4.42). Large portions of the flat bones of the skull, including the frontal, parietal, occipital, and temporal bones, form by this process (1,14). Also, since the cortices of all bones are largely created by

osteoblasts derived from the cambium layer of the periosteum, all bones, in at least some part, are formed by intramembranous ossification. Growth of membranous bone occurs only by the apposition of new bone, and the medullary cavites of membranous bones are created and maintained by endosteal osteoclastic activity. Initially, the marrow spaces of these bones are composed of highly vascularized loose connective tissue, which is eventually replaced by adipose and hematopoietic tissues.

Modeling and Remodeling

The processes of bone formation and resorption are tightly coupled, and their balance determines skeletal mass at any point in time (58). As the skeleton grows and enlarges (undergoes modeling) during childhood and young adulthood, bone formation predominates, whereas after the third or fourth decades bone resorption prevails. The breakdown and renewal of bone fundamental to the formation and maintenance of the skeleton is called remodeling. Remodeling is a dynamic process involving the removal and replenishment of both cortical and trabecular bone; it continues throughout life to maintain bone mass, skeletal integrity, and skeletal function. (39,59). This process is complex and at least partially controlled by the central nervous system through hormones (such as leptins) and by mechanically induced microdamage. It depends on the integrated actions of osteoblasts, osteocytes, and osteoclasts (60). Together these cells form the functional or basic multicellular unit of bone (BMU, or bone remodeling unit of Frost) and, in adults, are responsible for remodeling approximately 10% of the skeleton on an annual basis (Figures 4.43, 4.44) (61). This feat is accomplished by approximately 1 million BMUs that are active at any one time, and which likely first target sites that are experiencing fatigue and microdamage (33). The process may begin on any bony surface and incorporates three phases of cell activity: activation, bone resorption, and bone formation (62).

Many pathologic conditions of bone result from abnormalities in bone remodeling (1,9). These disorders may be generalized, in the form of a metabolic bone disease, or localized to small regions of the skeleton or individual bones. For instance, the diminished bone mass in postmenopausal osteoporosis, hyperparathyroidism, and hyperthyroidism results from increased osteoclastic bone resorption, which is not adequately compensated for by an appropriate amount of new bone formation. The lytic lesions in early Paget's disease or those caused by metastases and myeloma result from localized increased osteoclastic bone resorption, which is significantly greater in amount than any new bone that is deposited. The goal of therapy for this broad spectrum of diseases is to restore bone mass, balance bone formation and resorption, and protect and maintain strutural integrity.

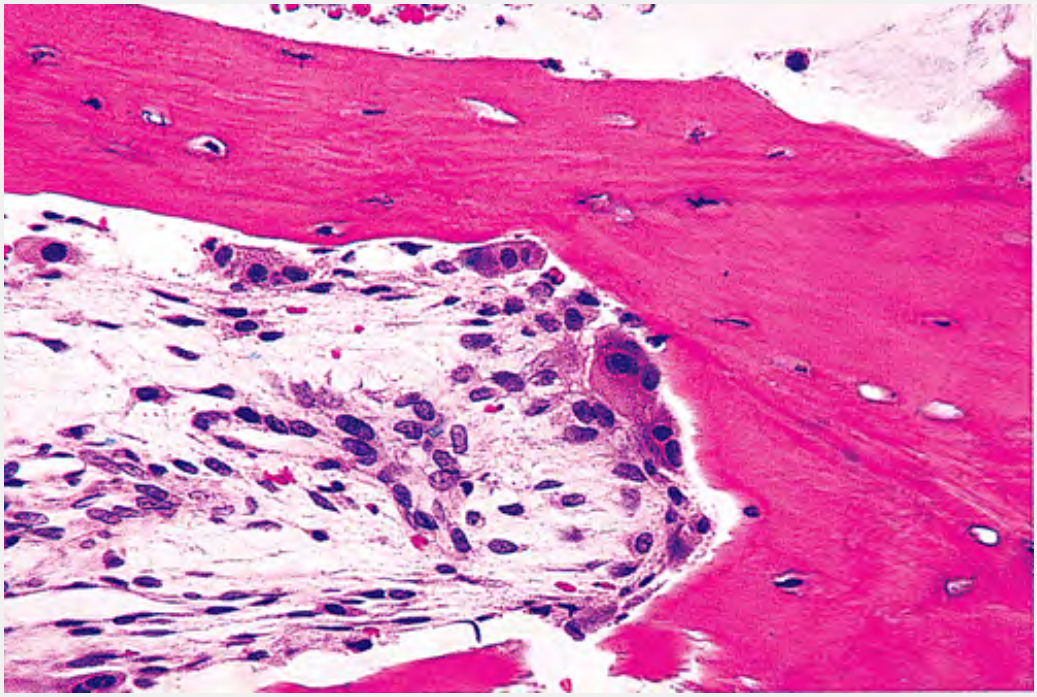

Figure 4.43 Basic multicellular unit (bone remodeling unit of Frost) of bone. Osteoclasts form the leading edge of the bone resorption (â€œthe cutting coneâ€•), and just behind them are

mononuclear macrophages and osteoblasts. The newly created space is filled with a vascular loose connective tissue.

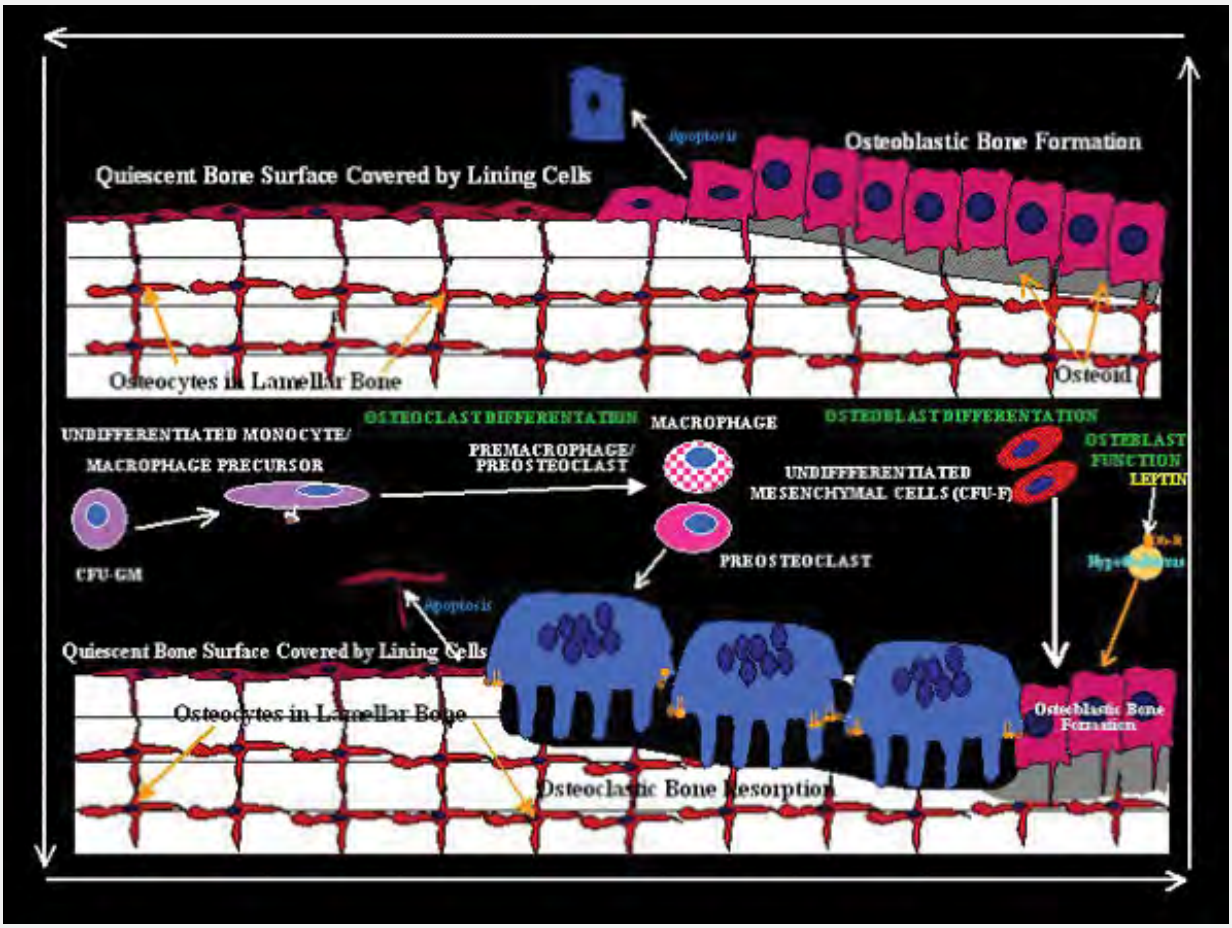

Figure 4.44 Drawing of the basic multicellular unit (bone remodeling unit of Frost) of bone. The resting osteoblasts are replaced by osteoclasts. New osteoblastic bone fills the resorbed lacunae of the haversian canal.

Joints

Peter G. Bullough

Introduction

Bone, cartilage, ligaments, and tendons have primarily a mechanical function: providing movement, stability, and protection. Unlike the liver or kidneys, which are composed mainly of cellular elements with a metabolic function, the connective tissues are mostly formed of an extracellular material (or matrix) made up of substances to resist the tensile and compressive forces to which they are subjected.

The Normal Joint

The ends of contiguous bones together with their soft tissue components, including cartilage, ligaments, and synovium, constitute a functioning unit: the joint. There are three types of joints. The most common is the diarthrodial joint, which is a cavitated movable connecting unit between two bones. (Hyalin cartilage covers the articulating surfaces of the diarthrodial joints, with the exception of the sternoclavicular and temporomandibular joints, which are covered by fibrocartilage.) The second type is the amphiarthrodial joint, typified by the intervertebral disk and characterized by limited mobility. The third type is the fibrous synarthrosis, such as the skull sutures, which are nonmovable joints and will not be discussed

further.

Diarthrodial Joint

Histology makes more sense when we have an understanding of both the function and dysfunction (i.e., the pathology) of the joint. In the diarthrodial joint normal function is characterized by: the maintenance of stability during use; freedom of the opposed articular surfaces to move painlessly over each other within the required range of motion; and an equitable distribution of load across joint tissues. Conversely clinical joint dysfunction is characterized by instability, loss of motion, maldistribution of load, and pain.

The three interdependent aspects of normal joint function depend on the shape of the joint, the mechanical properties of the extracellular matrices of the various tissues, and the integrity of the neuromuscular control.

The Shape

Perhaps the most obvious feature of any joint is the shape of its articulating surfaces. In general, one surface is convex and the other concave. The convex side of the articulation

usually has a larger surface than the concave side. These complementary shapes permit the normal range of motion, as well as providing stability and equitable loading during use.

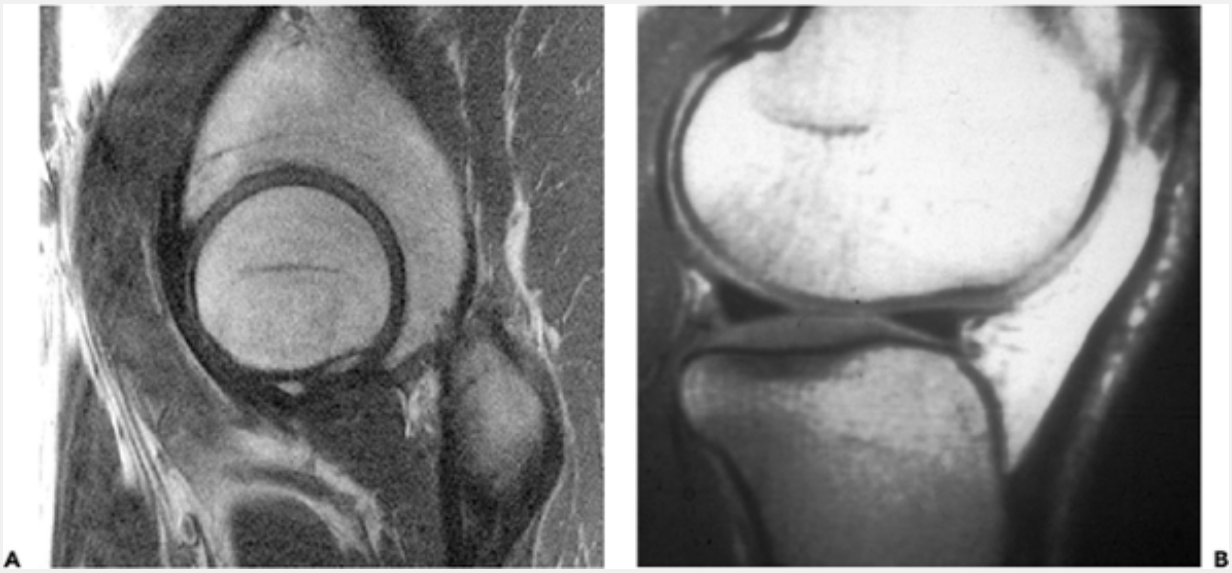

Figure 5.1 A. Sagittal section through the hip joint seen by MRI shows a close fit between the acetabulum and femoral head. B. Lateral MRI of a normal knee shows the gross incongruity of the articular surfaces. This is partially corrected by the interposed menisci, which act as load-bearing structures.

In some joints at first sight the articular surfaces appear to fit exactly (i.e., they appear congruent) (e.g., the hip and the ankle) (1). However, in other joints (e.g., the knee and finger joints), it is readily apparent that the surfaces are incongruent (Figure 5.1).

In a movable joint, congruence in all positions of the joint would necessitate that all joint surfaces were either perfectly spherical or cylindrical, which obviously they are not. Therefore no joint can be congruent in all positions (though in every joint there is usually a position in which it is *most* congruent) (2).

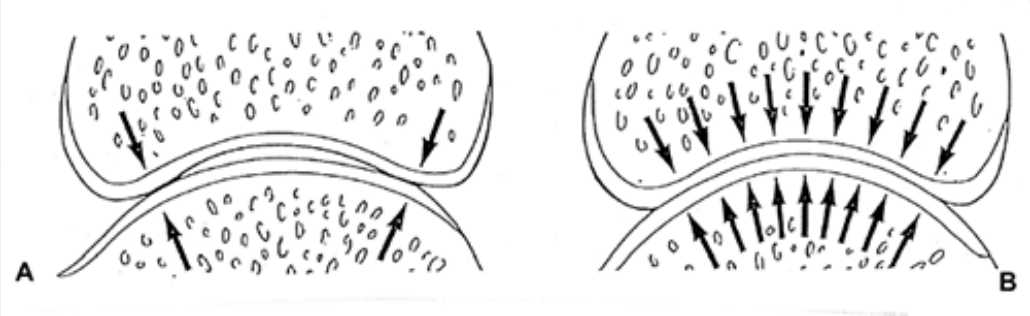

Figure 5.2 A. Light load. At rest and under light load, limited contact at the joint periphery assures access for synovial fluid to the joint space. B. Increased load. With increasing load, deformation of the bone and cartilage allow increased contact of the cartilage surfaces and an equitable distribution of the load. Cyclical loading permits circulation of the synovial fluid in the joint and between the articular surfaces to provide for the metabolic needs of the cartilage.

In some joints, of which the knee is a notable example, the gross incongruencies of the opposed surfaces are partially compensated for by the interposed, pliable intra-articular fibrocartilaginous menisci (3). The menisci constitute an important component contributing to joint morphology and function and cannot be removed or damaged without significant consequences.

In many joints, perhaps most, the initial contact between the opposed articular surfaces seems to be at the periphery of the joint. However, because the tissues that make up the articulating surfaces (particularly the cartilage but also the bone) undergo elastic deformation when loaded, the surfaces come into increasing contact as the load increases, thereby distributing the load more equitably (Figure 5.2).

The incongruence, the deformation of the joint space under load, and the movement of the joint provide for the circulation and mixing of the synovial fluid, which, because the articular cartilage has no blood supply, are essential to the metabolism of the chondrocytes.

The Mechanical Properties of the Extracellular Matrices

In 1743, William Hunter (4) noted that:

> The articulating cartilages are most happily contrived to all purposes of motion in those parts. By their uniform surface, they move upon one another with ease; by their soft, smooth and slippery surface, mutual abrasion is prevented; by their flexibility, the contiguous surfaces are constantly adapted to each other and the friction diffused equally over the whole; by their elasticity, the violence of any shock, which may happen in running, jumping, etc. is broken and gradually spent; which must have been extremely pernicious, if the hard surfaces of bones had been immediately contiguous.

These mechanical properties of articular cartilage (as of all other connective tissues) are determined by the extracellular matrices.

In each of the different connective tissues (bone, cartilage, ligament, etc.), as well as in each particular anatomic structure, the matrices have a unique composition and structural organization that provide for mechanical function at that locus. Disturbances in the structure and/or composition of the extracellular matrix of articular cartilage may result in joint dysfunction, and we should add that, since the joint also includes the bone beneath the cartilage as well as the

capsule and ligaments, alterations in the mechanical properties of bone or disruption of the ligaments could have equally disastrous effects on joint function. Clearly some knowledge of the matrix components is necessary to an understanding of connective tissue diseases.

The connective tissue matrices are mostly synthesized and to some extent broken down by their intrinsic cells (e.g., fibroblasts, osteoblasts, osteoclasts, chondrocytes). In maintaining the physicochemical and mechanical properties of tissues, the metabolism of these cells must be subject to highly sensitive feedback systems involving both local and systemic factors.

Collagen fibers, the principal extracellular component of connective tissues, are made up of bundles of fibrils, which in turn, are composed of stacked molecules formed from polypeptide chains arranged in a helical pattern. Fourteen different types of collagen molecule are now known, and these vary both in size and configuration (5).

Type I collagen is both the most common form of collagen and the major form of collagen found in skin, fascia, tendon, ligaments, and bone. Many other types of collagen are also aligned in a staggered array to form collagen fibrils. However there are also nonfiber-forming collagens that have varying functions, such as acting as binding sites for other matrix components (type IX collagen) or facilitating calcification (type X collagen) (6).

Articular hyalin cartilage has a unique type of collagen, type II, which is structurally characterized by three triple helical Î±-1 (II) chains. The type II fibrillar network gives articular cartilage its tensile strength and, together with the proteoglycans, is essential for maintaining the tissues volume and shape (7).

The fibrillar collagens provide tensile strength. However, connective tissues are also subjected to compression. In bone, the compressive load is resisted by hydroxyapatite. In cartilage, it is the filler

between the collagen fibers that provides the compressive strength of the tissue, as well as its viscoelastic properties. This filler is composed of large negatively charged macromolecular proteoglycan aggregates.

Proteoglycans (PGs) are a group of heterogenous molecules, consisting of protein chains and attached carbohydrates, which have a sticky gel-like quality. The major PG in cartilage is aggrecan (8), containing a protein core of Mr 2.15 Ã— 10^5 to which carbohydrate side chains (keratan and chondroitin sulfate) are attached. The core protein, which contains three globular domains, interacts with hyaluronic acid, and this interaction is stabilized by link protein. As many as 200 aggrecan molecules bind to one hyaluronic acid chain (Mr 1â€“2 Ã— 10^6) to form an aggregate (Mr 5 Ã— 10^7 to 5 Ã— 10^8).

The highly charged PG molecules attract water and swell considerably. However, within the cartilage, the expansion of the PGs is restricted by the collagen network to approximately 20% of the maximum possible; this creates a swelling pressure within cartilage tissue. When cartilage is loaded, some water is extruded and PGs are further compressed. Removal of the load permits the imbibing of water into the tissue, together with essential nutrients, until the swelling pressure of the PGs is again balanced by the tensile resistance of the collagen network.

Aggrecan shows an age-related decrease in size and enrichment in keratan sulfate relative to chondroitin sulfate, and these changes may relate to the observed age-dependent change in the stiffness and water content of the cartilage (9).

In addition to aggrecan, the extracellular matrix of cartilage contains many noncollagenous proteins and proteoglycans, whose precise functions are only just beginning to be understood. These molecules may serve a structural or regulatory roleâ€”and in some cases may do bothâ€”because degradation products of some of the structural molecules are known to influence the chondrocyte. The recognition of genetic disorders in which synthesis of the matrix molecules is

perturbed has aided greatly in our understanding of their functional role, but the reason for many site- and age-related restrictions in expression remains unclear. This is an area where there is still a wealth of information to be mined (10).

In a mature joint, cyclic hydrostatic fluid pressure through the entire cartilage thickness is comparable in magnitude to the applied joint pressure. Prolonged

physical activity can cause the total cartilage thickness to decrease about 5%, although the consolidation strains vary tremendously in the superficial, transitional, and radial zones. The superficial zone can experience significant fluid exudation and consolidation (compressing strains) in the range of 60%, while the radial zone experiences relatively little fluid flow and consolidation. The topological variation in the microscopic appearance and quantitative biochemistry of articular cartilage is influenced by the local mechanical loading of chondrocytes in the different zones. Patterns of stress, strain, and fluid flow created in the joint result in spatial and temporal changes in the rates of synthesis and degradation of matrix proteins. When viewed over the course of a lifetime, even subtle differences in these cellular processes may be expected to affect the micro- and macromorphology of articular cartilage.

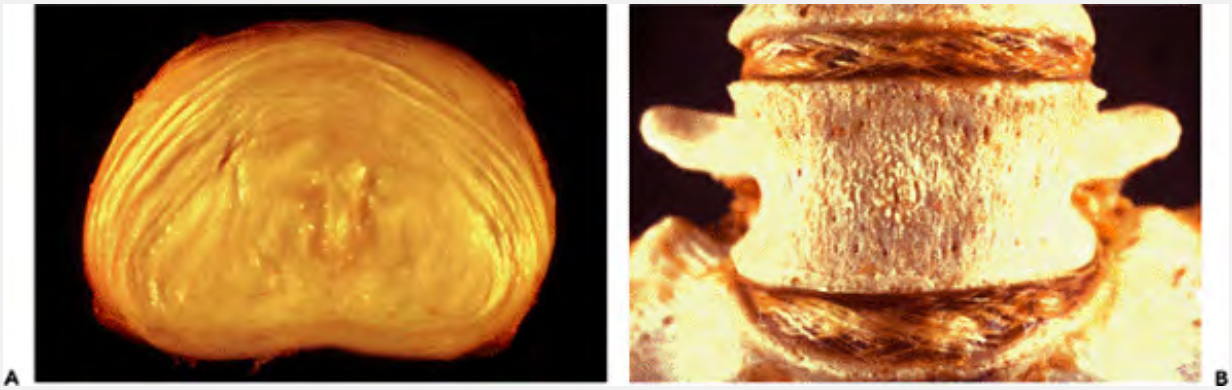

Figure 5.3 A. Photograph of an intervertebral disk seen in cross section. Note the layers of circumferential fibers that make up the annulus fibrosus and the well demarcated bulging central mass of the nucleus pulposus. Note also the decreasing width of the annulus from anterior (*top*) to posterior (*bottom*). B. In this desiccated specimen of the lower lumbar spine, the alternating oblique orientation of the collagen fibers in the annulus can be appreciated.

Capsular, Pericapsular Tissues, and Muscular Control

Any consideration of functional joint anatomy must include the capsule of the joint with its synovial lining; the ligamentous conjoining of the articulating surfaces; and the neuromuscular control of joint motion. Through the perception of touch, temperature, pain, and position, sensory feedbacks monitor our movements. Correct joint function is thus dependent on intact ligaments, muscles, and nerves. As recognized by Charcot a breakdown of neuromuscular coordination can lead to profound arthritis (11).

Amphiarthrodial Joint

The intervertebral disk can be divided into two components: the outermost fibrous ring (annulus fibrosus) and the innermost gelatinous core (nucleus pulposus).

The annulus, when viewed from above, is seen to contain fibrous tissue layers arranged in concentric circles. Each layer extends obliquely from vertebral body to vertebral body, with the fibers of one layer running in a direction opposite to that of the adjacent layer. This arrangement of alternating oblique layers provides for motion that is universal in direction (rotation, flexion and extension but restricted in degree (Figure 5.3).

The fibers of the annulus are attached by Sharpey's fibers to the bony endplates of the adjacent vertebral bodies. The fibrous lamellae are stronger and more numerous in the anterior and lateral aspects of the disk than in the posterior aspect, where they are sparser and thinner. The anterior annulus is therefore almost twice the thickness of the posterior annulus. This variation probably reflects the additional protection offered by the posterior elements of the vertebral bodies. As a result of the variation in thickness of the annulus, the nucleus pulposus typically occupies an

eccentric position within the disk space, being closer to the posterior margin.

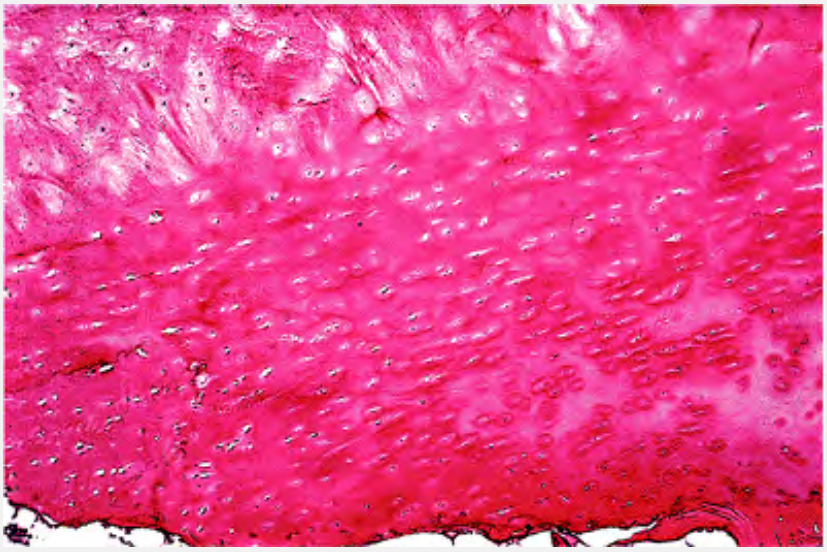

Figure 5.4 The nucleus pulposus of the disk (*top*) is separated from the bone (*bottom*) by a dense layer of hyaline cartilage, as demonstrated in this photomicrograph (H&E stain, Ã—4 objective).

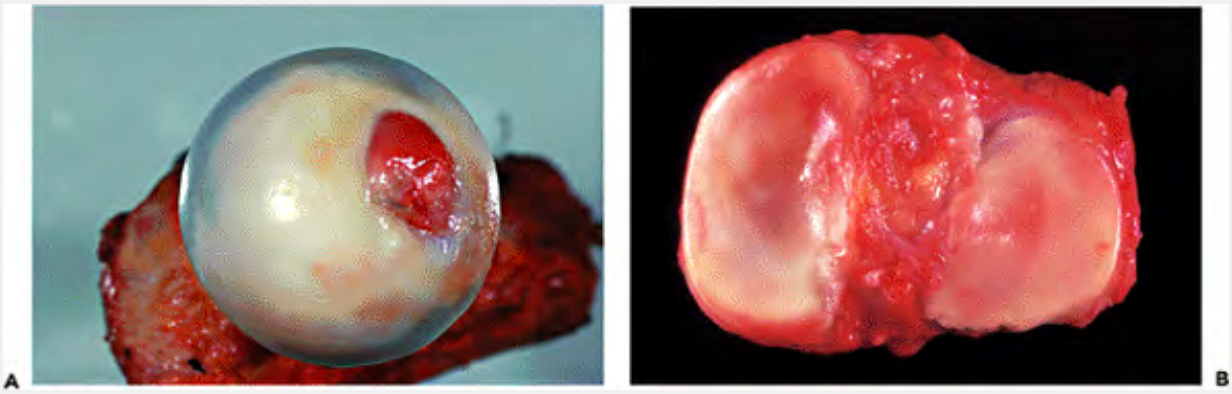

Figure 5.5 A. A femoral head, resected from a 16-year-old, demonstrates the blue-white translucency of young healthy cartilage. B. For comparison, the tibial plateau of a 50-year-old.

The cartilage is smooth and healthy in appearance but is more yellowish in color and opaque in quality than that of the 16-year-old.

The tissue of the nucleus is separated from that of the bone above and below by a clearly defined layer of hyalincartilage which extends to the inner margins of the insertion of the annulus (Figure 5.4).

On microscopic examination, the nucleus pulposus shows a varying number of stellate and fusiform cells suspended in a loose fibromyxoid matrix rich in proteoglycans.

Because no blood vessels are present in most of the adult disk tissue, nutrients must travel by diffusion from capillary beds at the disk margins. A restricted flow of nutrients to the nucleus and inner annulus may contribute to disk degeneration in the adult.

It should be noted that disk height, in general, is not the same in all segments of the spine, the cervical and thoracic disks being flatter than those of the lumbar region. There is also a variation in disk height from front to back, relative to the curvature of the spine. With age, the disk gets thinner as a result of age-related dehydration of the disk.

The Normal Joint Tissues

Articular Cartilage

Morphology

The articular ends of the bones are covered by hyalin cartilage, which is a nerveless, bloodless, firm, and yet pliable tissue. Hyalin cartilage deforms under pressure but recovers its original shape on removal of pressure (12). In growing children, cartilage is the most obvious precursor of the bony skeleton, and it is the means by which

the bones increase in length by the mechanism of endochondral ossification through the medium of the cartilaginous growth plate (physis).

In young people, hyalin cartilage is translucent and bluish-white; in older individuals, it is opaque and slightly yellowish (13) (Figure 5.5). This change in the appearance of the articular cartilage with advancing age is also seen in other connective tissues and is probably related to a number of factors, including dehydration of the tissues, increased numbers of cross linkages in the collagen, and the possible accumulation of pigment.

On microscopic examination, articular cartilage is characterized by its abundant glassy (hyalin) extracellular matrix with isolated, relatively sparse cells located in well-defined spaces (lacunae) (Figure 5.6). It is usually described as having four layers (or zones): superficial,

intermediate, deep, and calcified. In the superficial layer, the cells are flat. In the intermediate zone, the cells have a tendency to form radial groups that apparently follow the pattern of collagen disposition. In the deep zone, the cells are hypertrophied; and in the calcified zone (i.e., the zone adjacent to the bone), the cells are nonviable and the matrix is heavily calcified (Figures 5.7 and 5.8).

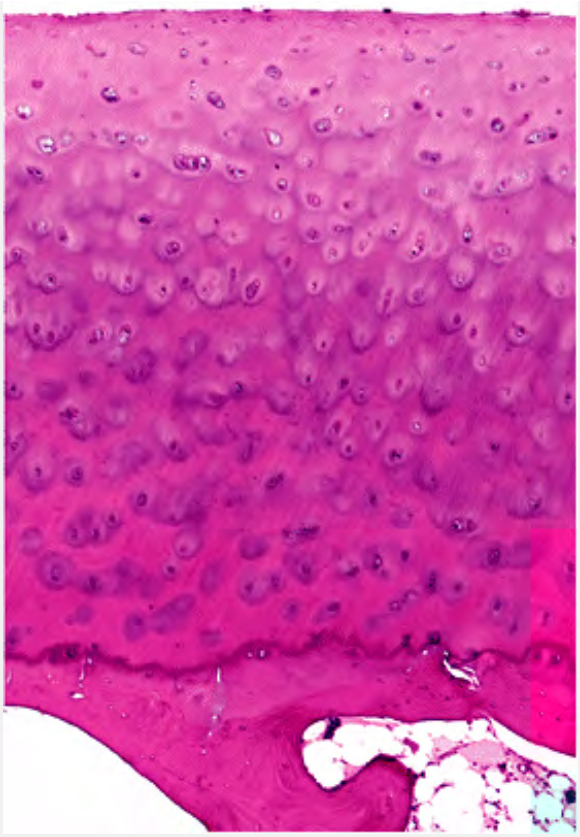

Figure 5.6 Photomicrograph of normal articular cartilage obtained from the femoral condyle of a middle-aged individual (H&E stain, Ã—4 objective).

Within the mineralized bone matrix, the cells are connected with one another by means of cytoplasmic processes; however, no such syncytial arrangement is present within the cartilage. The chondrocytes are dependent upon the diffusion of solutes through the extracellular matrix for their metabolism. Since the matrix of the deep calcified zone of the articular cartilage effectively blocks the passage of solutes from the subchondral bone, the articular cartilage is thus dependent on the diffusion of nutrients and the exchange of metabolites from the synovial fluid through the articular surface (14).

In the late nineteenth century, Hultkranz (15) demonstrated that the precisely organized fibrous system within normal articular cartilage is readily demonstrable by the simple expedient of pricking the articular surface with a pin. When this is done, a split results; if the pricking is repeated all over the surface, a pattern of split lines is revealed that is constant for each joint from individual to individual (16) (Figure 5.9).

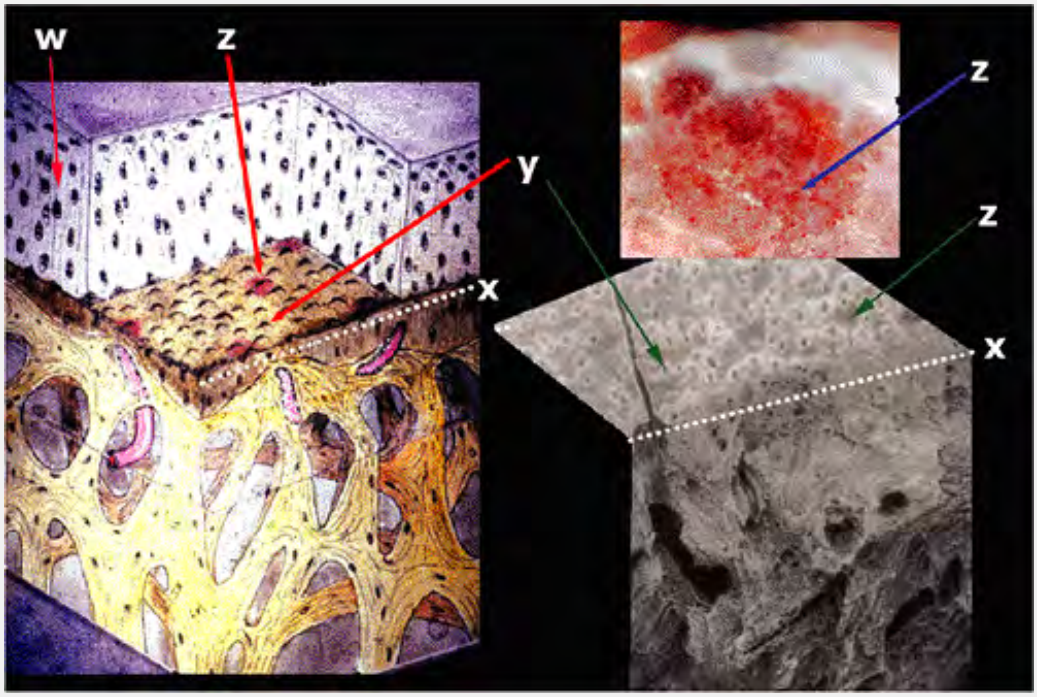

Figure 5.7 In this diagram of the articular surface, the organization of the articular surface seen on Figure 5.6 is shown diagrammatically. This distribution of the collagen arcades described by Benninghoff has been drawn in (w). Noncalcified articular cartilage has been removed to reveal the surface of the tidemark (x). The small â€œvolcanicâ€• structures (y) represent the location of the cells in the calcification front. The vessels that penetrate the calcification cartilage (z) are seen just beneath the calcification front. A dissection (*upper right*) shows the vessels when the cartilage has been pared away, and a scanning electron

photomicrograph (*lower right*) shows the section from which the diagram was reconstructed.

When the superficial layer of the cartilage is pared away and the exposed surface pricked, only small round holes appear instead of fissures. If the cut edge of the cartilage is pricked, a vertical split line is produced, and this occurs in all planes of section (Figure 5.10). If the fissures reflect the internal fiber arrangement of the cartilage, then at the articular surface the fibers run parallel to the surface and in the general direction of the split line, and in the deeper layers of the cartilage the fibers are predominantly vertical (17).

A combination of polarizing microscopy, transmission electron microscopy, and scanning electron microscopy have confirmed that the principal orientation of collagen fibers in articular cartilage is vertical through most of its thickness and horizontal at the surface (17) (Figure 5.11).

Electron microscopic studies have shown that, in the surface layer of normal articular cartilage, the collagen fibers are closely packed, of fine diameter, and mostly oriented parallel to the joint surface. The collagen content of cartilage progressively diminishes from the superficial to

the deep layer. In deep layers, collagen fibers are more widely separated, thicker in diameter, and are vertically aligned in such a fashion as to form a web of arch-shaped structures (18) (Figure 5.12). The collagen fibers are continuous with those in the calcified layer of cartilage but not with underlying subchondral bone. The morphology of the collagen-fibril network influences the local stresses and strains in the articular cartilage (19).

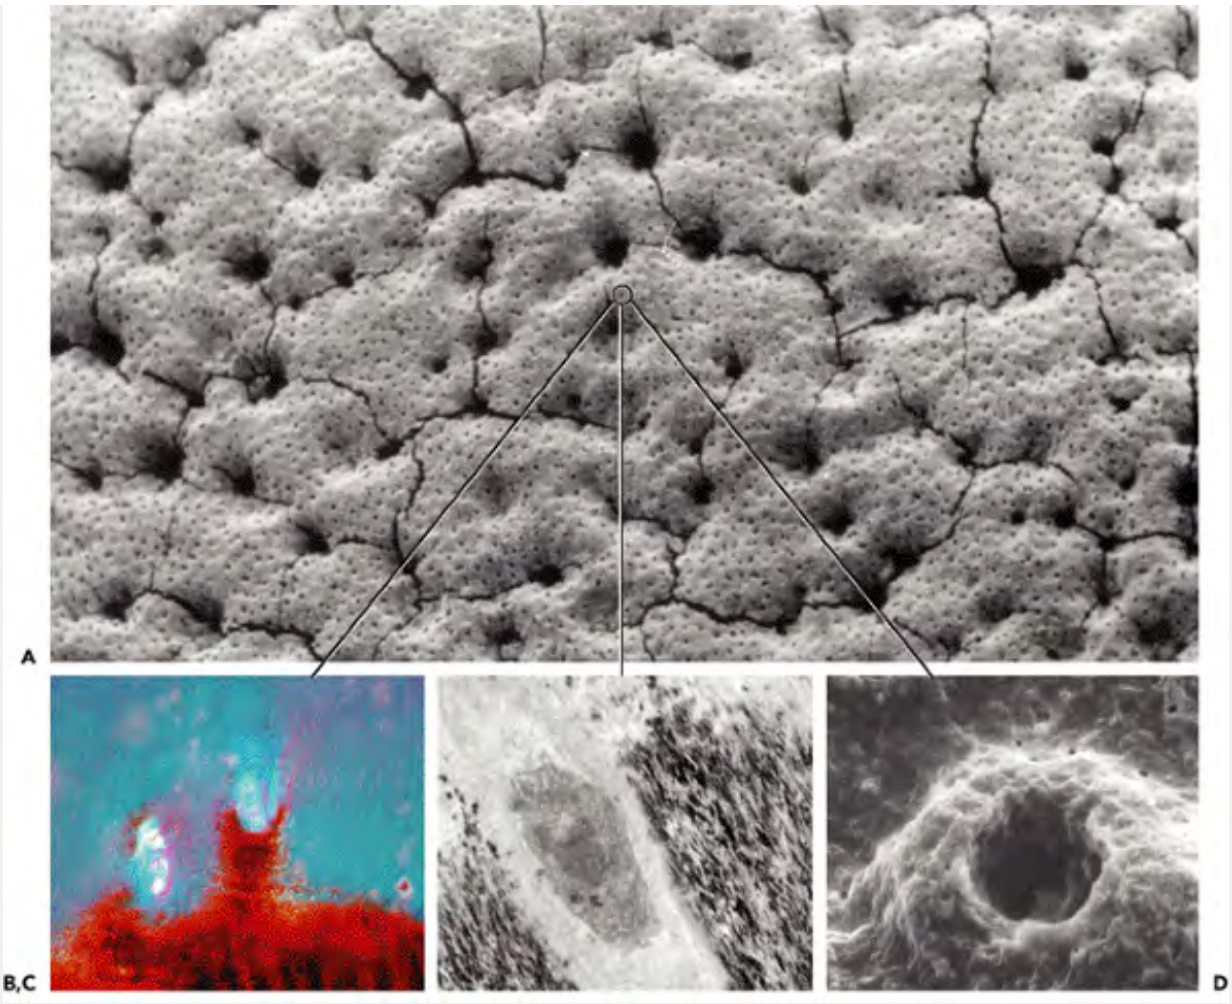

Figure 5.8 A. Scanning electron photomicrograph of the surface of the tidemark after the uncalcified articular cartilage had been digested away. The small dots represent chondrocytes embedded in the mineralization front (tidemark). The larger voids result from underlying vessels close to the tidemark. The cracks are preparation artifact. B. The appearance of chondrocytes embedded in this surface is shown in a cross sectional image of an H&E section, photomicrographed using polarized light. The same sample (as in B) is shown in C. as in a transmission electron and in D. as a higher power scanning image. It is hypothesized that this layer of embedded chondrocytes regulates the rate of active calcification at the tidemark.

The menisci of the knee are composed mainly of collagen, although some PG is also present. Microscopic examination of carefully oriented sections has shown that the principal orientation of the collagen fibers in the menisci is circumferential to withstand the circumferential tension within the meniscus during normal loading of the knee joint. The few small radially disposed fibers probably act as ties to resist any longitudinal splitting of the menisci that might result from undue compression (20) (Figure 5.13).

The precise organization of collagen in the cartilage, in the annulus of the intervertebral disc, and in the menisci is also present in all the connective tissues of the body (e.g., Langer's lines in the skin) and serves a mechanical function in all of these locations.

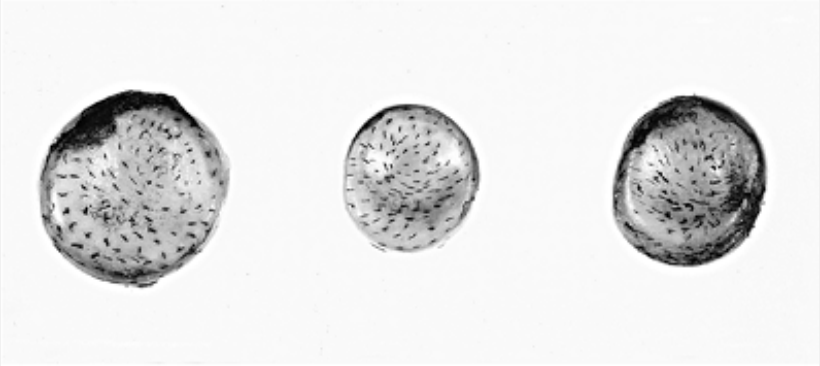

Figure 5.9 Photograph of the articular surfaces of three radial heads from three different individuals after the surfaces have been pricked with a pin whose tip had been dipped in India ink. Note the resulting pattern of split lines, which is unique for each joint in the body. Note that the pattern is similar from individual to individal.

Figure 5.10 Photograph of a portion of articular cartilage that has been sectioned vertically to show the cut edge and the underlying bone. The direction of pin pricks made on the surface can be seen; additional pin pricks have been made on the cut edge, all of which resulted in vertical splits.

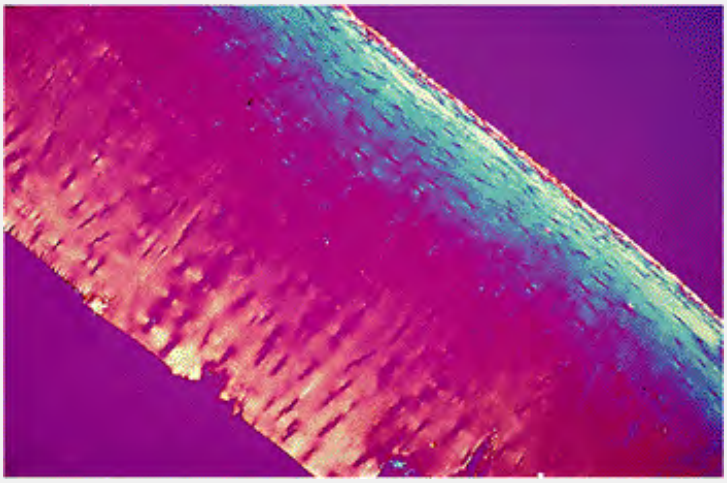

Figure 5.11 In this polarized-light photomicrograph, the surface

collagen fibers can be visualized as blue, the deeper collagen fibers (which are perpendicular) as yellow. Collagen cannot be seen in the intermediate area because the fibers in this zone are decussating as in the model of Benninghoff's arcade shown in Figure 5.7 (Ã—4 objective).

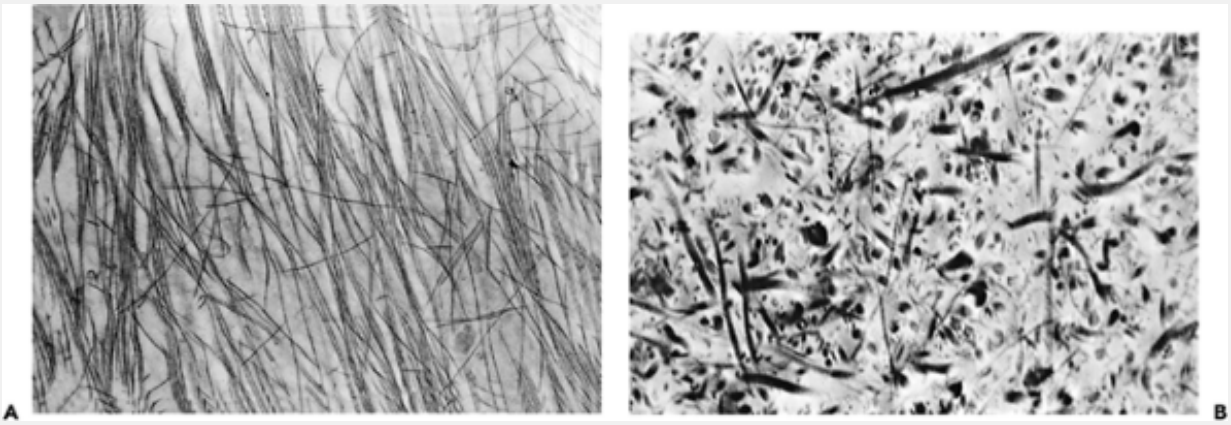

Figure 5.12 A. A transmission electron micrograph taken from tissue cut parallel to the surface collagen layer demonstrates thin closely packed and oriented fibers (Ã—10,000). B. Transmission electron micrograph, taken from tissue obtained from the midzone of the cartilage and cut randomly, demonstrates variable fiber thickness and more widely separated fibers than are seen at the surface (Ã—10,000).

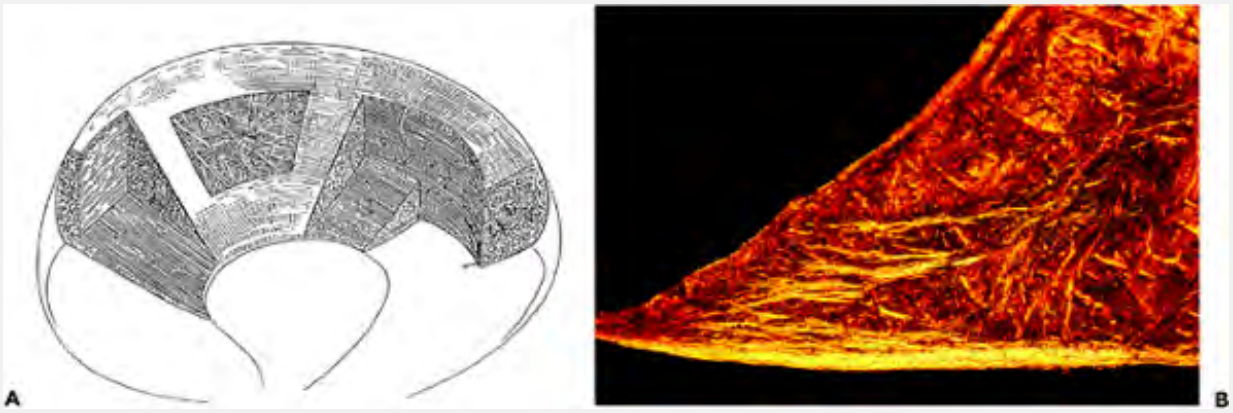

Figure 5.13 A. A drawing to illustrate the distribution of collagen fibers in the meniscus. The majority of the fibers are circumferentially distributed to resist the tension generated in the meniscus when the knee is under compressive load. The radially distributed fibers are most obvious on the tibial surface of the meniscus. (Modified from:
Bullough PG, Munuera L, Murphy J, Weinstein AM. The strength of the menisci of the knee as it relates to their fine structure. *J Bone Joint Surg Br* 1970;52:564â€“567
with permission). B. Photomicrograph of a cross section of meniscus seen with polarized light. The tibial surface is the bottom edge where most of the fibers are radially arranged (Ã—1 objective).

The distribution of PGs in the cartilage matrix is also related to the mechanical requirements. It varies quantitatively and possibly qualitatively from joint to joint, geographically within a single articular surface, and also as a function of age. (In general, PG distribution is more even in children than in adults.) The surface layers of the cartilage contain much less PG than do the deeper layers. In the deeper layers, there is a higher concentration of staining with safranin O and methylene blue around the cells (the

pericellular matrix) than between the cells (the intercellular matrix) (21) (Figure 5.14).

Besides the PG aggregates, the articular cartilage contains other extracellular matrix proteins. Chondrocalcin (type X collagen) is a protein probably involved in the calcification process. Anchorin (type IX collagen) is a protein on the surface of chondrocytes involved in binding of these cells to extracellular matrix components, possibly transmitting altered stress in type II fibers to chondrocytes. Fibronectin, thrombomodulin, and cartilage oligomeric high Mr matrix protein are all found in cartilage, but their precise functions are not yet established.

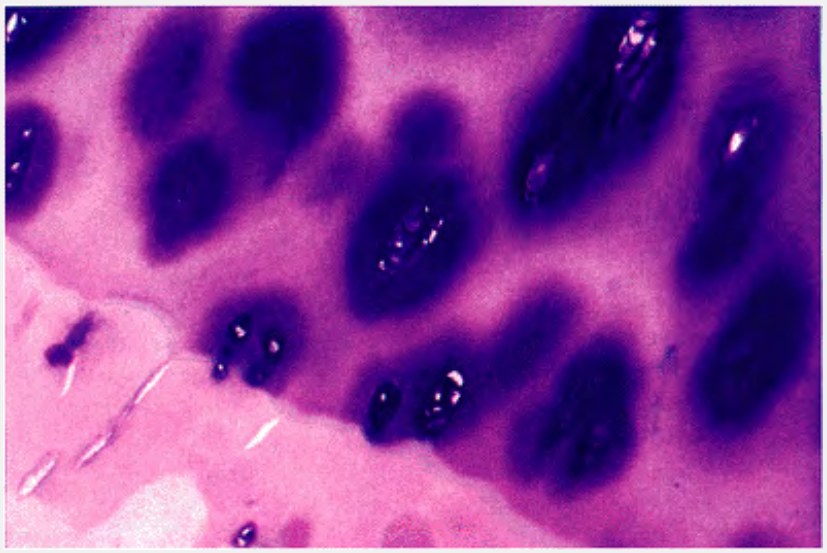

Figure 5.14 Portion of cartilage showing intense metachromasia around the chondrocytes in the deep part of the noncalcified cartilage. This represents staining of the proteoglycan. There is much less staining in the interterritorial matrix than around the cell. Even less staining is seen in the calcified cartilage (methylene blue stain, Ã—25 objective).

In histologic sections stained with hematoxylin and eosin, the

junction between the calcified cartilage and the noncalcified cartilage is marked by a basophilic line known as the tidemark (Figure 5.15). This basophilic line is not seen in the developing skeleton but is clearly visible in the

adult. In older individuals (over 60), replication of the tidemark is usually evident, and in osteoarthritic joints replication may be marked (Figure 5.16). Mechanical failure in the deep cartilage rarely, if ever, gives rise to separation at the bone cartilage interface. However, when failure occurs, it is often seen as a horizontal cleft at the tidemark, presumably because of the considerable change in the rigidity of the cartilage at this junction.

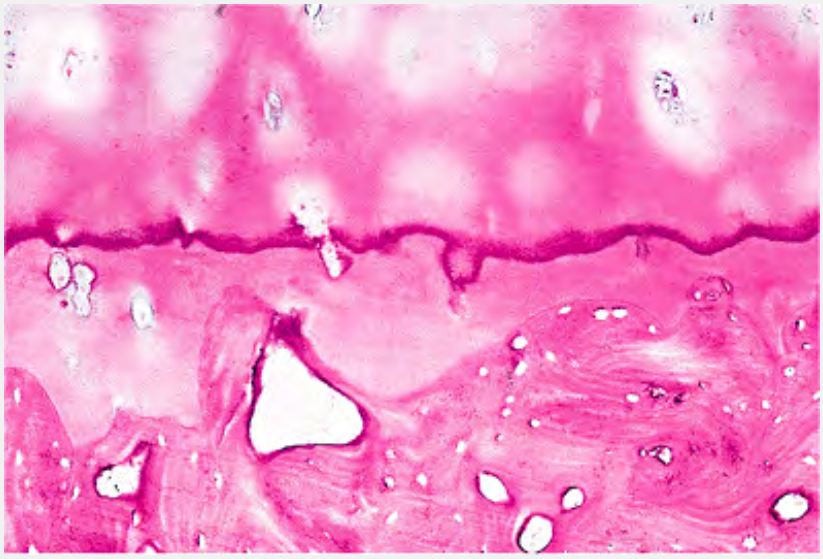

Figure 5.15 Photomicrograph of the deep and calcified layers of the articular cartilage. The deep layer is separated from the calcified layer by a basophilic line referred to as the â€œtidemark,â€• which represents the mineralizing front (H&E stain, Ã—4 objective).

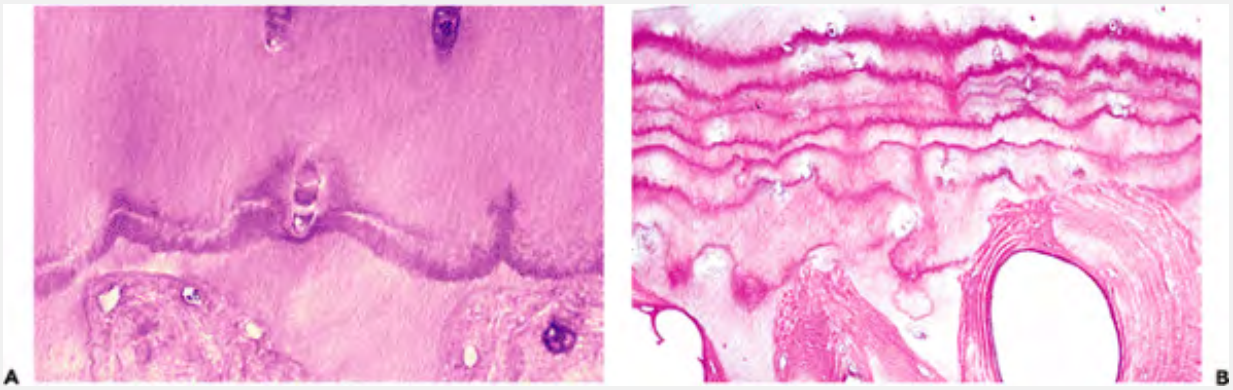

Figure 5.16 A. Photomicrograph demonstrating accelerated mineralization with a replicated tidemark. The mineralization front is almost certainly under cellular control; here, a chondrocyte is seen caught up in the tidemark (H&E stain, Ã—25 objective). B. In most areas of normal cartilage, only one tidemark is observed. However, in an early stage of osteoarthritis, seen here, multiple tidemarks indicating rapid advance of the mineralization front can often be seen (H&E stain, Ã—10 objective).

At its base, adult articular cartilage is bordered by the subchondral bone plate, and the calcified cartilage tissue is keyed into the irregular surface of the underlying bone, somewhat like a jigsaw puzzle. Because the cartilage adjacent to the bone is calcified and has a rigidity similar to that of bone, the keying is rigid (Figure 5.17).

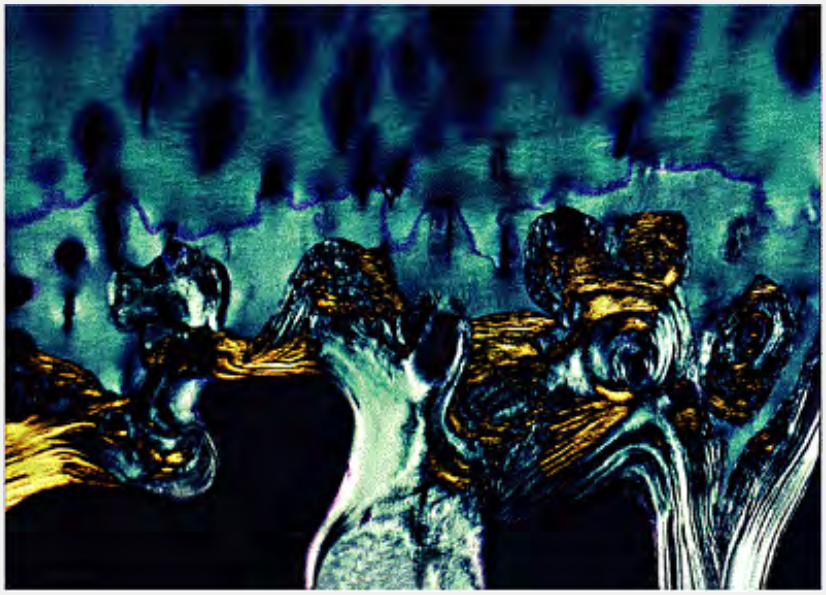

Figure 5.17 In this photomicrograph, taken with polarized light, the irregularity of the interface between the subchondral bone and the overlying calcified cartilage is obvious. The functional keying of the bone and cartilage depends on the two tissues having equal rigidity (Ã—4 objective).

The insertions of ligaments and tendons are also calcified, and their insertions into the bone are effected by a similar keying. Because the insertions of ligament and tendons into the bone are generally studied in dry bone specimens, the bone markings we see are in fact the calcified portion of the ligament or tendon. Because the sites of such insertions are approximately the same from individual to individual, there is a tendency to think of them as static structures. However, since in the child growth is taking place continuously and in the adult bone turnover is continuously taking place (albeit slowly), it follows that the insertions of ligaments and tendons must participate in this dynamic process. (Our knowledge of anatomy is for the most part based upon the dissection of the dead; but, for morphology to be understood, time must be put into the equation. Life is

characterized by continuous growth and change.)

The chondrocytes embedded in the cartilage matrix are responsible for synthesis and maintenance of the extracellular matrix of the tissue. The chondrocytes vary in size, shape, and number per unit volume of tissue, both from the superficial to the deep layers and in different anatomic locations (22) (Figure 5.18). Generally, cells at the cartilage surface are flatter, smaller, and orientated parallel with the cartilage surface. They also have a greater density than the cells deeper in the matrix (23). In the middle zones, chondrocytes are more spherical and arranged in columns. This vertical arrangement of cells probably reflects some interaction with the highly organized arrangement of collagen fibers in cartilage and suggests the possibility of movement of chondrocytes within the matrix substance as the collagen fibers are being laid down. (An analogy would be the precise organization of a spider's web that necessitates the movement of the spider.)

An interesting ultrastructural feature of chondrocytes is a nonmotile monocilium, which may have a mechanotransductory

function in regulation of matrix synthesis (24). This monocilium has been more frequently observed in young cartilage and reactive or reparative cartilage (25).

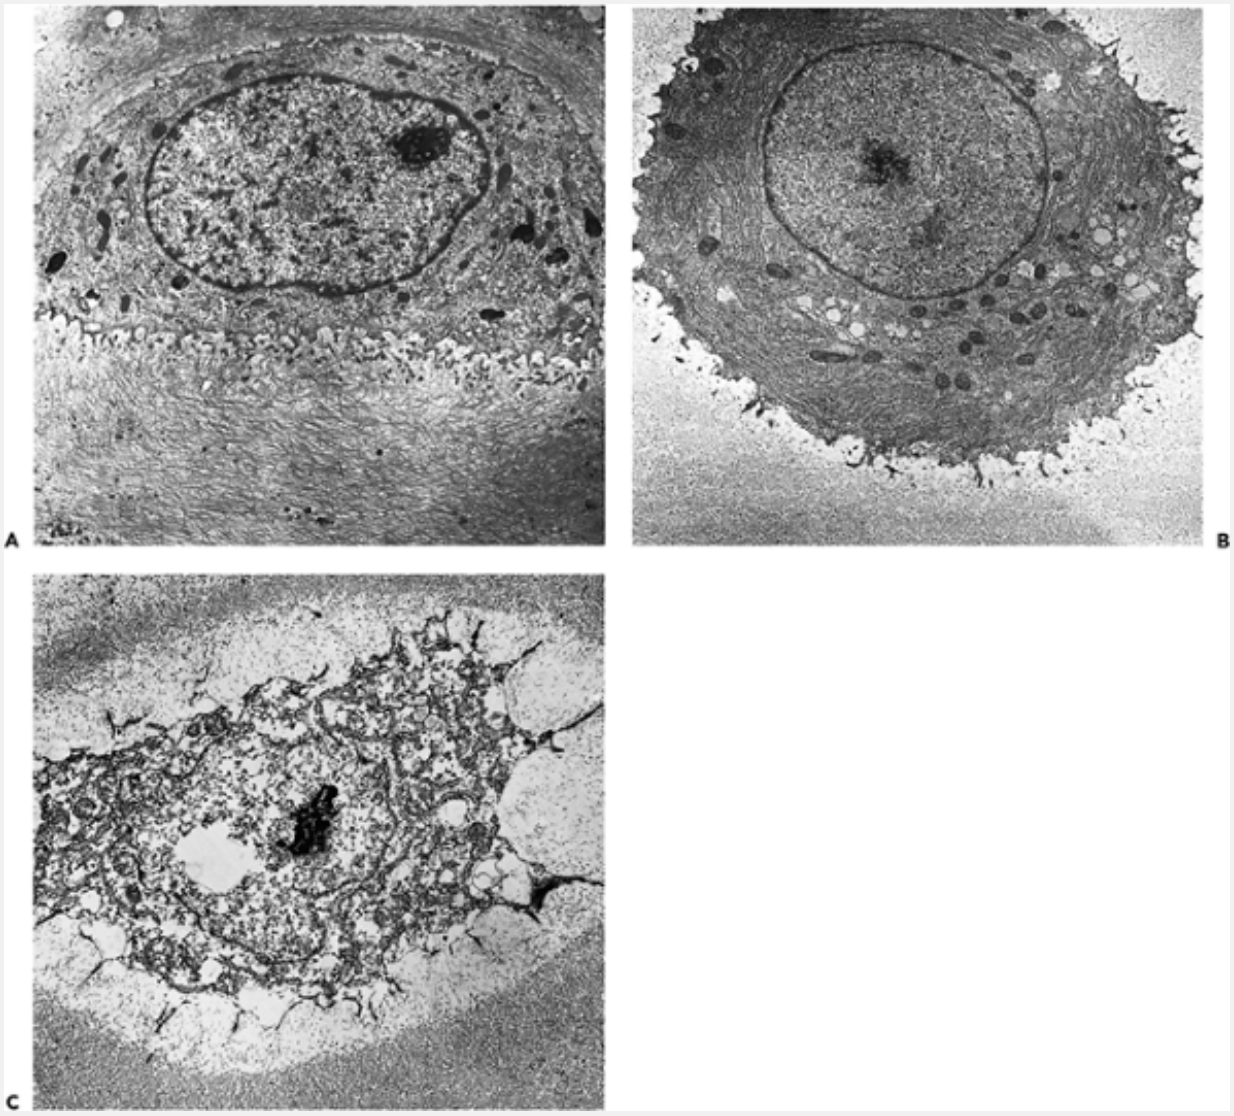

Figure 5.18 A. Electron micrographs to illustrate the typical appearance of chondrocytes at the A. surface, B. mid-zone, and C. deep-zone of articular cartilage. At the surface the cells typically show more cell processes on the inferior surface. The Golgi and endoplasmic reticulum are less well developed than in the mid-zone. In the deep zone, the cells are degenerate, with disaggregated chromatin in the nucleus and vacuolization and fragmentation of the cytoplasm (all approximately Ã—10,000).

Chondrocytes are encased in a specialized layer of matrix distinctly different from the bulk of extracellular matrix. This layer is rich in proteoglycans, has some hyaluronic acid, and contains relatively little collagen. Around this paucicollagenous layer is a basketlike structure composed of cross-linked fibrillar collagen encapsulating the cell or sometimes groups of cells, and this provides a protective framework. Collagen type VI is found in this region.

In chondrocytes, mitochondria are sparseâ€”probably as a result of their comparatively low rates of oxygen consumption. Cells in the deeper uncalcified zone have the most prominent endoplasmic reticulum and Golgi apparatus, indicating active protein synthesis as well as sulfation of proteoglycan carbohydrate side chains. The cell membrane shows numerous short, as well as some longer, branched cytoplasmic processes, but they make no connection with the processes of other chondrocytes. In the extracellular matrix adjacent to the chondrocytes that lie above the tidemark, as in the hypertrophic zone of the growth plate, small

membrane-bound vesicles are visible. These may play a role in the calcification of cartilage matrix (26).

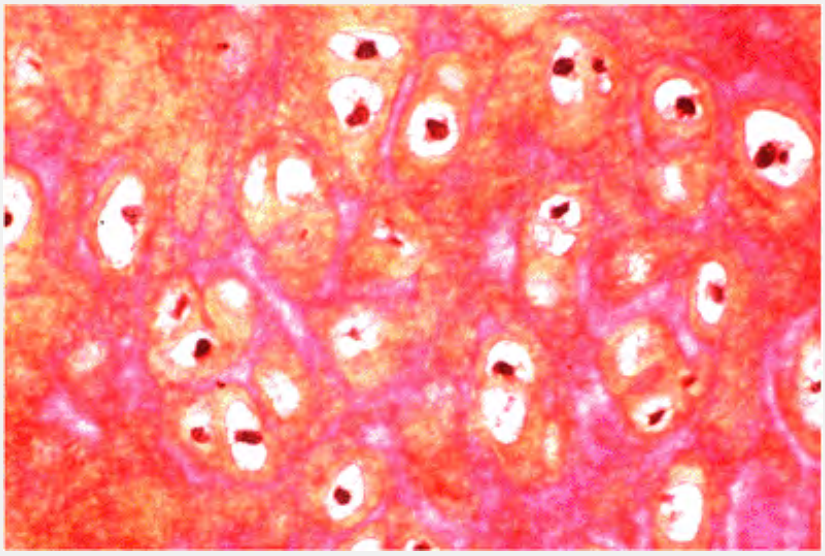

Figure 5.19 Photomicrograph of ear cartilage. Although the cells resemble those seen in hyalin cartilage, the matrix contains many elastic fibers that appear red in this section (phloxine and tartrazine stain, Ã—25 objective).

In addition to hyalin cartilage, of which articular cartilage is composed, two other forms of cartilage can be histologically recognized. Fibrocartilage is a tissue in which the matrix contains PG aggregates and a high proportion of type I collagen, the fibers of which are usually visible by transmitted light microscopy. Fibrocartilage may be found in the menisci of the knee, the annulus fibrosus, at the insertions of ligaments and tendons into the bone, and on the inner side of tendons as they angle around pulleys (e.g., at the malleoli). In all of these locations, the structures are subjected to compressive forces as well as tension. The second type of nonhyalin cartilage, elastic cartilage, contains a high proportion of elastin in the matrix and is found in the ligamentum flavum, external ear, and epiglottis (Figure 5.19). Compared to collagen, elastin has much greater elasticity; this is particularly important in the yellow ligaments, which make possible the flexion of the spinal canal.

Both the fibrocartilage and elastic cartilage incorporate the term â€œcartilageâ€• because the cells are rounded and lie in lacunae, which give them a superficial microscopic resemblance to the cells of hyalin cartilage. However, the mechanical functions of these tissues are very different from those of hyalin cartilage. Hyalin cartilage is mainly subjected to and resists compressive forces, whereas both fibrocartilage and elastic cartilage function principally as resisters of tension, with some element of compression.

Cartilage Turnover and Articular Remodeling

Wolff's law states that both bone density and bone architecture

correlate with the magnitude and direction of applied load. At the articular end of a bone, this implies that the subchondral bone trabeculae must also undergo a self-regulated modeling that maintains a joint shape capable of optimal load distribution. In other words, the shape of bones, *including their articular ends*, reflects a dynamic state that incorporates a feedback dependent on mechanical stress.

Endochondral ossification is an important mechanism for both growth and bone modeling. This is exemplified in the epiphyseal growth plate where calcified cartilage is invaded by blood vessels from the metaphyseal bone and is then replaced by bone tissue synthesized by osteoblasts lying close to the blood vessels.

Studies of adult joints have shown that replacement of the calcified layer of articular cartilage by bone tissue involves a similar process. Blood vessels from the subarticular bone penetrate the calcified cartilage, and new bone is laid down alongside the channels created by this process; thus the calcified cartilage is slowly replaced by new subarticular bone (Figure 5.20).

Replacement of the calcified layer of cartilage by bone might be expected to result in thinning and eventual disappearance of the calcified cartilage. However, histologic study of articular cartilage from subjects of various ages shows that the calcified cartilage remains much the same thickness throughout life. This is because the calcification front (tidemark) continues to advance into the noncalcified cartilage at a slow rate, which is in equilibrium with the rate of absorption of the calcified cartilage from the subarticular bone (27). Since the thickness of the articular cartilage does not significantly change during life, it can be postulated that articular cartilage is not a static tissue, as it was long believed to be. The extracellular matrix and the chondrocytes are being replaced throughout life; and, through these mechanisms, the joint undergoes continuous modeling. It seems likely that programmed cell death (apoptosis) plays an important role in this process in a similar way to

what Mitrovic (28) has demonstrated in joint formation during limb development (29).

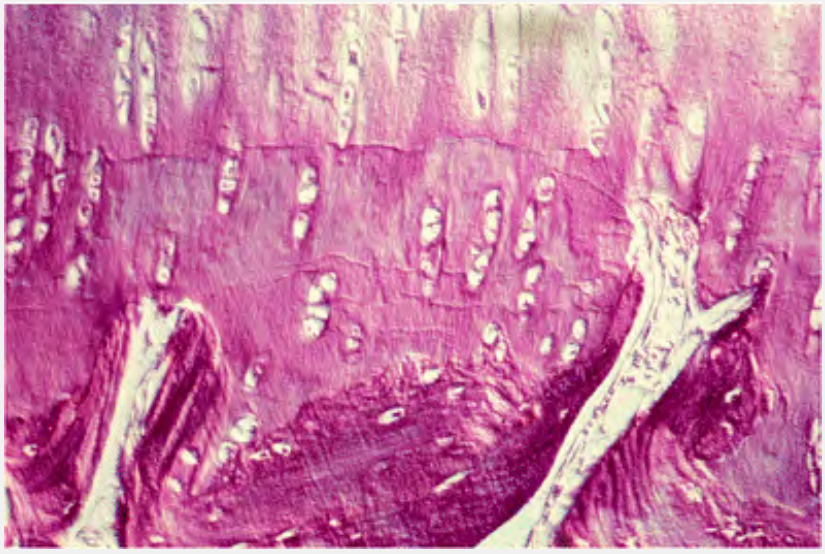

Figure 5.20 In this photomicrograph, two vessels can be seen that have extended into the calcified layer of cartilage. Around the circumference of each of these vessels, a thin layer of lamellar bone can be appreciated. By means of continuing endochondral ossification, the articular bone end is continuously modeled (H&E stain, Ã—10 objective).

Heterogeneity of articular cartilage, including morphological, biochemical, and biomechanical variations, can be observed within different regions of a normal weight-bearing joint. Considerable variation in cartilage thickness over an articular surface is present in most joints. A variation in stiffness in different areas of the femoral head has been related both to PG content and to the amount of water held by the tissue (30). The stiffness of the cartilage is the main factor that determines stress in the tissue and, together with the thickness of the cartilage, has the largest effect on the stress in the

calcified cartilage and underlying cancellous bone (31).

An example of the normal geographic variation in articular cartilage can be readily observed in the human tibial plateau, as well as in other animals, where there are distinct morphological differences between the articular cartilage that is covered by the meniscus and that which is not (32). These differences consist of a rough surface and soft matrix in the uncovered area as compared to the smooth, firm tissue that is covered by the meniscus. In adult human knee joints at autopsy, it has been found that articular cartilage that was not covered by meniscus (even as young as 17 years of age) always showed matrix softening and superficial fibrillation (33). The morphologic and biochemical findings in these two distinct articular areas as studied in the adult dog are summarized in Figure 5.21.

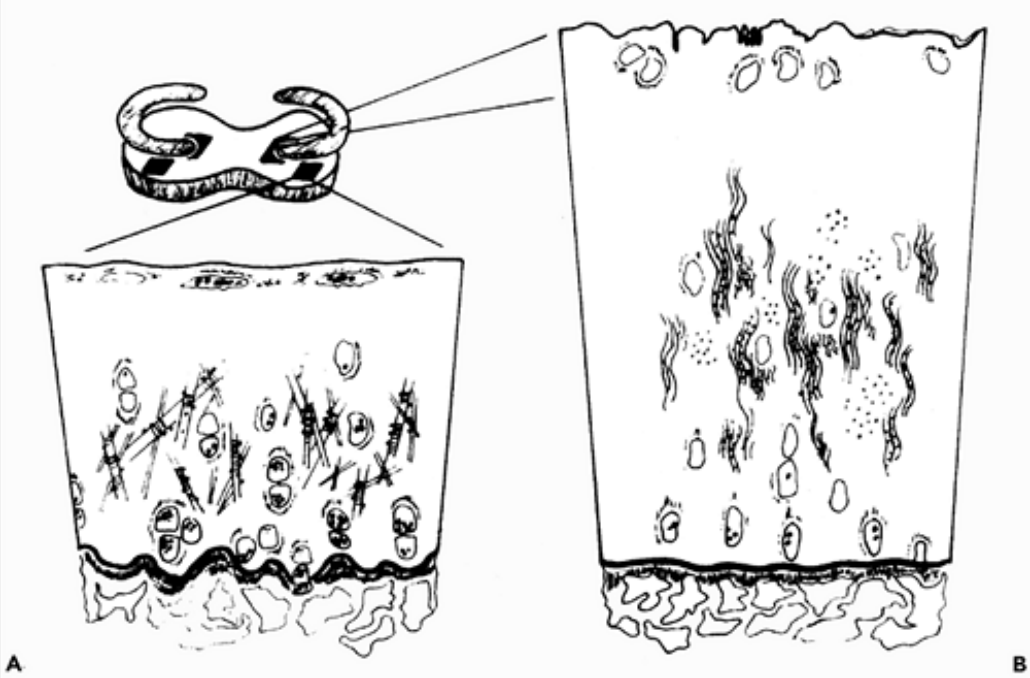

Figure 5.21 Morphological and chemical differences seen in the tibial articular cartilage under the meniscus, as compared with that not covered by the meniscus. A. In the covered area, the surface is smooth, and on the surface there is an amorphous

electron-dense layer; the chondrocytes are flattened. With respect to lipid, there is an increased intracellular accumulation in all three layers. Increased accumulation of extracellular lipid is noted at the surface, and there are increased numbers of extracellular matrix vesicles in the deep zone. In electron microscopy sections, collagen appears as randomly oriented fibers of varying diameter but with thicker mean diameter than seen in B; there is regular binding of proteoglycan to the collagen fibrils; and the concentration of proteoglycans per wet weight is increased. The tidemark is irregular. B. In the uncovered area, the surface is irregular, there is a detached electron-dense layer, and the chondrocytes are rounded. The concentration of water per unit volume is increased. Collagen appears in wavy aggregated bundles with thinner mean diameters that vary but little from each other, and binding of proteoglycan to the collagen fibrils is ill defined. Proteoglycan can be extracted more easily from the cartilage matrix. The tidemark is smooth. In both the covered and the uncovered areas, the cell size is the same histologically, and there is the same amount of DNA per dry weight of cartilage tissue. (Modified from:
Bullough PG, Yawitz PS, Tafra L, Boskey AL. Topographical variations in the morphology and biochemistry of adult canine tibial plateau articular cartilage. *J Orthop Res* 1985;3:1â€“16 with permission.)

It has been postulated that these naturally occurring variations in matrix structure and mechanical properties are related to joint loading. In the normally functioning knee, load is transmitted through the meniscus and onto the tibial cartilage underlying the meniscus, whereas the exposed cartilage, that which is not covered by the meniscus, remains relatively unloaded. Similar areas of possible disuse atrophy have been described around the rim of the

radial head, in

the roof of the acetabulum, and on the perifoveal and inferomedial aspects of the femoral head (34).

The extracellular matrix of the cartilage and of the other connective tissues is synthesized by their intrinsic cells under the control of both local and systemic factors. Both in vivo and in vitro studies have demonstrated that changes in the immediate environment of the joint lead to alterations of the cartilage matrix (35). Thus, immobilization or unloading of a joint results in decreased synthesis of glycosaminoglycans. Conversely, exercise appears to increase synthesis (36). These experimentally induced variations are in agreement with naturally observed topographic variations in joints that have been ascribed to normally occurring patterns of joint loading.

In general, it seems that low levels of mechanical stress (i.e., below the physiologic range) are associated with enhanced catabolic activity, whereas stress within the physiologic range is associated with more anabolic activity. Under conditions of supraphysiologic stress the chondrocytes are unable to adapt. In other words, there is a window of physiologic stress above or below which the chondrocytes cannot maintain an adequate functional matrix.

Although a number of factors have been implicated in the transduction of mechanical stimuli to metabolic events, the exact mechanism still remains unclear.

Histomorphogenesis of Articular Cartilage

Recent studies suggest that the histomorphogenesis of articular cartilage is regulated during skeletal development by the intermittent forces and motions acting at the site of diarthrodial joints. A key feature in this development is the formation of the superficial, transitional, radial, and zones through the cartilage thickness. The

histomorphological and mechanical characteristics of these zones have been correlated with the distribution of pressures, deformations, and pressure-induced fluid flow created in vivo (31). However, unlike muscle and bone, the thickness of articular cartilage does not appear to adapt to mechanical stimulation (38).

Synovial Membrane

The synovial membrane lines the inner surface of the joint capsule and all other intra-articular structures, with the exception of articular cartilage and the meniscus. In addition to lining the joints, synovial membrane lines (a) the subcutaneous and subtendinous sacs known as bursae, which permit freedom of movement over a limited range for the structures adjacent to the bursae, and (b) the sheaths that form around tendons wherever they pass under ligamentous bands or through osseofibrous tunnels.

Synovial membrane consists of two components. The first of these is the cellular lining (or intimal layer) bounding the joint space. This surface is smooth, moist, and glistening, with a few small villi and fringelike folds. The second component is a subintimal, supportive, or backing layer (39).

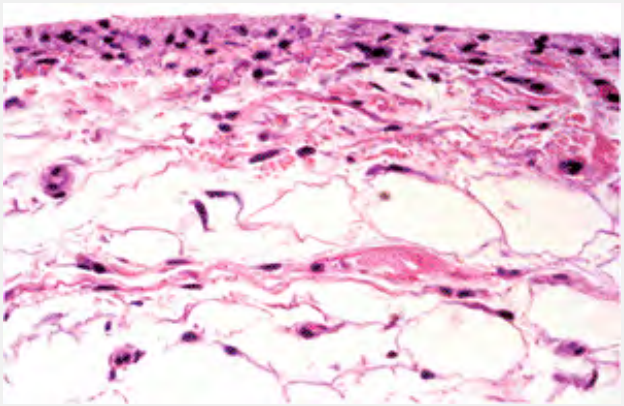

Figure 5.22 Photomicrograph of normal synovium. The ratio of

fat-to-fibrous tissue varies depending on the joint and the location within the joint (H&E, Ã—10 objective).

Along the edge facing the synovial cavity, microscopic examination of synovial membrane reveals a single row or sometimes multiple rows of closely packed cells with large elliptical nuclei (Figure 5.22). Beneath the surface layer in the subintima, there is vascularized fibro-adipose tissue that contains some histiocytes, and mast cells.

Electron microscopic studies reveal two principal types of synovial lining cells, designated by Barland as Types A and B. (Many cells have features of both types and have been called intermediate.) The less common cell (Type A) has many of the features of a macrophage, and there is good evidence that it is structurally adapted for phagocytic functions. The more common Type B cells are richly endowed with rough endoplasmic reticulum, contain Golgi systems, and often show pinocytotic vesicles. Normal synovial intima contains 25% Type A and 75% Type B cells (40).

The synovial membrane has three principal functions: secretion of synovial fluid hyaluronate (Type B cells); phagocytosis of waste material derived from the various components of the joint (Type A cells); and regulation of the movement of solutes, electrolytes, and proteins from the capillaries into the synovial fluid, thus providing for the metabolic requirement of the joint chondrocytes and possibly also providing a regulatory mechanism for maintenance of the matrix through the role of various mediators.

Ligaments and Tendons

Ligaments, which are structures that join together two adjacent bones, are formed mainly of collagen. The arrangement of the collagen bundles within a particular ligament depend on the required movements within the joint; and,

because these movements are complex, the arrangement of the collagen bundles is similarly complex.

The collagen fibers of the ligament are calcified where they enter the bone, and the calcified portion of the ligament interdigitates and locks onto the underlying bone in the same way as does the calcified cartilage (vide supra). Just adjacent to the calcified portion of the ligament, the extracellular matrix of the ligament will be found to contain some proteoglycan; and, in association with this finding, the cells will be found to be contained within lacunaelike chondrocytes (41). The reason for this is that generally tendons enter the bone at an acute angle; for this reason a shear force acts on the ligament at its insertion and the normal tension in the ligament is complicated by an added compressive force (Figure 5.23).

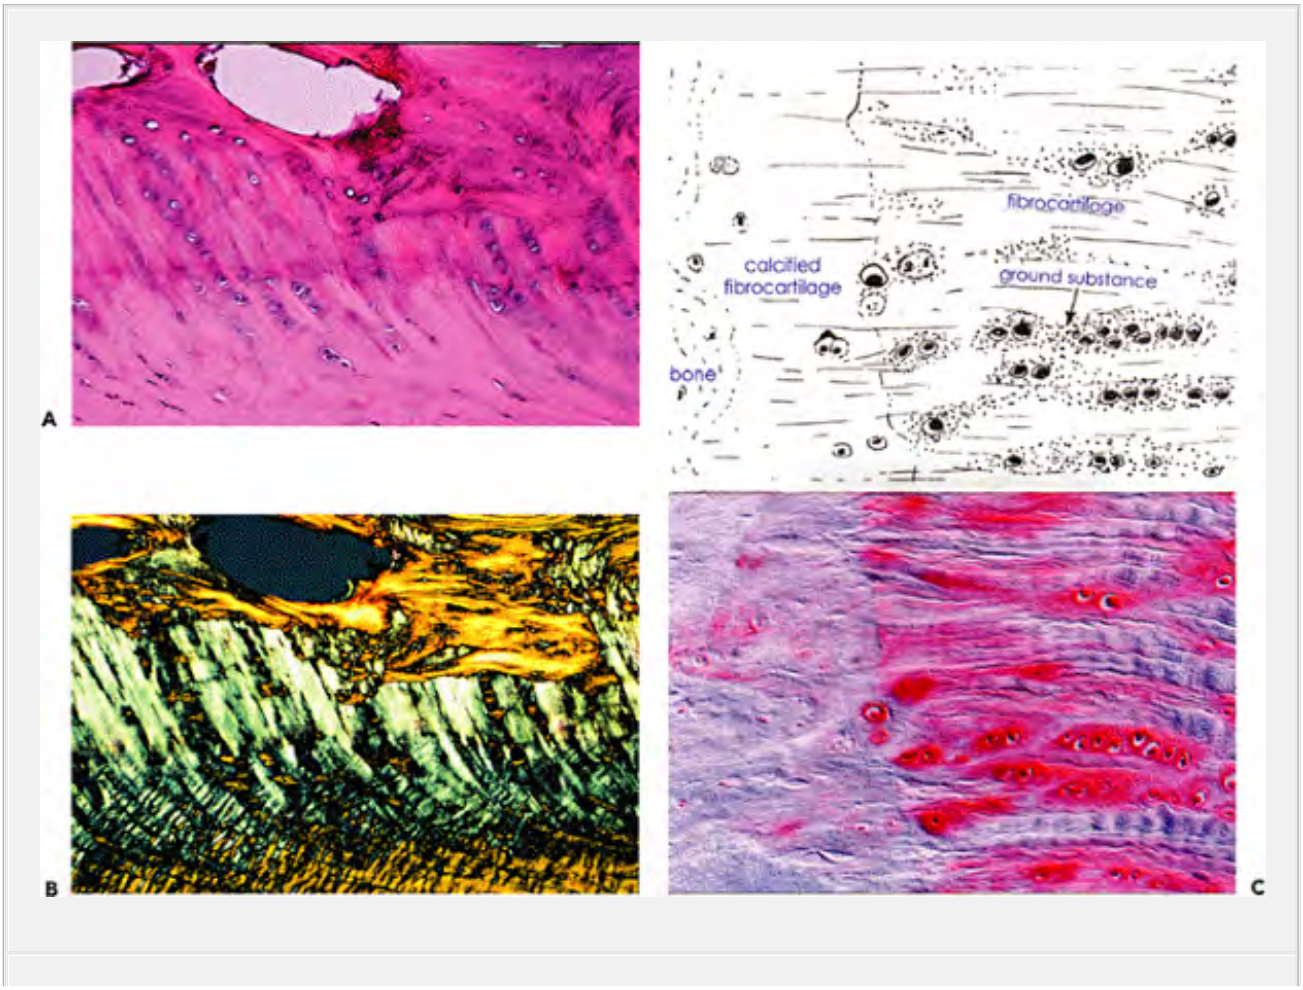

Figure 5.23 A. Photomicrograph of a ligamentous insertion using transmitted white light (H&E stain, Ã—10 objective). B. Polarized light. The portion of the ligament that interfaces with the bone is calcified, and the edge of the calcified portion of the ligament is marked by a basophilic line (tidemark) that represents the mineralization front. Note the similarity with the bone cartilage interface illustrated in Figure 5.17. C. A higher powered view to demonstrate the rounded cells lying in lacunae, which are seen at the insertion site of both ligaments and tendons (fibrocartilaginous metaplasia). The red staining in the matrix indicates the presence of proteoglycans (safranin O stain, Ã—25 objective).

Tendons are specialized connective tissue structures that enable muscles to concentrate or extend their action. The Achilles tendon is a good example of a tendon that concentrates the power of several bulky muscles to one limited area of insertion; the long tendons of the hands and feet exemplify the function of extending the effect of distant muscles. Many muscles have no obvious tendinous insertions; for example the paravertebral and the gluteal muscles have short fan shaped fibrous insertions, which hardly justify their description as tendons.

The majority of cells within normal tendons are relatively inactive fibrocytes scattered in a sparse longitudinal pattern between the collagen bundles (Figure 5.24). There is a slight gradient in the cell population, the proximal (muscular) portion of the tendon being more cellular than its distal

insertion. The surfaces of the flexor tendons of the hand which glide within a synovial sheath, are covered by a single layer of synovial cells (the endotenon) and a similar layer covers the parietal surface of the fibrous tendon sheath (the epitenon). In the palm of the hand the tendons are covered by a fine vascular adventitia (paratenon)

nourished by vessels from the deep palmar arch (42).

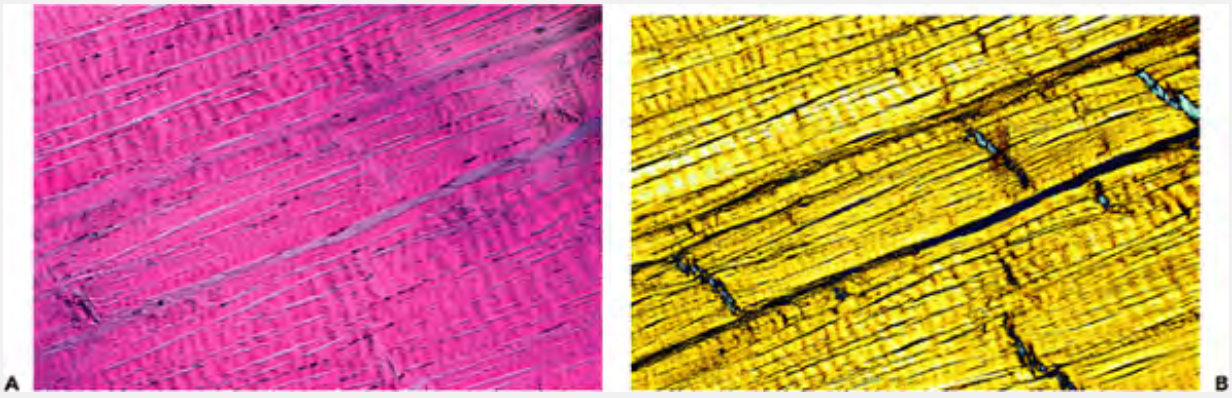

Figure 5.24 Photomicrograph of the same field of a tendon that has been photographed in transmitted light in A and in polarized light in B. Both images demonstrate the scant and elongated fibroblasts lying between the dense parallel collagen bundles characteristic of tendon (H&E stain, Ã—4 objective).

The feeding arteries to the tendons of the hands and feet, both the vessels in the vinculae, and the vessels in the palmar or plantar paratenon are long, coiled vessels that can stretch as the tendons move. (The flexor tendons may glide some 6 cm between full flexion and full extension.)

Human tendons are poorly innervated. Apart from the nerve fibers associated with blood vessels and the free nerve endings in the region of the vinculae, there are very few nerve endings in the tendon proper.

Wherever a tendon turns a corner, or has to bend in association with neighboring joints, it is restrained under a pulley, or retinacular system, and is lubricated in this region by means of a synovial sheath. Because of the compression that occurs in these locations, just as at the insertion of the tendon or ligament, there is some

cartilaginous metaplasia with the accumulation within the tissue of PGs that resist the compressive component of the load.

The Arthritic Joint

Clinical arthritis is the consequence of a breakdown in the joint's normal function; that is to say, it involves loss of capacity for the articulating surfaces to move over one another easily, loss of joint stability, and almost always pain.

The loss of freedom of motion may be the result of a change in joint shape that results in severe incongruities or, on the other hand, a change in the tissue matrices that affects their mechanical properties. Instability may result from alterations in ligamentous support and neuromuscular control. Pain may originate in the bone as a result of maldistribution of load; in the synovium as a result of reactive synovitis; or in the muscle as a consequence of reflex spasm.

Malfunction of a joint results from acute or chronic morbid conditions that produce either:

- Anatomic alterations in the shape of the articulating surfaces (e.g., a transarticular or subarticular fracture, increased modeling activity, Paget's disease, or acromegaly) (43).
- Loss of structural integrity of the cartilage tissue or of the support structures around the joint (e.g., by enzymatic destruction in inflammatory arthritis [septic or rheumatic arthritis] or, more commonly, traumatic injury).
- Alterations in the mechanical properties of the tissue matrices making up the joint (e.g., brittle collagen as occurs in ochronosis).

During the past century, several types of arthritis have been well delineated on the basis of their characteristic clinical presentations

and their morbid anatomy. These include the infectious arthritides, both granulomatous (TB) and pyogenic (septic); the metabolic arthritides (e.g., gout, pseudogout, and ochronosis); and the arthritis that complicates many cases of aseptic subchondral bone necrosis (44). The various â€œrheumatic syndromesâ€• have been classified according to their clinical and immunologic characteristics; histologically, these inflammatory arthritides show chronic synovitis and a destructive pattern involving the bone, cartilage, and periarticular structures. However, they are difficult to differentiate from each other solely by microscopic examination.

Even when these various etiologies have been considered, there remain a large number of cases of arthritis affecting

especially certain small joints of the hands and feet and some larger joints, of which the hip and knee are most commonly involved. These cases, which run a chronic course, are essentially noninflammatory and usually occur in older individuals. The clinical presentation and morbid anatomy in these cases are similar enough for all of them to be classified under the general appellation of *osteoarthritis* or *degenerative joint disease*. In the majority of cases, the etiology is unclear; however, the important role of mechanical trauma is not in dispute. The onset of osteoarthritis in middle age can often be traced in sport-related injuries in adolescence and young adulthood. Repetitive impact loading, such as occurs in running on hard surfaces with poorly designed shoes, is recognized as contributing to knee arthritis. A study designed to understand the relationship between impactor energy and mass on injury modalities in the canine knee has shown that injuries were typically more frequent and more severe with the largest mass at each energy level. Histologic analysis of the patellae revealed cartilage injuries at low energy, with deep injuries in the underlying bone at higher energies (45).

Alteration in Shape

A change in joint shape is characteristic of most forms of arthritis. In the inflammatory arthritides tissue loss results from destruction. On the other hand, although bone and cartilage loss play an important part in the osteoarthritic process, it is the addition of new bone and cartilage in the form of osteophytes, particularly at the joint periphery and sometimes beneath the articular surface, that forms one of the characteristic features of the disease.

We now recognize that a change in joint shapeâ€”either sudden, as with a fracture, or gradual, as in acromegaly or other metabolic disturbances such as Paget's diseaseâ€”may play an important role in the etiology of arthritis. In other words a change in the shape of the joint is an expected result of arthritis, but a change in shape may also be the cause of arthritis.

Tissue Response to Injury

Regardless of the etiology, joint injury is characterized by certain basic cellular and tissue responses.

- There is usually macroscopic and microscopic evidence of both degeneration and of repair in the cells and in the extracellular matrix. (In the extracellular matrix, the changes may result from direct physical injury, from alteration in the cellular synthesis of the matrix, or from enzymatic breakdown of the matrix constituents. These changes are probably most apparent in the surface cartilage (46).
- In the vascularized tissues, injury is followed by an acute and then by a chronic inflammatory response. As a result, the necrotic injured tissue is removed and replaced by proliferative vascular tissue (granulation tissue). The inflammatory response results in â€œrepairâ€• of injured tissue by fibrous scar. Independently of scarring, a second mode of repair involves regeneration of tissue similar to that which was injured originally. In nonvascularized tissue, such as cartilage, an

inflammatory response and subsequent scarring cannot occur, but this does not preclude tissue regeneration. Note that cartilage injury always eventually invokes an inflammatory response since some vascularized tissues (i.e., bone and/or synovium) are inevitably involved.

Cartilage

Macroscopic (naked eye) evidence of injury to cartilage is evident only in the extracellular matrix, mainly the collagenous component; one of the earliest findings is a disruption of the collagen fibers at the surface, which, instead of being smooth, becomes rough and/or eroded (47). The local stresses and strains in the collagen fibrils, which cause the damage, cannot be determined dependably without taking the local arcadelike collagen-fibril structure into account (21). Three patterns of macroscopic alteration involving the cartilage surface and, to a variable degree, the underlying cartilage tissue can be identified: fibrillation (generally age related), erosion (ulceration), and cracking (probably trauma related) (48).

The term *fibrillation* is used to describe replacement of the normally smooth, shiny surface by a surface similar to cut velvet. This type of transformation can be observed both on very thick cartilage, such as the patella, and on very thin cartilage, such as that found in the interphalangeal joints. The â€œpileâ€• of the fibrillated area may be short or shaggy. The junction between the fibrillated area and the adjacent normal appearing cartilage is morphologically usually well defined and generally distinct (Figure 5.25). A recent study has concluded that both microscopic magnetic resonance imaging and polarized light microscopy can detect quantitative changes in collagen fiber architecture in early osteoarthritis and also resolve topographical variation in cartilage microstructure of canine tibial plateau (49).

In this regard, continuing collaborative studies of morphology,

including imaging studies, biochemistry, and biomechanics, are urgently needed.

For the morphologist, there appear to be two patterns of fibrillation. Well-defined areas of fibrillation affecting particular locations in certain joints are present in everyone from an early age (35). It is suggested by this author that these areas may be related to underloading of the cartilage. In osteoarthritic joints, there are areas of fibrillation that appear in different areas of the joint than those previously mentioned and that appear to be secondary to mechanical abrasion of the cartilage surface. The microscopic

characterization of these two distinct types of fibrillation is incomplete, but perhaps the latter is distinguished by deeper clefts and a greater tendency for the chondrocytes to form proliferating clones.

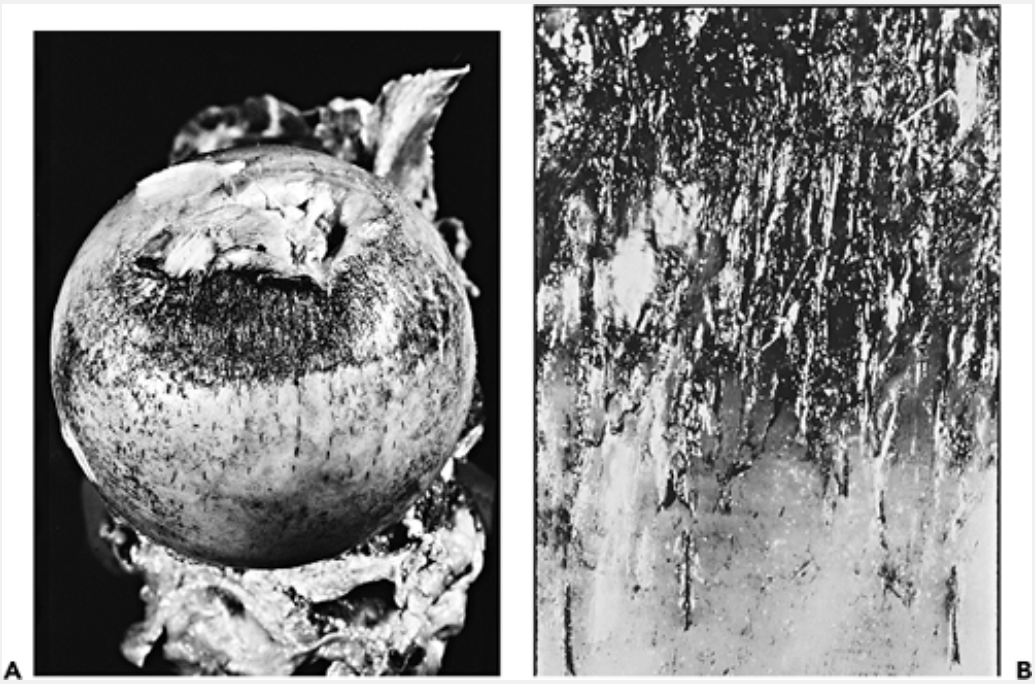

Figure 5.25 A. Photograph to demonstrate superficial fibrillation of the cartilage on the femoral head in the perifoveal region. The

fibrillated cartilage has been highlighted by India ink. B. In a close up photograph, pin splits in the cartilage seem to follow the orientation of the collagen fibers in the fibrillated area.

Cartilage ulceration, or solution of the surface, is characteristic of progressive degenerative changes in the joint. The base of the erosion appears initially to be either contoured or smooth. Tissue damage may eventually be so extensive as to completely denude the bone surface of its covering cartilage layer (eburnation).

The last form of structural lesion in this group, which is distinctly less common than either fibrillation or ulceration, is deep cracking of the cartilage. These cracks extend vertically deep into the cartilage and microscopically often have a deep horizontal component. Perhaps these result from severe impact loading (Figure 5.26).

In considering the pathogenesis of these three histologic types of cartilage matrix damage in the early stages of osteoarthritis, it is important to recognize that they may affect the opposed articular surfaces in different areas and to different degrees. This is in marked contrast to eburnation, in which both of the opposed surfaces are affected. It therefore appears that in many cases fibrillation and other cartilage alteration cannot be ascribed simply to abrasion.

An increase in the ratio of water to PG in the cartilage matrix leads to softening of the cartilage (chondromalacia), and this may be evidence of insufficient loading of the joint. Chondromalacia and fibrillation usually occur together, but chondromalacia may be present before there is any obvious gross evidence of fibrillation.

Injury at a cellular level is recognizable only microscopically. Necrosis can be identified when only the ghost outlines of the chondrocytes remain. This ghosting, usually scattered but focal in distribution, is a common finding in arthritis. Less often, all of the chondrocytes are seen to be necrotic (Figure 5.27).

Just as the effect of injury to the articular cartilage is reflected by the histologic response of both matrix and cells,

so too is the subsequent reparative cartilage regeneration. Within the preexisting cartilage matrix, there is focal cell proliferation with clumps, or clones, of chondrocytes. When the tissue is stained with toluidine blue, there is often intense metachromasia of the matrix around these clumps of proliferating chondrocytes, evidence of increased PG synthesis. This process can be thought of as â€œintrinsicâ€• repair (50) (Figure 5.28).

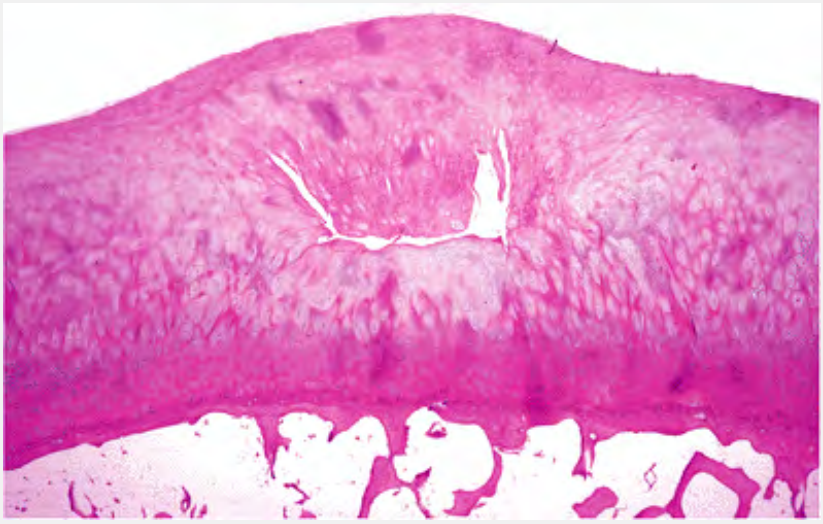

Figure 5.26 Photomicrograph demonstrating deep cracking of the cartilage matrix. The lesion shown is characteristic of a blisterlike lesion, which is seen in many cases of chondromalacia patellae (H&E stain, Ã—4 objective).

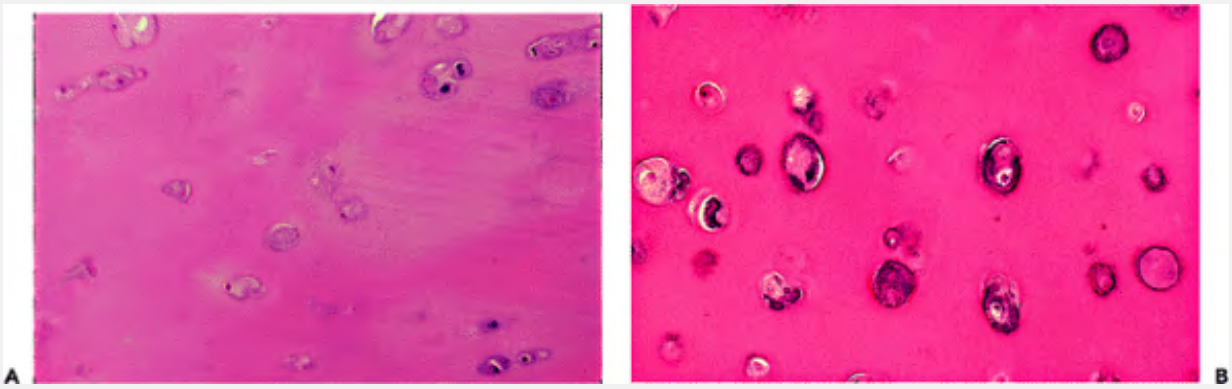

Figure 5.27 A. A photomicrograph to demonstrate focal chondrocyte necrosis. In cases of degenerative arthritis, focal areas of necrosis (such as seen here) are common. Rarely, the necrosis is extensive. In inflammatory arthritis, chondrocyte necrosis is also common and often associated with an irregular lysis of the matrix around the necrotic cells, the so-called Weichselbaum's lacunae (H&E stain, Ã—10 objective). B. Photomicrograph to demonstrate focal calcification around necrotic chondrocytes in the deep zone of the cartilage (H&E stain, Ã—25 objective).

In a damaged joint, cartilage repair may also be initiated from either or both of two possible sites, either the joint margin or the subchondral bone. Extrinsic repair of cartilage, which develops from the joint margin, can be seen as a cellular layer of cartilage extending over, and sometimes dissecting into, the existing cartilage. This extrinsically repaired cartilage is usually much more cellular than the preexisting articular cartilage, and the chondrocytes are evenly distributed throughout the matrix (Figure 5.29).

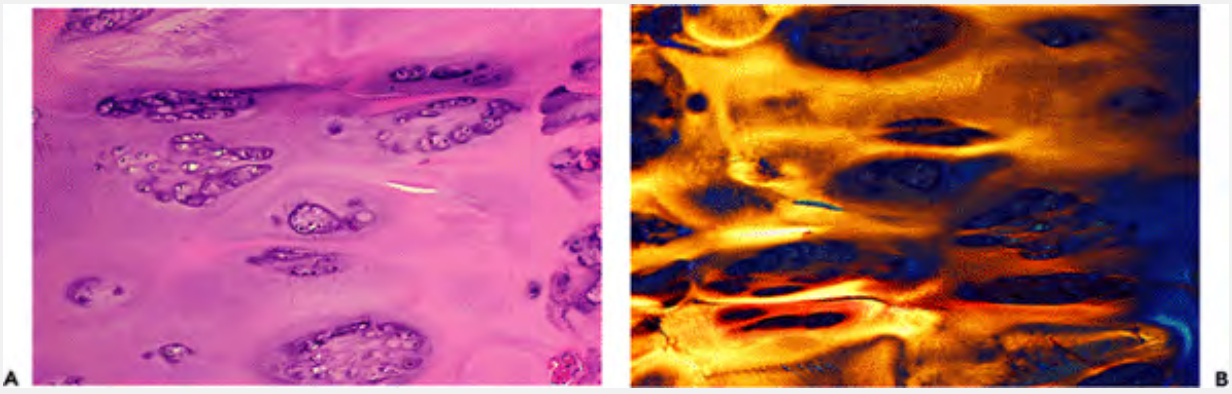

Figure 5.28 A. Photomicrograph to demonstrate clones of regenerating chondrocytes. Note the basophilia around the clones, which correspond to increased proteoglycan synthesis by the cells (H&E stain, Ã—10 objective). B. When examined by polarized light, the proliferating clones are visibly displacing the existing collagen matrix.

On microscopic examination this type of repair cartilage can easily be overlooked. However, examination under polarized light will clearly demonstrate the discontinuity between the collagen network of the repair cartilage and that of the preexisting cartilage (Figure 5.30), as well as the denser thicker collagen fibers of the repair cartilage.

In arthritic joints in which loss of the articular cartilage has denuded the underlying bone, especially in cases of osteoarthritis, there are frequently small pits in the bone surface from which protrude small nodules of firm white

tissue. On microscopic examination, these nodules have the appearance of fibrocartilage arising in the marrow spaces of the subchondral bone. They may extend over the previously denuded surface to form a more or less continuous layer of repair tissue. Most

specimens obtained from cases of osteoarthritis reveal both intrinsic and extrinsic repair of cartilage (51).

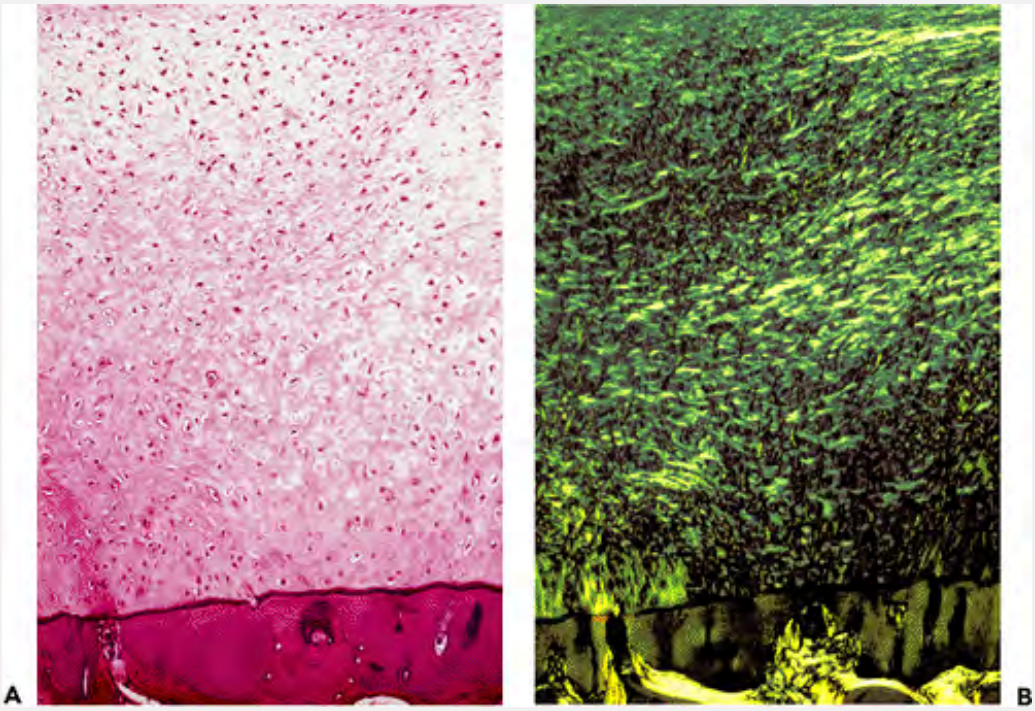

Figure 5.29 A. A section through the articular surface of an arthritic joint demonstrates extrinsic reparative fibrocartilage, which extends to the tidemark of the original articular hyaline cartilage (H&E stain, Ã—10 objective). B. The same field photographed with polarized light shows the discontinuity of the collagen between the calcified zone and the reparative cartilage.

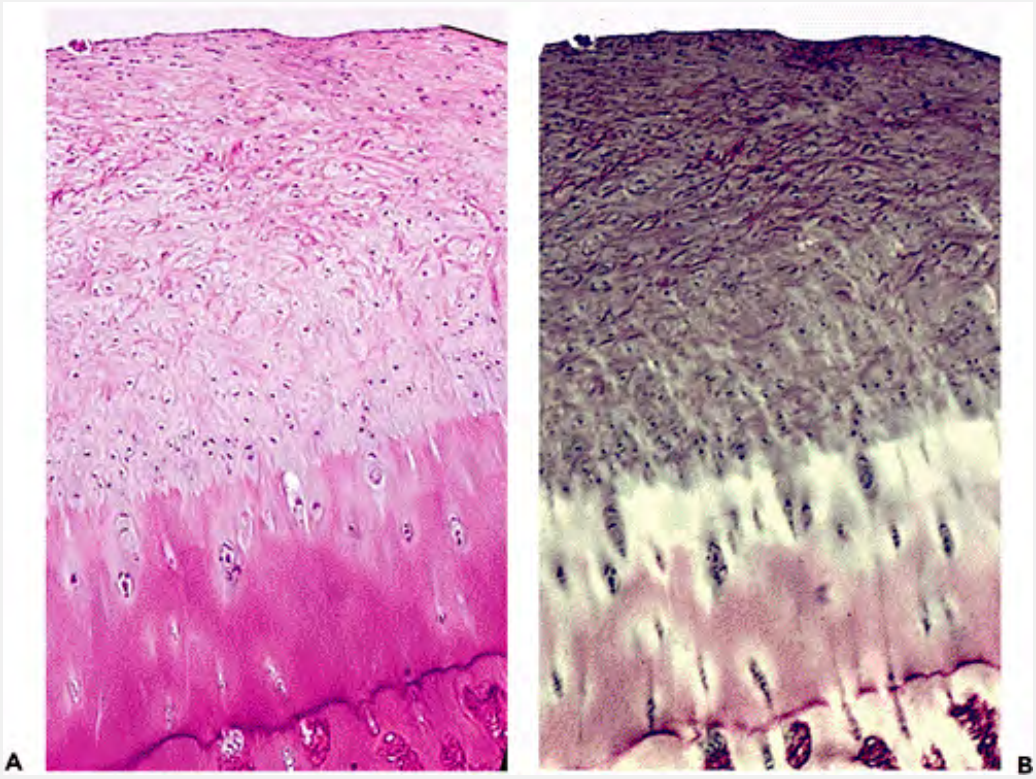

Figure 5.30 A. Photomicrograph showing reparative cartilage extending over preexisting damaged cartilage (H&E stain, Ã—4 objective). B. Same field photographed with polarized light.

Bone

Arthritis is a disease that affects not only the articular cartilage, but also the underlying bone and the structures around the joint.

As the articular cartilage is eroded from the surface, the underlying bone is subjected to increasingly localized overloading. In subarticular bone that has been denuded, there is proliferation of osteoblasts and formation of new bone, which occurs both on the surfaces of existing intact trabeculae and around microfractures (52) (Figure 5.31). In x-rays of arthritic joints, this new bone appears as

increased density or sclerosis.

A further result of increased local stress is that the bone at the articulating surface is likely to undergo focal pressure necrosis (Figure 5.32). (This superficial necrosis is different both in its etiology and pathogenesis from that associated with â€œprimaryâ€• subchondral infarction, which itself leads to secondary osteoarthritis. However, in clinical practice, differentiation between the two may be difficult, especially in the late stages of primary subchondral infarction.) (53)

Subarticular cysts are usually seen only where the overlying cartilage is absent. Such cysts are common in cases of osteoarthritis and are believed to result from transmission of intra-articular pressure through defects in the articulating bony surface into the marrow spaces of the subchondral bone (54). The cysts increase in size until the pressure within them is equal to the intra-articular pressure.

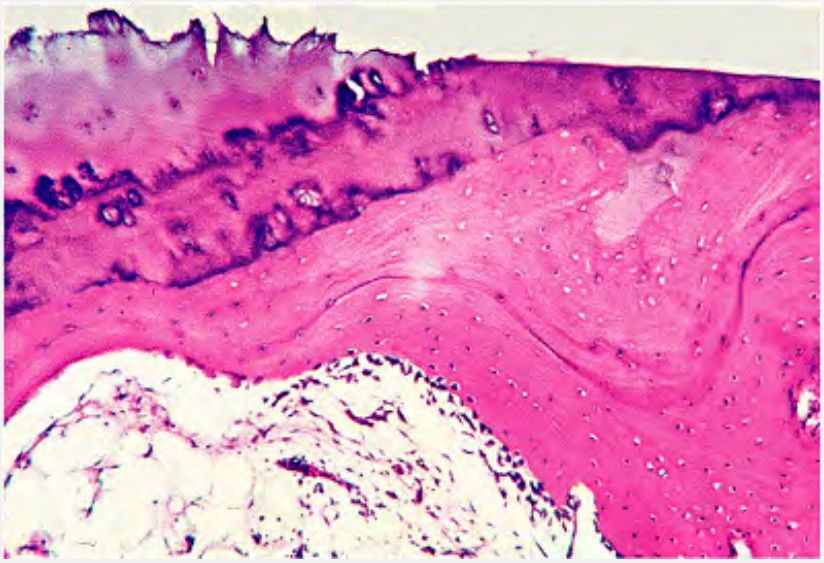

Figure 5.31 Photomicrograph of the edge of an eburnated area of bone in a case of osteoarthritis. There is a very prominent layer of osteoblasts covering the sclerotic bone that underlies the area denuded of cartilage (H&E stain, Ã—4 objective).

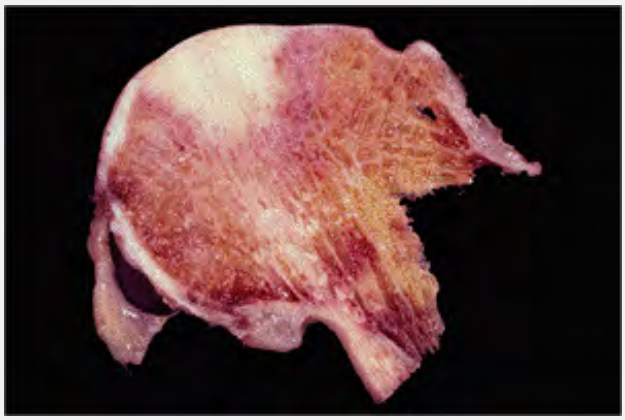

Figure 5.32 A section through an osteoarthritic femoral head shows a large wedge shaped area of necrosis of the superior portion of the head.

Cysts may also occur because of focal tissue necrosis (55). (In cases of arthritis due to rheumatoid disease or gout, periarticular radiologic â€œcystsâ€• may be associated with erosion of the marginal subchondral bone by the diseased synovium.)

Separated fragments of bone and cartilage from a damaged joint surface may become incorporated into the synovial membrane and digested, or they may remain free as loose bodies in the joint cavity. Under certain circumstances, proliferation of cartilage cells occurs on the surface of these loose bodies and consequently they grow larger (Figure 5.33). As they grow, their centers become necrotic and calcified. In histologic sections it is possible to visualize periodic extension of this central calcification in the form of concentric rings, which increase in number as the loose body grows larger. Sometimes the loose bodies reattach to the synovial membrane at a later stage, in which case they are invaded by blood vessels. Endochondral ossification then occurs, and the loose bodies again develop a viable

bony core.

There is some degree of loose body formation in many cases of arthritis, but they are especially prominent in Charcot's joints and in other types of rapidly destructive osteoarthritis. Occasionally, in cases of osteoarthritis, the loose bodies are so numerous that they must be distinguished from those that occur in primary synovial chondromatosis (56).

Ligaments

Microscopic evidence both of lacerations and of repair by scar tissue is common in the ligamentous and capsular tissue around an arthritic joint. These changes are readily recognized by the use of polarized microscopy, where the

alterations in the organization of the collagen are made very clear (Figure 5.34). Whether these lacerations preceded the arthritic process or whether they are a consequence of it cannot usually be determined by microscopic examination.

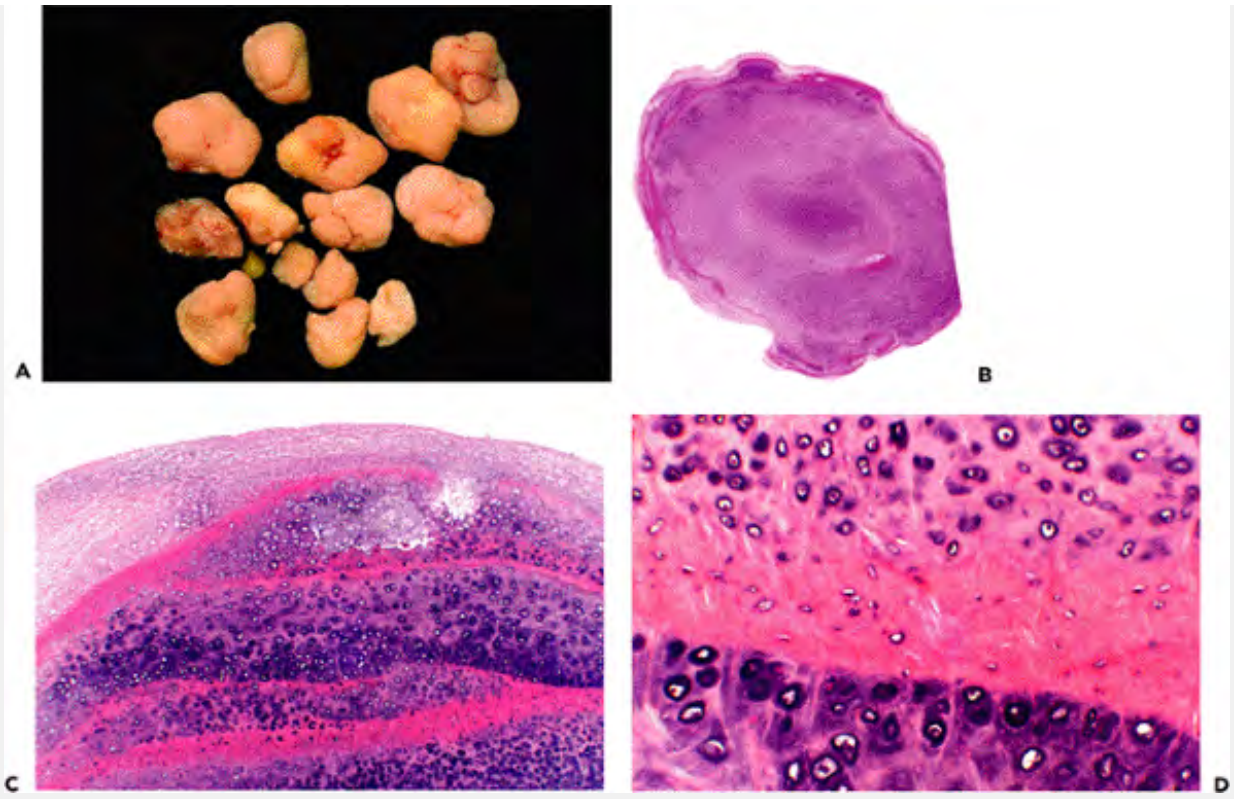

Figure 5.33 A. Gross photograph of multiple loose bodies in a case of osteoarthritis of the hip joint. B. Low-power photograph of a cross section of a loose body showing concentric growth rings (H&E stain, Ã—1 objective). C. Photomicrograph showing crowded proliferating chondrocytes and a growth ring (H&E stain, Ã—4 objective). D. Photomicrograph to show benign proliferating chondrocytes (H&E stain, Ã—25 objective).

Synovial Membrane

Injury and breakdown of cartilage and bone result in increased amounts of breakdown product and particulate debris within the joint cavity. This is removed from the synovial fluid by phagocytic cells (the Type A cells) of the synovial membrane. In consequence, the membrane becomes both hypertrophic and hyperplastic, and the

breakdown products of the cartilage and bone matrix frequently evoke an inflammatory response (Figure 5.35).

For this reason, some degree of chronic inflammation can be expected in the synovial membrane of arthritic joints, even when the injury has been purely a mechanical one. Inflammation is especially prominent where there has been rapid breakdown of the articular components as evidenced by the presence in the synovium of bone and cartilage detritus.

Histologic studies have shown that there may be a similarity between the degree of inflammatory response as seen in some cases of severe osteoarthritis and that of rheumatoid arthritis (57). However, in osteoarthritis the synovial inflammation is likely to be the result of cartilage breakdown, whereas in rheumatoid arthritis the synovial inflammation is the cause of cartilage breakdown.

Extension of the hyperplastic synovium onto the articular surface of the joint (i.e., a pannus) is a common finding even in osteoarthritis, particularly in the hip (Figure 5.36). However, the extent and the aggressiveness of this pannus with respect to underlying cartilage destruction is much less marked in osteoarthritis than in rheumatoid arthritis.

Since, under normal conditions, the synovial membrane is responsible for the nutrition of articular cartilage, it might be expected that the chronically inflamed and scarred synovial membrane of an arthritic joint would function less effectively than that of a normal joint. Disturbance in synovial nutrient function, as well as increased enzymatic

activity, may very well contribute to the chronicity of the arthritic process.

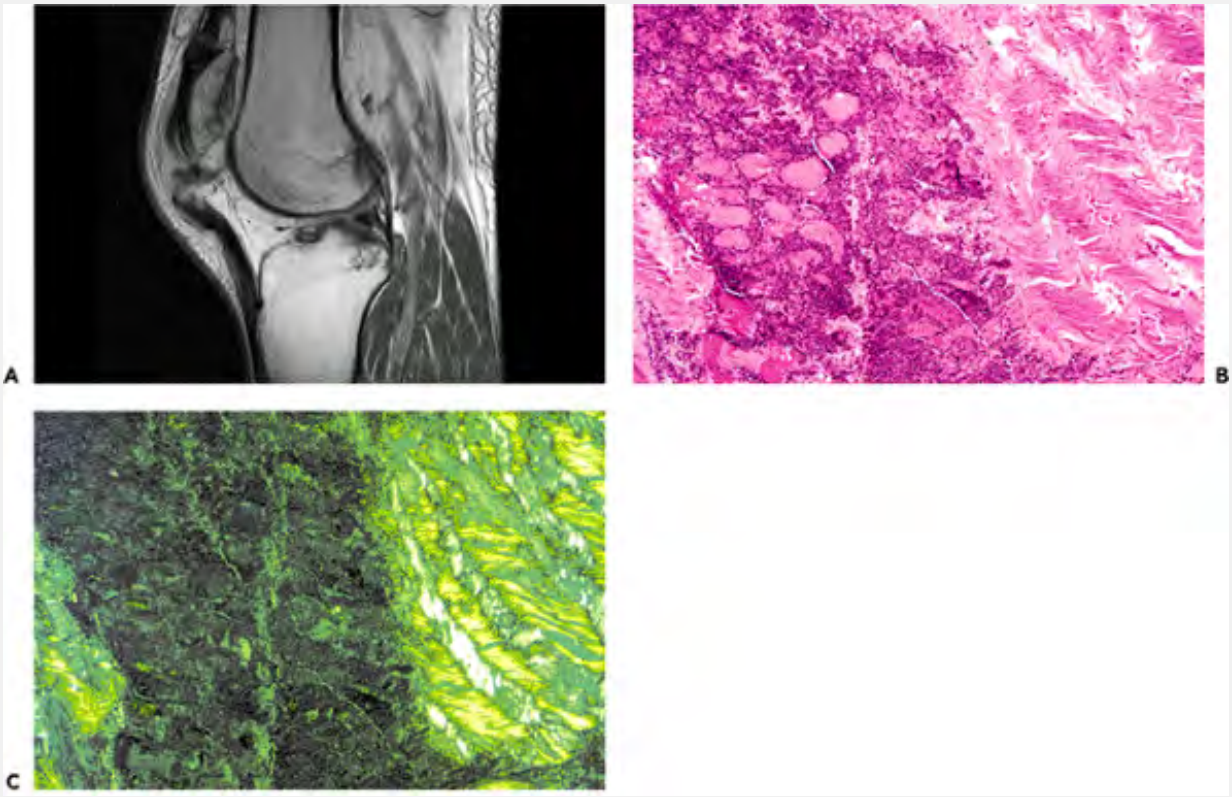

Figure 5.34 A. A magnetic resonance image of a knee shows rupture of the patellar ligament. B. Photomicrograph to demonstrate an area in a ligament where a laceration has occurred. The well-oriented collagen of the lacerated ligament is clearly demarcated from the resultant defect, which can be seen to have been filled with a vascularized cellular fibrous scar tissue (H&E stain, Ã—10 objective). C. Same field photographed with polarized light.

The hypertrophied and hyperplastic synovium associated with arthritis is also likely to be traumatized as it extends into the joint cavity. Evidence of bleeding into the joint, with subsequent hemosiderin staining of the synovial membrane, is a common histologic finding and may occasionally be marked. When this is the case, and despite their similar color, the orange-brown staining of

the fine villous synovium seen at operation should not be confused with the swollen papillary synovium of pigmented villonodular synovitis.

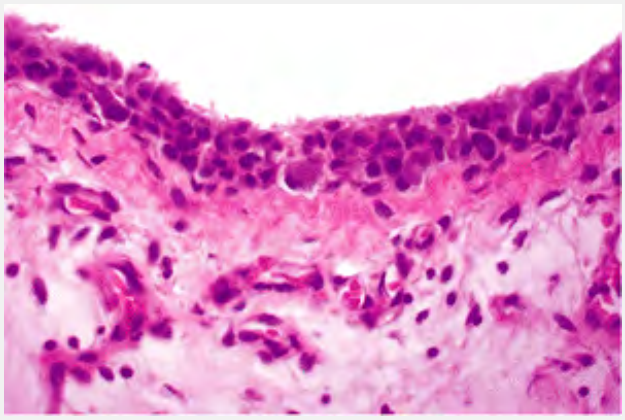

Figure 5.35 Photomicrograph of the synovium removed from the joint of a patient with a moderate degree of osteoarthritis reveals not only a hypertrophy of the synovial lining cells, but also hyperplasia that has resulted in a piling up of the synoviocytes. In the subsynovial tissue, there is increased vascularity and a mild chronic inflammatory infiltrate (H&E stain, Ã—25 objective).

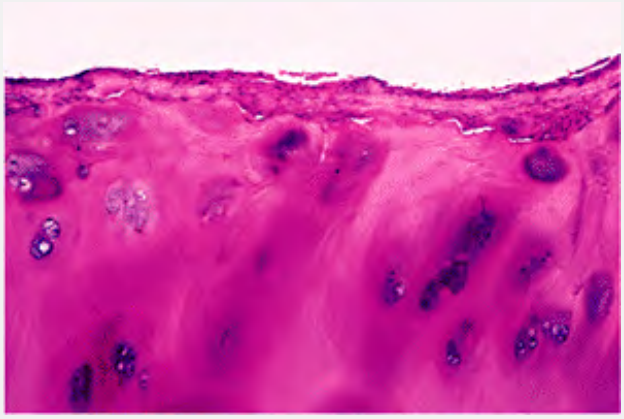

Figure 5.36 Photomicrograph of a portion of the articular surface of a femoral head in a case of osteoarthritis. A fibrous pannus extends over the articular surface (H&E stain, Ã—10 objective).

Synovial Fluid

Examination of synovial fluid is extremely helpful in the diagnosis of arthritis, both for determining the cause and the stage of the disease. Whatever the cause of arthritis, the synovial fluid is altered.

Normal synovial fluid, a dialysate of plasma to which hyaluronic acid produced by the Type B cells of the synovial lining is added, is viscous, pale yellow, and clear. Even in large joints the volume is small.

In cases of inflammatory arthritis, there is an increased volume of synovial fluid with a high count of inflammatory cells. The amount of hyaluronic acid is markedly diminished, leading to a typical decrease in viscosity. On the other hand, in degenerate forms of arthritis the amount of hyaluronic acid is increased, resulting in an extremely viscous fluid. There is also an increase in volume, although not to the

same degree as that which is seen in the inflammatory arthritides.

Discovery of the Myofibroblast

The myofibroblast was discovered in 1971 in electron micrographs from contracting (healing) experimental granulation tissue (1). Soon thereafter, its biochemical, pharmacologic, and immunohistochemical features were delineated (2,3,4,5). Since these early days, the list of pathologic conditions in which this cell has been identified has grown considerably (6,7,8). Looking back, it is somewhat surprising that such a pivotal element of diverse fundamental processes had not been defined earlier (9).

The road to discovery stems from interest in the process of wound healing as traced from the time of fossils to the ancient world (10). Indeed, the fate of civilizations rested on the ability of people to recover from wounds inflicted through battle or disease. Nearly a century ago, Carrel and Hartmann hypothesized that contractile forces were present in granulating wounds (11). For years it was believed, even taught, that collagen was the element essential for

wound contraction. Dogma changed (slowly) with two reports in the mid-1950s. In one, experiments established that wound contraction was normal in guinea pigs rendered scorbutic (12). In the other, fibroblasts, under appropriate conditions, could be induced to contract in vitro (13). These findings cast doubt on the contractility of collagen and suggested that cells were central to tissue contraction.

In 1969, Majno and colleagues performed seminal experiments that established that histamine caused postcapillary venular interendothelial gaps that brought about vascular leakage (14). In electron micrographs, such endothelial cells were shrunken, distorted, and with notched nuclei. On this basis, they reasoned that gap formation might be produced by active endothelial contraction (14). This suggestion, made before the establishment of the concept that nonmuscle cells contain contractile proteins, was not easily accepted; in turn, it stimulated work based on the possibility that endothelial and other mesenchymal cells could exert contractile activities.

A few years later, the ultrastructural observation was made that the cytoplasm of granulation tissue fibroblasts was loaded with bundles and aggregates of microfilaments (1), a feature typical of smooth muscle cells. On this basis, the possibility that these modified fibroblastic cells were responsible for granulation tissue contraction was relatively

easy to suggest (1); however, acceptance took some time (15). Further experiments, employing pharmacologic agents known to effect cellular contraction/relaxation, established that granulating wounds indeed contained contractile cells, and the term *myofibroblast* was proposed (2). Subsequently, myofibroblasts were found to be capable of being decorated by human smooth muscle antibodies (4); these were then shown to be specifically directed against actin (5). Shortly thereafter, myofibroblasts were identified within nodules of Dupuytren's disease (16) and in human granulation

tissue (17) and shown to transmit their contractile forces from cell to cell through intermediate (adherens) junctions and from cell to stroma by means of microtendons, the whole being synchronized by intercellular gap junctions (18). The microtendon, an apparatus connecting myofibroblasts to the surrounding extracellular matrix, was named *fibronexus* (19).

In the late 1970s, Tremblay (20) described the presence of myofibroblasts in the stroma of invasive mammary carcinomas. The neoplasms in which these myofibroblasts had been noted were firm and retracted, unassociated with an inflammatory infiltrate. Because myofibroblasts are normally not present in mammary stroma, it was suggested that they contributed to the retraction phenomena and desmoplasia, which characterized these neoplasms (20). It was then reasoned that such contractile cells might be contained in diverse carcinomas characterized by retraction and desmoplasia. Accordingly, a series of invasive and metastatic carcinomas was examined ultrastructurally. Myofibroblasts were present in the stroma of each tumor and were particularly numerous in those that were hard, sclerotic, and retracted (21). Within several years, the spatial distribution of such cells within invasive and metastatic carcinomas was described (22,23), and it was proposed that similarities between the process of wound healing and the stromal response to neoplastic invasion might exist (22).

In the following years detailed studies of intermediate filament proteins and actin isoforms of myofibroblasts in various settings and conditions were performed; this led to the finding that myofibroblasts from diverse pathologic settings were heterogeneous in their content of intermediate filaments and actin isoforms (24,25). The presence of Î±-smooth muscle actin, the actin isoform characteristic of vascular smooth muscle cells, was suggested as the marker of the myofibroblastic phenotype (25). In these works, it was shown that there is a correlation between the phenotypic modulation of myofibroblasts and the clinical behavior of lesions containing these cells. In particular, it was shown that myofibroblasts in granulation

tissue of normally healing wounds express Î±-smooth muscle actin only temporarily (25), whereas myofibroblasts with a smooth muscle phenotype persist in hypertrophic scars, fibrocontractive diseases, quasi-neoplastic proliferative conditions, and within the stroma of certain neoplasms (24,26).

More recently, it was shown that transforming growth factor Î²1 (TGF-Î²1) is the most important stimulator of myofibroblastic differentiation (27,28), as well as of collagen production by this cell (29). For TGF-Î²1 to be active, the ED-A splice variant of cellular fibronectin must be present in the extracellular matrix (30). This provided the first hint of the mechanisms controlling the modulation of the myofibroblastic phenotype. It was also shown that myofibroblasts undergo apoptosis during the transition between granulation tissue and scar tissue (31). The possibility that myofibroblasts could arise from such specialized mesenchymal cells as hepatic perisinusoidal stellate cells (32), mesangial (33) and renal tubular cells (34), and mesothelial cells (35) was demonstrated. Quite unexpectedly, the hematogenous origin of myofibroblasts in several human and experimental pathologic settings was recently established (36,37).

In 2005, some 34 years after the initial discovery and four decades after the quest began, the myofibroblast is recognized as a central element in normal and abnormal wound healing, in diverse reactive proliferative conditions, and within the stroma of certain invasive and metastatic neoplasms.

The sections that follow more fully characterize the myofibroblast, describe the settings in which it is found, and relate recent studies that provide further insight into the biology of this unique cell.

Characterization of the Myofibroblast

Ultrastructural

As initially described in granulation tissue and nodules of Dupuytren's disease (1,16), myofibroblasts share morphologic features in common with fibroblasts and smooth muscle cells.

Fibroblasts of adult animals and humans display a slender fusiform and smooth, contoured nucleus, a well-developed Golgi area, numerous and often dilated cisternae of rough endoplasmic reticulum, scattered mitochondria, and small numbers of microfilaments, the latter sometimes arranged in discrete bundles beneath the plasma membrane. Cell contours are generally smooth or display a few short cytoplasmic extensions. Plasmalemmal attachment plaques, dense patches or dense bands (38,39), basal lamina, pinocytotic vesicles, intercellular junctions, and cell-to-stroma attachment sites are absent.

Smooth muscle cells are enveloped by a continuous basal lamina. Their plasma membrane is studded with plasmalemmal attachment plaques or so-called membrane-associated dense bodies, dense plaques, dense patches or dense bands (39), and numerous pinocytotic vesicles. Intercellular gap junctions and adherens junctions are present (40).

The cytoplasm is laden with bundles of microfilaments, usually disposed parallel to the long axis of the cell, among which numerous dense bodies are interspersed. The material of the dense bodies appears similar to the one forming the dense bands, which are attached to the cell membrane in certain vascular smooth muscle cells. Some dense bodies are in continuity with dense bands. Dense bodies and dense bands probably correspond to Z-lines of striated muscle fibers. In both structures, Î±-actinin has been demonstrated by immunohistochemical techniques (41,42). Force transmission from the contractile apparatus to the cell membrane in smooth muscle cells occurs via the insertion of bundles of actin filaments into the dense bands (38). Transmission of the contractile force occurs also across cell membranes of smooth muscle cells and from cell membranes to the stroma. Although it seems clear that the traction

generated by the myofilaments is transmitted to the dense bands, the exact mechanism of the transmission of the traction across the cell membrane is not fully understood. The fibronectin receptor as a transmembrane receptor glycoprotein complex (43,44,45,46) has extracellular binding sites for fibronectin (47), suggesting specific interactions between cytoplasmic actin filaments and extracellular fibronectin fibers across the plasma membrane at cell-to-matrix attachment sites. A close association between bundles of cytoplasmic actin filaments (stress fibers) and bundles of extracellular fibronectin fibrils has been observed in transformed fibroblasts and in myofibroblasts of granulation tissue in vivo; this structure, designated fibronexus, is specialized for enhanced cell-to-matrix connections (48,49). Contractile forces from cell to cell are transmitted through adherens or intermediate junctions, which are symmetrical structures formed by two complementary dense bands that match each other in adjacent smooth muscle cells (38). Their nuclei are elongated with blunt ends and are deformed by shallow invaginations. In contrast to fibroblasts, the Golgi area and the rough endoplasmic reticulum are poorly developed.

Myofibroblasts (Figure 6.1 Aâ€“E) disclose irregular, often stellate, cellular outlines with numerous and long cytoplasmic extensions and are connected by intermediate or adherens junctions (Figure 6.1D) (50) and by gap junctions (Figure 6.1E), the latter considered as low-resistance pathways for intercellular communications (18). In addition, myofibroblasts are partly enveloped by a basal lamina and display plasmalemmal attachment plaques, dense patches or dense bands, and pinocytotic vesicles (Figure 6.1C). They are also connected by microtendons to the extracellular matrix by cell-to-stroma attachment sites through the fibronexus, a transmembrane complex of intracellular microfilament bundles in apparent continuity with extracellular fibronectin fibers (Figure 6.1B) (19,49). At the surface of myofibroblasts, three types of fibronexus are observed: (a) plaquelike; (b) tracklike; and (c) tandem associations (49). These cell-to-stroma attachment sites are well-developed and numerous in

myofibroblasts compared with their attenuated appearance in smooth muscle cells. Myofibroblasts contain numerous bundles of cytoplasmic microfilaments (stress fibers), usually arranged parallel to the long axis of the cell and among which are interspersed numerous dense bodies (Figure 6.1A). As in vascular smooth muscle cells, these structures may be in continuity with dense bands or plasmalemmal attachment plaques. Rough endoplasmic reticulum and Golgi area are well developed. The nucleus displays deep indentations (Figure 6.1A), an ultrastructural feature that has been correlated with cellular contraction in several systems (51,52,53,54). Several nuclear bodies are usually present, and nucleoli are conspicuous. Myofibroblasts generally are surrounded by substantial amounts of extracellular matrix.

A precise definition of the myofibroblast is an issue of major importance for the surgical pathologist. In our opinion, a myofibroblast can only be defined by ultrastructure, since immunohistochemical studies reveal that myofibroblasts have a heterogeneous and complex pattern of protein expression. The three essential ultrastructural elements that define a myofibroblast are: (a) stress fibers (i.e., bundles of micro- (myo-) filaments with interspersed dense bodies running parallel to the long axis of the cell, commonly located beneath the cell membrane); (b) well-developed cell-to-stroma attachment sites (fibronexus); and (c) intercellular intermediate and gap junctions (55,56). This definition has now been accepted by several major textbooks (57,58,59) in regard to the issue of myofibroblasts in tumor pathology. We do not deny that the light and immunohistochemical microscopic differences between smooth muscle cells and myofibroblasts may be subtle, especially when considering degrees of differentiation of smooth muscle and myofibroblastic proliferations. Nonetheless, the myofibroblast is defined as a highly differentiated cell by ultrastructure alone.

Histologic

Although morphologically defined with the electron microscope, myofibroblasts disclose several typical histologic traits that permit their presumptive recognition in routine paraffin or (even better) in plastic sections in settings in which they previously were identified by ultrastructure. The cells are usually large, spindle-shaped, and often stellate (spiderlike) with several long cytoplasmic extensions, and they possess distinct acidophilic to amphophilic and fibrillar cytoplasm with cablelike condensations (stress fibers) running through the subplasmalemmal cytoplasm parallel to the long axis. The nuclei often are indented or reveal strangulations of nuclear segments, a feature thought to reflect cellular contraction, and contain finely granular, regularly dispersed chromatin and conspicuous nucleoli (Figure 6.2). Well-differentiated myofibroblasts with the previously mentioned traits are observed in poorly-collagenized and edematous areas of various settings in which they were

originally described; for example, in granulation tissue, in zones of early invasive carcinomas, in invasive and metastatic carcinomas characterized by retraction and desmoplasia, and in several other proliferative conditions. In heavily collagenized zones, myofibroblasts are difficult to recognize with the light microscope since they correspond ultrastructurally to poorly-developed myofibroblasts or fibroblasts.

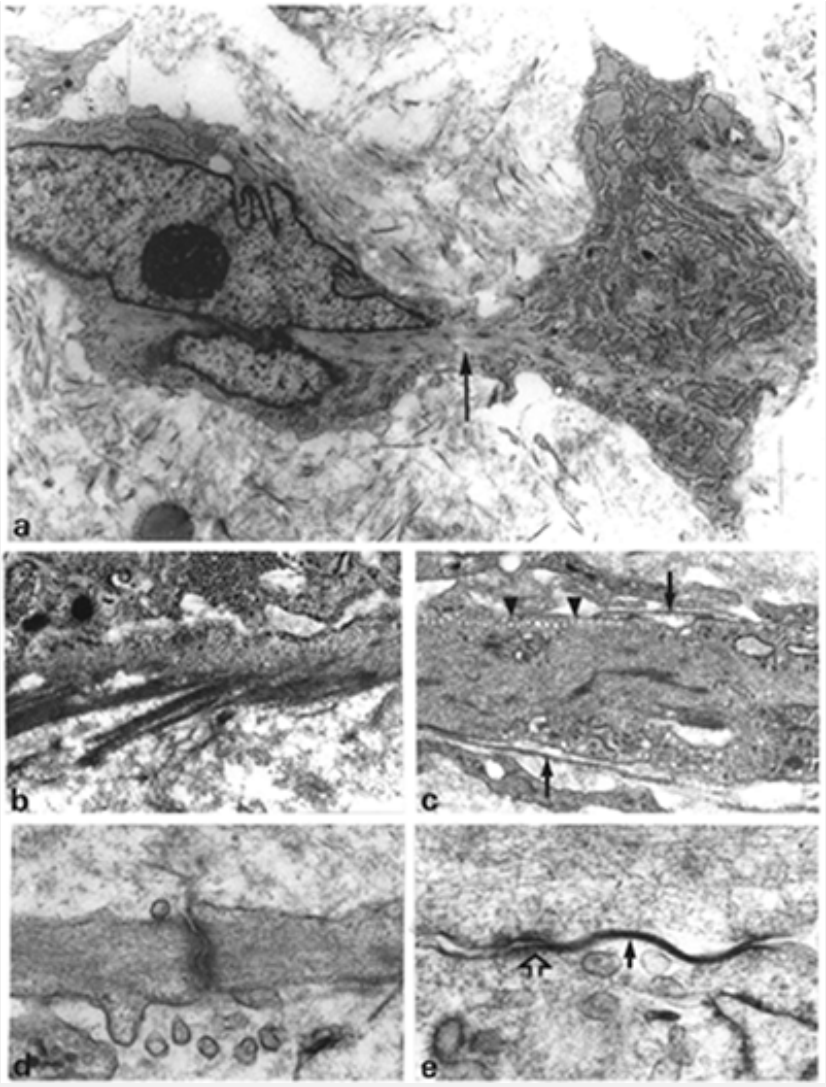

Figure 6.1 Ultrastructural characterization of the myofibroblast. A. Typical myofibroblast with irregular shape and cytoplasmic extensions, well-developed rough endoplasmic reticulum, and bundle of cytoplasmic microfilaments (*arrow*) with numerous dense bodies running through the cytoplasm (stress fibers) giving rise to â€œstrangulationâ€• of a nuclear segment. ) (Uranyl acetate and lead citrate; A, Ã—9900; B, Ã—25,000; C, Ã—18,200; D, Ã—39,000; E, Ã—78,000.)

It is possible that in the near future myofibroblasts might be clearly recognized and defined by immunohistochemical examination of the complex stress fiberâ€“associated cell-to-matrix junctions, using multiple labeling techniques and employing confocal laser microscopy on paraffin sections (for illustrations see Figure 6.3 and 6.4).

Immunohistochemical

For a better understanding and appreciation of the various cytoskeletal phenotypes of myofibroblasts, a detailed description of cytoskeletal proteins of muscular tissues, particularly smooth muscle cells, is presented.

Specific cytoskeletal proteins have been defined during the differentiation of muscular tissues (60,61,62,63). These proteins have served as reliable markers of cellular adaptation to physiologic and pathologic conditions (64).

Desmin is a muscle differentiation marker that appears early in embryogenesis (65,66). This intermediate filament, however, does not permit one to distinguish between different muscle types (67).

stromal cells of several organs, which traditionally were considered fibroblastic in nature (68). When smooth muscle cells are cultured, desmin disappears (69). Smooth muscle myosin is a precise marker of smooth muscle differentiation. This contractile protein, however, disappears rapidly from smooth muscle cells in several conditions in vivo and also early in culture (69,70). These findings suggest that smooth muscle myosin is a more reliable marker of smooth muscle differentiation than smooth muscle origin. Vascular smooth muscle cells are heterogeneous with respect to intermediate filament proteins. Most contain vimentin as their sole detectable intermediate filament; a lesser proportion also expresses desmin (71,72,73,74,75). Parenchymal smooth muscle cells of the respiratory, gastrointestinal, and genitourinary tracts represent a homogeneous population in which desmin is almost the exclusive intermediate filament protein (76,77,78).

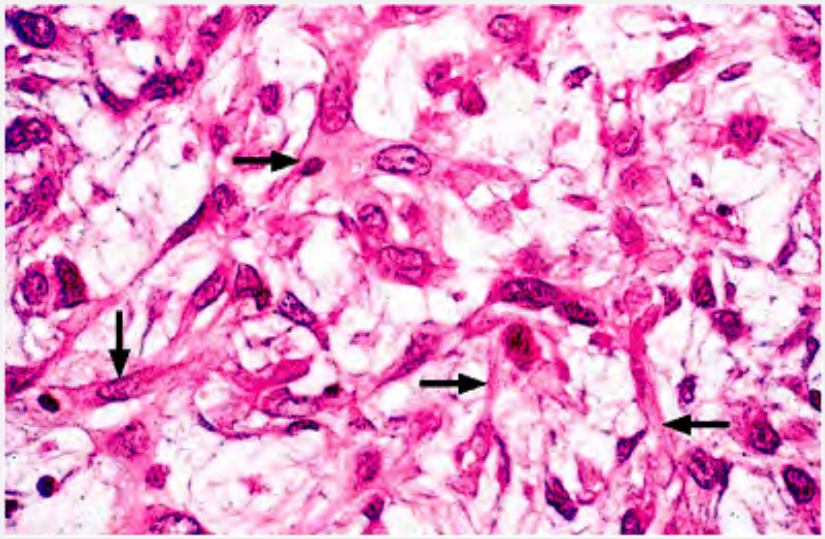

Figure 6.2 Histological aspect of myofibroblasts from the exudativo-productive layer of human granulation tissue, approximately 15 days old. Myofibroblasts disclose stellate,

spiderlike shapes with long cytoplasmic extensions and distinct fibrillar cytoplasm with cablelike (*arrows*) subplasmalemmal condensations (stress fibers) (hematoxylin-phloxine-saffron).

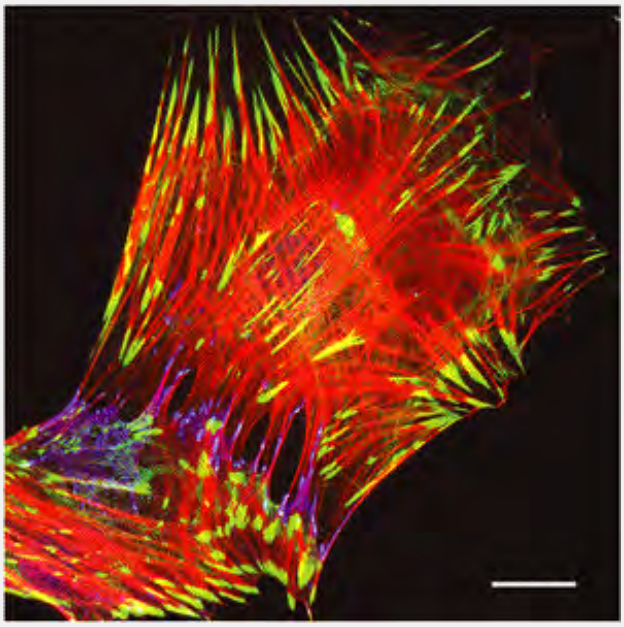

Figure 6.3 Stress fiberâ€“associated cell-to-matrix and cell-to-cell junctions in cultured myofibroblasts. Rat lung myofibroblasts were cultured on planar glass substrates and immunostained for Î±-smooth muscle actin (red) as a component of contractile stress fibers, paxillin (green) as a component of cell-matrix focal adhesions, and Î²-catenin (blue) as a marker for cell-cell adherens junctions. Myofibroblasts form large, â€œsupermatureâ€• focal adhesions with the extracellular matrix and adherens junctions with adjacent cells; both structures are located at the terminal portion of Î±-smooth muscle actinâ€“positive stress fibers. (Bar, 20 Âµm.)

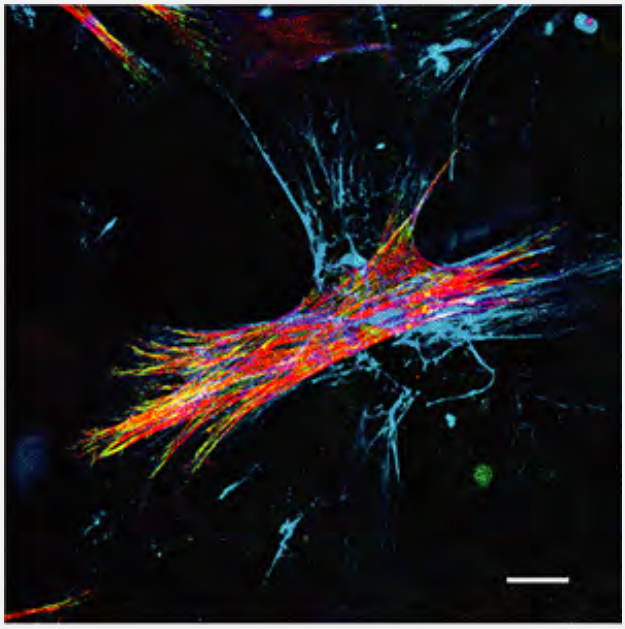

Figure 6.4 Fibronexus organization in myofibroblasts placed in three-dimensional collagen gels. Rat lung myofibroblasts were cultured in restrained collagen gels and immunostained for Î±-smooth muscle actin (red) in stress fibers, vinculin (green) in cell-matrix adhesions, and ED-A fibronectin (blue) in the extracellular matrix. The image has been reconstructed from the overlay of 10 optical sections of 0.2 Âµm acquired with a laser scanning confocal microscope; yellow color indicates colocalization of Î±-smooth muscle actin and vinculin; white shows colocalization of both proteins with ED-A fibronectin. Note that extracellular fibronectin fibrils are co-orientated with intracellular stress fibers; they also penetrate in the surrounding extracellular matrix in the continuation of stress fibers. This organization corresponds to the fibronexus originally described by means of electron microscopy. (Bar, 20 Âµm.)

With regard to actin expression, at least six isoforms are defined in mammals (79,80,81): two nonmuscle actins (Î² and Î³), two smooth

muscle actins (Î± and Î³) and two sarcomeric actins (Î±-cardiac and Î±-skeletal). The emergence of distinct muscle and cytoplasmic actin isoforms is phylogenetically ancestral, dating before chordates (82,83). The nonmuscle actins, the so-called cytoplasmic actins, are considered the archetypes (80) because of their presence in all nonmuscle cells, including eukaryotic unicellular organisms. According to amino acid patterns, Î±-skeletal actin represents the most

differentiated isoform (80). At the protein level, Î±-skeletal actin is most closely related to Î±-cardiac actin, whereas Î±-smooth-muscle actin is more closely related to the cytoplasmic actins. Some years ago it was suggested that both Î±-cardiac and Î±-smooth muscle actin represent embryonic or fetal actin isoforms, as they are expressed during skeletal myogenesis (60). Two-dimensional gel electrophoresis resolves only three isoforms: Î² and Î³ (nonmuscle and muscle actins) and the Î±-actins (smooth, striated skeletal, and striated cardiac). The biochemical identification of the six actin isoforms requires chemical analysis of the amino-terminal tryptic peptide in cellular extracts. The six actin isoforms may also be determined by RNA extraction and Northern blot hybridization using specific probes (84) and, more recently, with specific antibodies for the six actin isoforms (85). Vascular smooth muscle cells are characterized by a predominance of the Î±-smooth muscle actin isoform. In contrast, parenchymal smooth muscle cells contain large amounts of the Î³-smooth muscle actin isoform (79,80,81,86). The pattern of Î±-, Î²- and Î³-actin isoform expression varies in smooth muscle tissues of adult mammals (86). This pattern varies also during nonneoplastic pathologic conditions, such as atheromatosis (87,88), but changes only slightly in uterine leiomyomas, compared with normal myometrium (86). During the early months of life, 50% of cells in the aortic media lack Î±-smooth muscle actin, whereas Î±-smooth muscle actinâ€“negative cells constitute less than 1% in the adult. These findings demonstrate that, at least in arteries,

differentiation of smooth muscle cells is completed after birth (67). These observations collectively suggest that the pattern of Î±-actin isoform expression and, particularly, the expression of Î±-smooth muscle actin in vascular smooth muscle cells are related to the degree of smooth muscle differentiation.

Pericytes resemble vascular smooth muscle cells (89). In a meticulously executed treatise published in 1923, Zimmermann showed that pre- and postcapillary pericytes are connected to vascular smooth muscle cells (90). In 1991, an elegant study showed that pre- and postcapillary pericytes indeed expressed Î±-smooth muscle actin, whereas the midcapillary pericytes fail to express this actin isoform (91). Pericytes were also shown to resemble vascular smooth muscle cells by their intermediate filament expression. Both cell types express vimentin or vimentin and desmin (92). In addition, the intermediate filament composition of pericytes discloses species and tissue differences similar to those observed in vascular smooth muscle cells (71,72,73,74).

Myofibroblasts in normal tissue, granulation tissue, and pathologic tissues disclose five cytoskeletal phenotypes: phenotype V, represented by cells expressing only vimentin; phenotype VA, represented by cells expressing vimentin and Î±-smooth muscle actin; phenotype VAD, represented by cells expressing vimentin, Î±-smooth muscle actin, and desmin; phenotype VD, represented by cells expressing vimentin and desmin; and phenotype VA (D) M, representing myofibroblasts expressing vimentin, Î±-smooth muscle actin, and smooth muscle myosin heavy chains, with and without desmin. The five phenotypes are readily defined in frozen and paraffin sections using immunohistochemistry, employing single, double, or triple staining techniques. Myofibroblasts of the various immunophenotypes may also express the Î²-and Î³-cytoplasmic actins, although it is more common that they express Î±-smooth muscle actin. This has led to the misconception that, for a cell to be classified as a myofibroblast, it must express Î±-smooth muscle actin. This is not true, as cells other than myofibroblasts express Î±-

smooth muscle actin. There are situations in which cells have the ultrastructural characteristics of myofibroblasts (e.g., stress fibers) but do not express Î±-smooth muscle actin; for example, interstitial cells in alveolar septa and the early phase of granulation tissue (93,94). (For illustration see below.) Considering these data, it is apparent that the distinction between smooth muscle cells and myofibroblasts remains complex at the immunohistochemical level and that no single immunophenotype is distinctive for myofibroblasts.

Biochemical

Myofibroblasts possess not only contractile forces, but also synthetic properties. Four major groups of macromolecules comprise the extracellular matrix: (a) collagens; (b) glycoproteins (e.g., fibronectins, laminins, tenascin); (c) proteoglycans (e.g., aggrecan, synchrons, perlecan, decorin); and, (d) elastins with their associated proteins (95). Myofibroblasts possess synthetic properties for several extracellular matrix components: collagens type I, III, IV and V (29,96,97,98), glycoproteins (99), and proteoglycans such as fibronectin, laminin, and tenascin (100). In addition, liver myofibroblasts in the murine schistosomiasis model secrete lysyl oxidase, an enzyme that initiates the first step in the cross-linking of collagen and elastin, a crucial function for the stabilization of the extracellular matrix (101,102).

Concerning collagen synthesis in granulating wounds, the collagen initially produced is type III. This form of collagen imparts a measure of plasticity to the wound in the early phase of healing. When granulation tissue is resorbed following wound closure, myofibroblasts disappear through the process of apoptosis (see below) and the more rigid type I collagen is biochemically identified (97,98). In similar fashion, the proliferative cellular phase of palmar fibromatosis and the young edematous mesenchyme of areas corresponding to early stromal invasion of breast carcinomas, both

rich in myofibroblasts, contain increased amounts of type III collagen (26,103,104). Increased amounts of type V collagen are biochemically identified in desmoplastic human breast carcinomas, apparently also produced by myofibroblasts (98).

Pharmacologic

Strips of granulation tissue exposed in vitro to a variety of pharmacological agents contract and relax in a manner analogous to smooth muscle. Prostaglandin F_1, bradykinin, serotonin, endothelin-1, histamine, angiotensin, norepinephrine, epinephrine and vasopressin initiate contraction. The intensity of the response depends on the origin, age, and initial degree of contraction of the granulation tissue tested. Prostaglandins E_1 and E_2 and papaverine induce relaxation in tissues in a contracted state (2,3,17). Cytocholasin B abolishes the contraction of granulation tissue, probably as the result of microfilament disruption (105). Trocinate (Î²-diethylaminoethylphenylthioacetate), another inhibitor of smooth muscle contraction, has been reported to decrease contraction when applied topically on rabbit wounds (106).

Strips of cirrhotic liver, when exposed to smooth muscle stimulating agents, contract significantly when compared with strips of normal liver (107). Pronounced myofibroblastic interstitial fibrosis is also produced in lungs of bleomycin-injected rats. When strips of these fibrotic lungs are exposed to acetylcholine, epinephrine, and a K^+-depolarizing solution, the force developed is approximately twice that of normal lung tissue strips (108). The relative reactivity to various stimulating agents of myofibroblasts from diverse sources varies; thus, acetylcholine causes contraction of strips of fibrotic lungs but not of granulation tissue from a skin wound or a granuloma pouch, and serotonin induces retraction of the granuloma pouch but not strips from a skin wound (3). In addition to this heterogeneity in the pharmacological reactivity of granulation tissue strips from various

sources, there are also differences between the response of strips of granulation tissue and strips of smooth muscle; the former reach their peak contraction slower but maintain it longer than the latter.

Whereas the various enumerated agents were shown to reveal their activity on granulation tissue in vitro, the exact mechanism leading to myofibroblast contraction in vivo remains to be elucidated. In this context, it is noteworthy that when hepatic stellate cells are subjected to in vivo ischemia reperfusion injury, they exhibit a de novo temporary increase of Î±-smooth muscle actin expression. A similar phenomenon takes place during the initial phases of liver transplantation in humans (109). Likely, this represents a response to ischemic injury.

Endothelin-1 was originally isolated from the conditioned medium of cultured porcine endothelial cells and was shown to be the most potent vasopressor substance yet characterized (110). Endothelin-1 may be an endogenous modulator of myofibroblast-mediated contraction because it causes reversible and concentration-dependent contraction of granuloma pouch granulation tissue, the 21-day granulation tissue being the most responsive. This response can be inhibited by calcium antagonists (111,112). The vasopressor effect of endothelin-1 possibly is controlled and mediated through the action of cytokines, among others, TGF-Î² (113,114), which, in turn, is able to induce Î±-smooth muscle actin expression in fibroblasts and myofibroblasts. More recently it has been shown that the intracellular administration of the N-terminal peptide of Î±-smooth muscle actin, the actin isoform responsible for myofibroblast contraction (see below), decreases force generation by myofibroblasts in vitro and inhibits wound contraction in vivo (115); this may represent a useful tool for the control of tissue retraction and remodeling during several pathological situations.

In Vitro Culture Studies

When myofibroblasts from various sources (granulating wounds,

Dupuytren's disease, and invasive breast cancer) are cultured, they maintain to a certain extent their unique resemblance to fibroblasts and smooth muscle cells. Cultured fibroblasts may express different phenotypic features, and a spectrum of differentiation steps has been described (116). In particular, primary passaged fibroblastic cells in culture express Î±-smooth muscle actin (68,79,117). Cytoskeletal proteins such as desmin and smooth muscle myosin heavy chains are also variably expressed by cultured fibroblasts derived from different organs or pathologic tissues, but expression is generally low and absent in several populations (118). Myofibroblasts cultured from skin wound granulation tissue maintain some biologic features different from those of dermal fibroblasts (119). If the growth rate and the actin concentration of cultured fibroblasts from normal dermis and myofibroblasts of human granulation tissue are compared, myofibroblasts grow slower than fibroblasts (120) and contain a significantly higher concentration of actin (121). Wound-healing fibroblasts were shown to develop greater contractile properties than dermal fibroblasts (122). Similarly, fibroblastic cells cultured from Dupuytren's nodules maintain biologic features different from those of normal dermis or fascial fibroblasts yet are similar to those of neoplastic or embryonic fibroblasts (123). However, it is important to state that the percentage of cells exhibiting myofibroblast features in culture does not necessarily reflect their proportion in the tissue of origin. When fibroblast cultures from various species, including man, were established using cloning and subcloning techniques, a certain percentage of cells was positive for Î±-smooth muscle actin (118). This concept of fibroblast heterogeneity is now well-established in vitro (124) and in vivo [see review by Schmitt-GrÃ¤ff et al. (8)]. Alpha-smooth muscle actin is expressed by fibroblasts cultured from the lens of the eye, mammary gland, perisinusoidal cells of the liver, and glomerular mesangial cells, sites where stromal cells normally expressing this protein do not occur (125,126,127,128) but which may give rise to reactive stromal cells expressing

Î±-smooth muscle actin in pathologic conditions. It is likely that Î±-smooth muscle actin expression in cultured fibroblasts stems from the culture conditions imposed upon the fibroblasts. Fibroblastic modulation to a myofibroblast phenotype in vitro may thus reflect a cellular response to their altered biochemical and mechanical environment, somewhat analogous to that which occurs in wounds.

Myofibroblast Development: A Two-Stage Model

Fibroblasts cultured on planar culture dishes rapidly attach to the wall of the container and move across its surface; adherence and mobility are attributed to the de novo development of a system of microfilament bundles called stress fibers (129). These may measure up to 2 Âµm in diameter and connect to the extracellular matrix at sites of focal adhesions (130) and to adjacent cells at sites of adherens junctions (50) (Figure 6.3). Initially, stress fibers are mainly composed of cytoplasmic actins, as shown by immunofluorescence and immunoelectron microscopy with specific antibodies (131,132,133). Several studies have shown that stress fibers also contain actin-associated proteins such as myosin, tropomyosin, Î±-actinin, and filamin (7). The formation of stress fibers and cell-matrix adhesions is in sharp contrast to the cortical arrangement of actin in fibroblasts in most normal connective tissues and represents the first step in the development of the myofibroblast phenotype. The term *protomyofibroblast* was recently proposed for fibroblasts with contractile stress fibers that do not (yet) express Î±-smooth muscle actin (134).

Development of the protomyofibroblast is predominantly controlled by the mechanical properties of the extracellular matrix [for reviews see (134,135)] and requires the permanent feedback between intracellular and extracellular tension. Stress fiber formation in fibroblasts on rigid glass or plastic surfaces is increased after

contractile activity stimulation and is lost upon application of inhibitors of contraction (136). In contrast, fibroblasts grown on compliant substrates fail to develop protomyofibroblastic features even in the presence of contraction agonists (137). When embedded in a three-dimensional gel of newly polymerized collagen, fibroblasts acquire a dendritic morphology similar to that in normal dermis (138); they extend and retract long processes, possibly to explore and organize the new environment (139). In free-floating collagen gels the forces developed by such processes lead to collagen gel condensation (139). However, since collagen fibers are free to move, overall matrix stress does not develop, and fibroblasts maintain their dendritic appearance (139). In contrast, collagen reorganization in restrained gels produces matrix stiffening and increases global stress, inducing alignment of fibroblasts along the lines of tension and the formation of stress fibers (134,139) (Figure 6.4). Similarly, after stress-release of restrained collagen gels, protomyofibroblasts rapidly loose stress fibers and matrix contacts (140). Importantly, fibroblasts are capable of adjusting their contractile activity according to the external load; controlled stress-release of collagen gels in a culture increases fibroblast contractile activity, whereas gel stretching leads to fibroblast relaxation, a phenomenon that has been termed *tensional homeostasis* (141).

A similar mechanism of protomyofibroblast development appears to apply in vivo. In most normal connective tissues, fibroblasts are protected from external tensile stress by their surrounding matrix (134). This situation changes dramatically with an altered microenvironment, such as when a dermal wound is provisionally filled with a clot of fibrin and blood platelets, which, in conjunction with white blood cells, release a variety of cytokines (142,143). These changes stimulate fibroblasts to migrate into the wound bed, where they proliferate and initiate restoration of the dermis by secreting and organizing the dermal matrix. The increasing number of migrating fibroblasts enhances matrix rigidity by applying tractional forces to the newly formed granulation tissue, ultimately

leading to the development of stress fibers.

A number of recent studies have demonstrated that mechanical stress is a prerequisite for the second step of myofibroblast development, signaled by the expression of Î±-smooth muscle actin in stress fibers (134,68). In vitro, the level of Î±-smooth muscle actin expression increases with increasing matrix rigidity, as demonstrated by growing differentiated myofibroblasts in collagen substrates or on polyacrylamide elastomers exhibiting different degrees of stiffness (144,145). In vivo, application of mechanical stress to granulation tissue fibroblasts by splinting the wound edges with a plastic frame accelerates expression of Î±-smooth muscle actin compared to normally healing wounds; stress release by removal of the frame rapidly leads to the disassembly of stress fibers and loss of Î±-smooth muscle actin expression (146).

In addition to mechanical stress, transformation of the protomyofibroblast into the differentiated myofibroblast requires the concerted action of cytokines and specific components of the extracellular matrix. It is increasingly accepted that TGF-Î²1 is the major growth factor inducing myofibroblast differentiation (27,147,148) from fibroblastic cells (147,149) and mesangial cells (33,150). More recently, thrombin (151) and endothelin-1 (152) have been shown to induce myofibroblast differentiation, the latter either directly or in coculture with epidermal cells (153). It has been demonstrated in experimental animals that the subcutaneous administration of granulocyte macrophageâ€“colony stimulating factor (GM-CSF) promotes the development of granulation tissue rich in Î±-smooth muscle actinâ€“positive myofibroblasts (154,155); this action, however, is indirect and could be mediated by TGF-Î². TGF-Î²â€“mediated expression of Î±-smooth muscle actin depends

upon the presence of the fibronectin splice variant ED-A fibronectin (30) in the extracellular matrix (Figure 6.4). This clearly demonstrates the complex interplay of diffusible and immobilized factors in promoting the development of differentiated

myofibroblasts. Other cytokines and/or growth factors have been shown to facilitate or inhibit myofibroblast development and proliferation. Nerve growth factor (156) facilitates the process, however, it is not known whether this action is independent of TGF-Î²1; interferon-Î³ inhibits the process (118).

Mechanisms of Force Generation and Transmission

Several observations suggest that stress fibers are the force-generating elements in wound contraction, since they contract upon addition of adenosine triphosphate to glycerinated fibroblasts (13,157,158). As well, microinjection experiments revealed that stress fibers are functionally analogous to skeletal muscle fibers (158,159). Several models have been developed to study the contractile activity of fibroblastic cells in vitro. Using two-dimensional deformable silicone substrates, fibroblasts have been shown to produce long-lasting wrinkles of the substrate, suggesting the production of continuous isometric tension (160). This technique has been greatly improved over the past years by employing different elastic polymers and mathematical models to calculate cell-generated forces from substrate distortions [for a review see (161)]. In a more tissuelike approach to assess the dynamics of wound contraction, fibroblasts are cultured in collagen or fibrin matrices that are either free-floating and retracting over days or mechanically restrained for days and then stress released, leading to contraction within minutes [for review see (139)]. Importantly, stress fibers and matrix adhesion (i.e., the myofibroblastic phenotype) only develop in mechanically restrained gels. Hence, the choice of the appropriate collagen model facilitates study of the traction forces of migrating fibroblasts or stress fiber-mediated contraction.

Similar to what occurs in smooth muscle, stress fiber contraction may be regulated by elevated levels of intracellular Ca^{2+}, leading to activation of myosin light chain kinase and phosphorylation of the

myosin light chain. However, experimental and clinical observations show that granulation tissue retraction, in contrast to rapid and reversible contraction of smooth muscle, is the result of a continuous isometric force exerted on the surrounding connective tissue. This retraction is then stabilized by deposition of newly synthesized matrix components and thus becomes irreversible (134). In the last few years, the work of several laboratories has suggested that the isometric tension produced by stress fibers is regulated by Rho/Rho-kinase, which in its active form leads to long lasting tensile activity by the inhibition of myosin phosphatase (162). Phosphatase inhibitors stimulate myofibroblast contraction in vitro in the absence of any other contraction agonist (163). In contrast, increasing intracellular Ca^{2+} with ionophore has no contractile effect, indicating that activation of myosin light chain kinase alone is not sufficient to promote myofibroblast tension development (164). More recently it has been reported that thrombin activation of human lung myofibroblast tension development is mediated by protein kinase CÎµ and RhoA and depends on the activation of Ca^{2+}-mediated and Rho-kinase signaling pathways (151).

During the past several years, it has become evident that the expression of Î±-smooth muscle actin in stress fibers is instrumental in force generation by myofibroblasts. Compared with Î±-smooth muscle actinâ€“negative fibroblasts, myofibroblasts develop higher contractile force as demonstrated using deformable silicone substrates (164,165) and contracting collagen gels (165,166). Stable transfection with Î±-smooth muscle actin confers upon fibroblasts a higher contractile activity compared with transfection with cytoplasmic or sarcomeric actin isoforms; this effect is exerted in the absence of any change in the expression of other contractile proteins, such as smooth muscle or nonmuscle myosin (165). The mechanism by which Î±-smooth muscle actin promotes myofibroblast-enhanced contractile activity has not been defined; however, it is inhibited in vitro and in vivo and by the intracellular delivery of the Î±-smooth muscle actinâ€“specific N-terminal

sequence AcEEED (115).

The force generated by stress fibers is transmitted to the extracellular matrix at sites of cell-matrix adhesions (130). In vivo, myofibroblasts form a specialized adhesion complex, the fibronexus (49), which is characterized by a firm co-alignment of intracellular actin fibers with extracellular fibronectin fibrils (Figure 6.1B); these in turn are connected to collagen in the wound matrix (19). In vitro, differentiated myofibroblasts communicate with the extracellular matrix through specialized â€œsupermature focal adhesionsâ€• (145,167), which have a diameter of 6 to 30 Âµm and strongly express the cytoplasmic proteins vinculin, paxillin, and tensin and the transmembrane integrins Î±vÎ²3 and Î±5Î²1 (145,167). This is in contrast to smaller focal adhesions (FAs) (2â€“6 Âµm) of Î±-smooth muscle actin-negative fibroblasts that do not exhibit significant levels of tensin and Î±5Î²1 integrin or to fibrillar adhesions that are generally negative for vinculin, paxillin and Î±vÎ²3 integrin (130,168). Focal adhesion supermaturation depends on the high contractile activity developed by Î±-SMAâ€“containing stress fibers (145), analogous to the maturation of classical FAs from nascent focal complexes in response to up-regulated cell contractile activity (136). It has been proposed that supermature focal adhesions are particularly efficient in promoting tissue contraction (134,135) by providing high adhesion to the substrate (145) and by immobilizing the cells in the wound bed (169).

Tissue Distribution of Myofibroblasts

Normal Tissues

Myofibroblasts were described in normal human and animal tissues on the basis of ultrastructural and/or immunohistochemical evidence of smooth muscle differentiation. The normal settings in which myofibroblasts were observed include the external theca of the rat

ovarian follicle (170); developing human palatal mucosa (171); rat, rabbit, and human intestinal mucosa (172,173,174); rat and mouse adrenal capsule (175), human, lamb, and monkey pulmonary alveolar septa (176); rat testicular stroma (68); rat testicular capsule (177); human theca externa of the ovary (178); Wharton's jelly of human umbilical cord (179); bovine endometrial caruncle (180); and periodontal ligament of the mouse (181) and rat (182), where they facilitate tooth eruption. Stromal cells with myoid features were also identified in rat and human lymph nodes and in the human spleen (183). Another group of stromal cells with myoid features include hepatic perisinusoidal cells (184), those in the human uterine submucosa (185) and human bone marrow (186), glomerular mesangial cells of mouse, rat, and human (187), and, possibly, pre- and postcapillary pericytes (89,91).

Figure 6.5 Human chronic granulation tissue from pleural empyema. A. The four layers *(L1â€“L4)* are clearly discernible: L1, alterative; L2, exudative; L3, exudativo-productive; L4, cicatrizing (hematoxylin-phloxine-saffron). B. Most myofibroblasts from the exudative and exudativo-productive layer (L2 andL3) reveal intense immunostaining for Î±-smooth muscle actin (phenotype VA) (avidin-biotin-complex-peroxidase). Note that myofibroblastic cells change their orientation within the different layers. Within the exudative layer, their long axis is perpendicular to the surface, whereas in the exudativo-productive layer their long axis is often oblique to the surface. Within the cicatrizing layer, myofibroblastic cells are oriented parallel to the surface, which indicates that the modulation of cellular orientation serves to transmit contractile forces to effect

wound closure. C. In the cicatrizing layer (L4), numerous myofibroblasts express desmin (phenotype VAD). (B and C are step-sections.)

Immunohistochemical studies disclosed heterogeneous cytoskeletal phenotypes among all of these stromal cells (myofibroblasts) in terms of intermediate filament protein, smooth muscle actin, and smooth muscle myosin expression; these include V, VD, VA (D) M, VA, and VAD phenotypes (188,189). This cytoskeletal heterogeneity could reflect different functional needs since all of these stromal cells seem to participate in visceral contraction or extracellular matrix remodeling, a view supported by the observation that stromal cells with myoid features are generally present in organs requiring contraction or high degrees of remodeling (190). Another recently advanced interpretation proposes that most spindle cells in normal tissues cited as being myofibroblasts might be closer to pericytes,

smooth muscle cells (191), or stromal cells with myoid features of variable degrees that correspond to functional demands. As shall be seen in the following sections, myofibroblasts and/or stromal cells with myoid features are not stable in terms of cytoskeletal phenotypes. In normal, abnormal, and pathologic conditions, the phenotype V may change into phenotype VA, VAD, VD, and, eventually, into VA (D) M, but terminal smooth muscle differentiation (smooth muscle metaplasia) is never attained. Thus, the myofibroblast remains an enigmatic cell, one that appears and disappears after completion of its functions or, exceptionally, one that may persist in certain pathologic conditions.

Granulation Tissue

Granulation tissue (Figures 6.5,6.6,6.7) consists of a bed of fibroblastic cells separated by a collagenous matrix containing capillary buds, fibrin, and inflammatory cells. According to the

relative predominance of each constituent, four layers are classically distinguished: (a) alterative; (b) exudative; (c) exudativo-productive; and (d) cicatrizing (Figure 6.6A). Granulation tissue fibroblasts characteristically disclose ultrastructural features of myofibroblasts. They are most numerous and best developed within the exudativo-productive layer and become progressively replaced toward the deepest cicatrizing layer by fibroblasts. The orientation of the myofibroblasts varies in the different layers of granulation tissue. In the exudative layer, the long axis is perpendicular to the surface, whereas in the exudativo-productive and cicatrizing layers, the long axis is parallel to the surface (Figure 6.6A). These data suggest that the spatial orientation of myofibroblasts in granulating wounds varies, possibly to maximize the transmission of contractile forces and thereby effect wound closure. When the collagenous matrix is analyzed, type III collagen predominates. When granulation tissue is resorbed following wound closure, myofibroblasts disappear (25,97,192) and the more rigid type I collagen is identified (96).

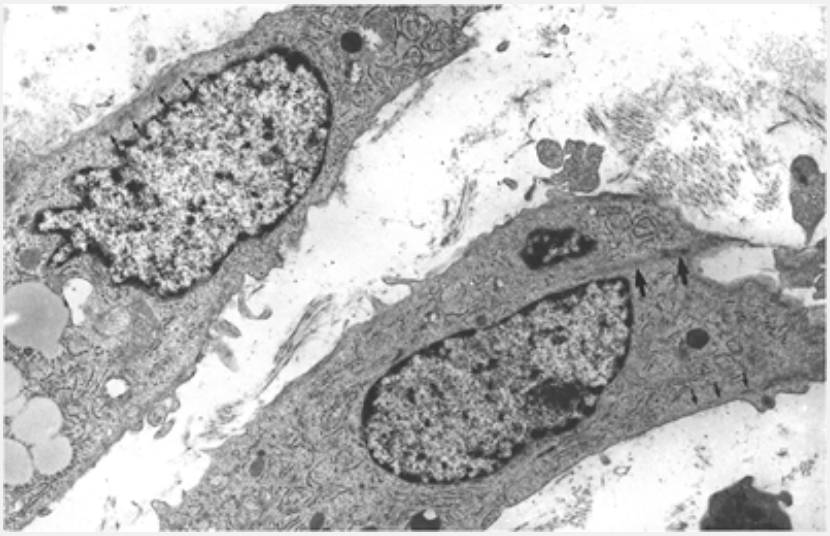

Figure 6.6 Human granulation tissue, approximately 5 days old, composed of phenotype V myofibroblasts. These cells disclose subplasmalemmal bundles of microfilaments with few dense

bodies (*small arrows*) and also intracytoplasmic bundles of microfilaments with dense bodies (*large arrows*) corresponding to stress fibers in formation (uranyl acetate and lead citrate,Ã—12,500).

Analysis of cytoskeletal proteins by immunohistochemical methods reveals that myofibroblasts from normal healing wounds never express desmin or smooth muscle myosin heavy chains during the process of wound closure in the experimental animal (25). Smooth muscle differentiation in early granulation tissue is absent and myofibroblasts are often poorly-developed and correspond to V cells (Figure 6.5). Smooth muscle differentiation of myofibroblasts, however, becomes temporarily apparent because myofibroblasts express Î±-smooth muscle actin (VA cells) (Figure 6.7A and B) in increasing amounts from the eighth to the fifteenth day; this protein is located within bundles of microfilaments (stress fibers), as illustrated by immunoelectron microscopic techniques (Figure 6.7C and D). This actin isoform disappears progressively from myofibroblasts and is not detectable after the thirtieth day by immunohistochemical and immunoelectron microscopic methods. These results clearly indicate that granulation tissue myofibroblasts temporarily acquire a VA phenotype. This is valid when wound repair is accomplished by primary intention. When repair is accomplished by secondary intention in chronic granulation tissue (e.g., chronic gastric ulcer, cutaneous ulceration, or pleural empyema), myofibroblasts of the VAD phenotype may be detectable (Figure 6.6B and C).

The study of the ontogenesis of wound healing reveals that many species possess the unique ability to heal wounds without scarring (193,194,195,196,197,198). Estes et al. (199),

examining fetal wounds in the fetal lamb, recently showed that there are differences between early and late gestational wound healing. In

the lamb, term gestation is approximately 145 days. Early gestational wounds (75 days) healed without scarring by repair of the epidermis, reconstitution of epidermal appendages, and remodeling of the dermal collagenous network. In contrast, late gestational wounds (100 and 120 days) healed with scarring through formation of granulation tissue containing myofibroblasts that were mostly derived from local resident fibroblasts. The situation appears to be different in healing corneal wounds, in which corneal keratocytes transform into repair corneal fibroblasts or myofibroblasts (200,201,202).

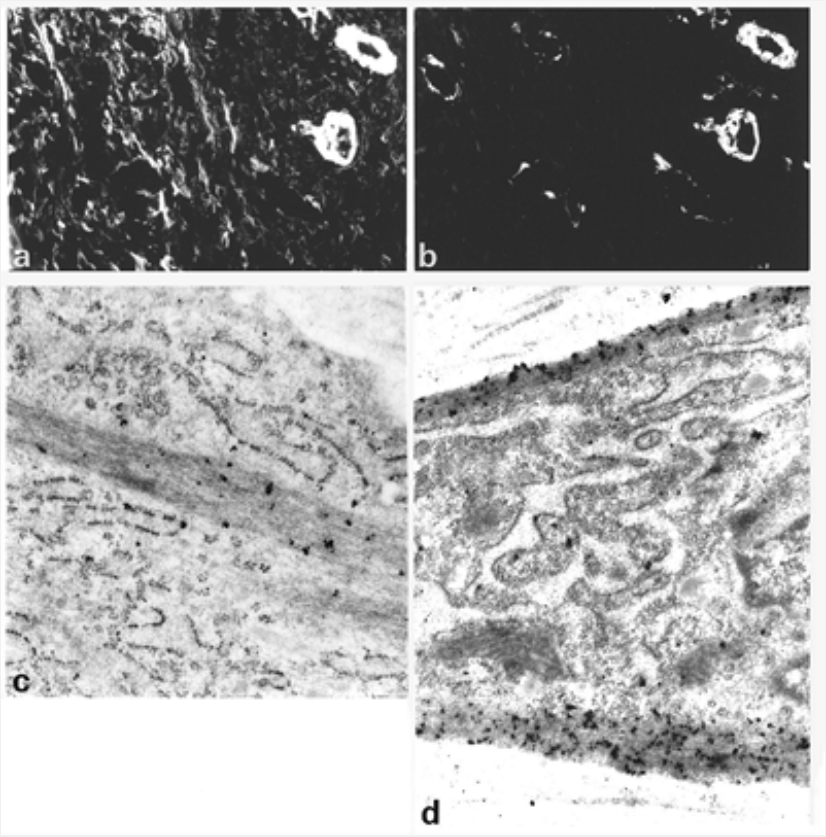

Figure 6.7 Experimental granulation tissue from the rat, 15 days old. A. Double immunofluorescent staining for Î±-smooth muscle actin (A). B. Double immunofluorescent staining for desmin. Myofibroblastic cells reveal intense staining for Î±-smooth

muscle actin (A) but are negative for desmin (B). Vascular smooth muscle cells are positive both for Î± smooth muscle actin and desmin. C. Immunoelectron microscopic localization of Î±-smooth muscle actin within intracytoplasmic bundles of microfilaments, that is, stress fibers. D. Immunoelectron microscopic localization of Î±-smooth muscle actin in subplasmalemmal bundles of microfilaments. (C, Ã—31,000; D, Ã—28,400.)

Pathologic Tissues

Upon analysis of the many pathologic conditions in which myofibroblasts have been described, three fundamental processes emerge: (a) responses to injury and repair phenomena or situations related to inflammation and tissue remodeling; (b) quasineoplastic proliferative conditions; and (c) the stromal response to neoplasia (6,203). This

concept, enunciated some 25 years ago, appears valid to this day (6).

Responses to Injury and Repair Phenomena

Responses to injury and repair phenomena comprise human and experimental cirrhosis (204,205,206), tenosynovitis (207), radiation-induced pseudosarcoma of skin (208), burn contracture (209), ischemic contractures of intrinsic muscles of the hand (210), renal interstitial fibrosis during obstructive nephropathy (211), pulmonary sarcoidosis (212), giant cell granuloma of jaws (213), schistosomal liver fibrosis (214), regenerating tendon (215), fibrous capsule around silicon mammary implants (216,217), nodular hyperplasia of the liver (218), ganglia of soft tissue (219), hypertrophic scars (220), cataract (221), bleomycin-induced pulmonary interstitial

fibrosis in the rat (222), fibrous heart plaque in the carcinoid syndrome (223), atherosclerotic lesions in humans and experimental animals (224,225,226,227), localized and systemic scleroderma (228), and experimental hydronephrosis (229). When cytoskeletal proteins of these conditions are analyzed most reactive cells correspond to the VA, some to the VAD, and few to the VD and VA (D) M phenotype (188,192).

A recent report proposed that a reactive myofibroblastic proliferation with increased deposition/formation of extracellular matrix might be responsible for the progressive and irreversible obstruction of airways in chronic bronchial asthma (230). In asthma, it appears that epithelial-mesenchymal interactions may play an important role in its pathogenesis. Epithelial injury and subepithelial collagen deposition are characteristic of asthma. It was proposed that epithelial cell proliferation increases after airway injury in asthmatics, that epithelial cells stimulate lung myofibroblast collagen production, and that both processes are modulated by allergen-recruited inflammatory cells, proinflammatory cytokines, growth factors, and mediator-generating enzymes. Beneath the damaged bronchial epithelium, there is an increase in the number of subepithelial myofibroblasts that deposit interstitial collagens, causing thickening and increased density of the subepithelial basement membrane (231,232,233).

Focal segmental glomerular hyalinosis/sclerosis (FSGS) is another state which might belong to the group of responses to injury and repair phenomena (Figure 6.8Aâ€“I). The condition is associated with significant proteinuria and hypertension; many patients develop chronic renal failure, requiring dialysis and eventual renal transplantation. In FSGS, mesangial cells, which normally express only cytoplasmic actins and therefore correspond to myofibroblasts with a V phenotype, may gradually acquire a VA phenotype, expressing Î±-smooth muscle actin as revealed by immunohistochemical techniques (Figure 6.8D). Moreover, they develop stress fibers as observed by ultrastructural examination

(Figure 6.8I). These findings are similar to those in experimental immune complex nephritis in which mesangial expression of smooth muscle actin correlates with mesangial cell proliferation (33). In FSGS, mesangial cells expressing Î±-smooth muscle actin become progressively apparent in the early stage of the disease (podocytosis; Figure 6.8C and D) (234). Their numbers increase as the lesion progresses to the hyalinosis stage (Figure 6.8E and F). At the stage of sclerosis, the number of mesangial cells immunostained for Î±-smooth muscle actin is reduced, somewhat analogous to that which occurs over time in wound healing (Figure 6.8G and H).

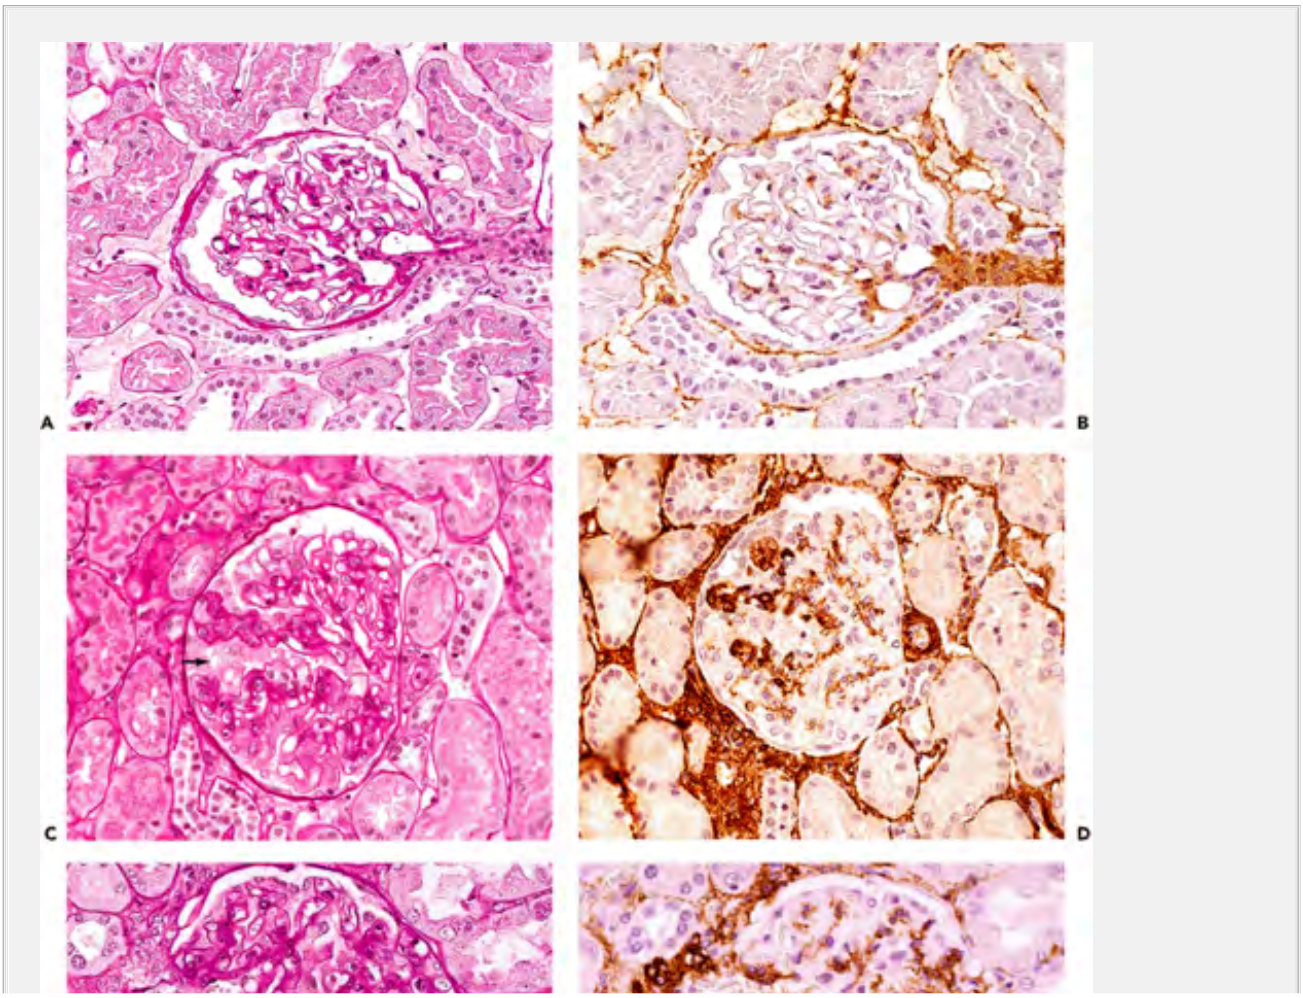
In abnormally healing wounds (hypertrophic scars and keloids), one observes several important differences. Hypertrophic scars always exhibit nodular structures in which fibroblastic cells, small vessels, and fine randomly organized collagen fibers are present. Within these nodules, numerous myofibroblasts of the VA phenotype and, in lesser numbers, myofibroblasts of the VAD phenotype are identified (Figure 6.9Aâ€“H). Exceptionally, myofibroblasts of the VA (D) M phenotype are observed. Keloids contain large thick bands of closely packed cell fibers and rare nodular structures, the latter containing few or no VA cells (235,236). VAD cells are not observed within classical keloids (231), however VA and VAD cells are frequently observed in relatively small keloids of Caucasians (237).

Quasi-neoplastic Proliferative Conditions

This group embodies the poorly-understood but very important and frequent soft tissue proliferations included under the broad heading of fibromatoses, as well as many other soft tissue proliferations (often mimicking sarcomas) that share a predominant myofibroblastic composition and a variable proliferative potential yet do not disseminate or metastasize (6,203).

Myofibroblasts constitute the principal cellular components of superficial and deep musculoaponeurotic fibromatoses (238). Superficial (fascial) fibromatoses include palmar fibromatosis

[Dupuytren's disease (16,103,239,240,241)], plantar fibromatosis [Ledderhose's disease (16)], penile fibromatosis [Peyronie's disease (240)], and knuckle pads (243). Deep musculoaponeurotic fibromatoses comprise extra-abdominal, abdominal and intra-abdominal variants, collectively named desmoid tumors (238). To this group belong the infantile fibromatoses (244). Other soft tissue proliferations predominantly composed of myofibroblasts are nodular fasciitis (245), proliferative fasciitis (246), proliferative myositis (247), giant fibroma of oral mucosa (248), dermatofibroma (249), elastofibroma (250), plasma cell granuloma of the lung (251), digital fibroma of infancy (252), and juvenile nasopharyngeal angiofibroma (253). Myofibroblasts are also present in cardiac myxomas (254) and in uterine plexiform tumors (255).



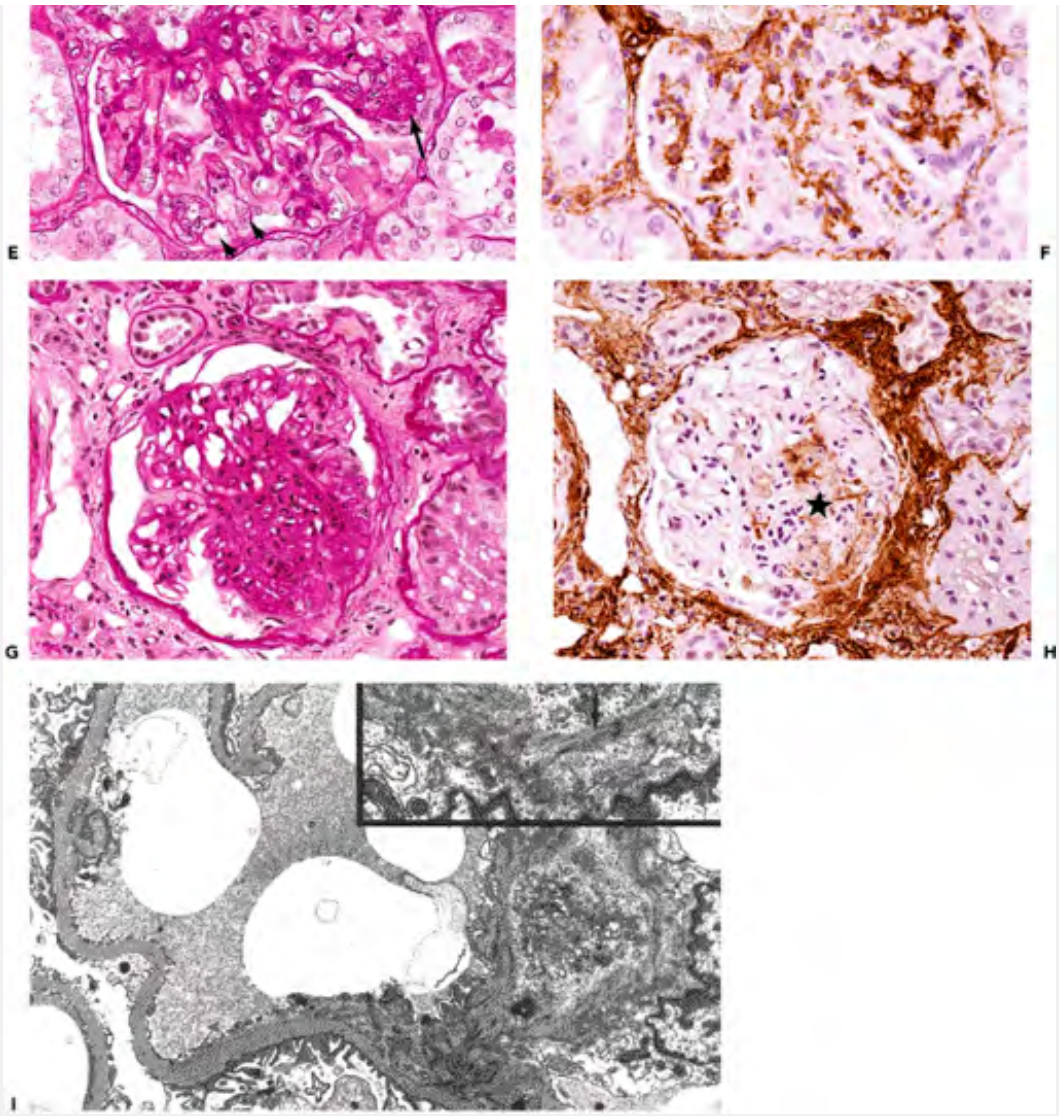


Figure 6.8 Evolution of focal segmental glomerular hyalinosis/sclerosis using step-sections stained with PAS and Î±-smooth muscle actin. A. and B. Normal glomerulus; B is without significant immunostaining of mesangial cells for Î±-smooth muscle actin. C. and D. Early stage of focal segmental hyalinosis characterized by vacuolar degeneration of podocytes with hyalin PAS-positive droplets and increased mesangial matrix in two glomerular segments; that is, podocytosis (*arrow*). Mesangial cells of the two glomerular segments disclose significant immunostaining for Î±-smooth muscle actin (D). E. and F.

Typical segmental lesion with hyaline endomembranous PAS-positive deposit (*arrow*) and foam cells (*arrowheads*). Mesangial cells disclose significant immunostaining for Î±-smooth muscle actin. G. and H. Segmental sclerosis with decreased immunostaining for Î±-smooth muscle actin (*asterisk*). I. Mesangial cell disclosing stress fibers composed of microfilaments with dense bodies (*arrow*), enhanced in inset (uranyl acetate and lead citrate, Ã—8000; inset Ã—15,150).

Dupuytren's Disease

Among quasineoplastic proliferations, Dupuytren's fibromatosis has been studied extensively by morphologic, immunohistochemical, and biochemical techniques (24,26,256,257). Cytoskeletal proteins have been widely used as markers of differentiation for neoplastic and quasineoplastic proliferations and as markers of adaptation to physiologic situations, particularly for muscular and related soft tissue proliferations (24,26,64).

According to Luck (258), the nodules of Dupuytren's disease are assigned to three different phases, depending on the histologic pattern: (a) proliferative phase; (b) involutional phase; and (c) residual phase (Figure 6.10Aâ€“D). Patients with Dupuytren's disease often present multiple nodules showing considerable variation in their histologic appearance. The classification is, therefore, based on the predominant histologic pattern (105,259).

Sections from proliferative phase nodules feature high cellular density, decreasing from the center to the periphery (Figure 6.10A). They are well-vascularized and display a poorly-collagenized appearance. Ultrastructurally, they are composed of myofibroblasts with numerous and long cytoplasmic extensions, joined by numerous gap and adherens junctions (Figure 6.11A and inset). Their plasma

membrane displays focal deposition of basal lamina, plasmalemmal attachment plaques, and pinocytotic vesicles, as well as cell-to-stroma attachment sites in the form of fibronexus (49). The cytoplasm features a well-developed rough endoplasmic reticulum and Golgi apparatus and numerous stress fibers, the latter usually oriented parallel to the long axis of the cell (Figure 6.11A). The nucleus is typically indented and often contains one or several nuclear bodies. The extracellular matrix is composed of a few mature collagen fibers (64 nm periodicity) admixed

with indistinct granular and basal lamina-like material (Figure 6.11A).

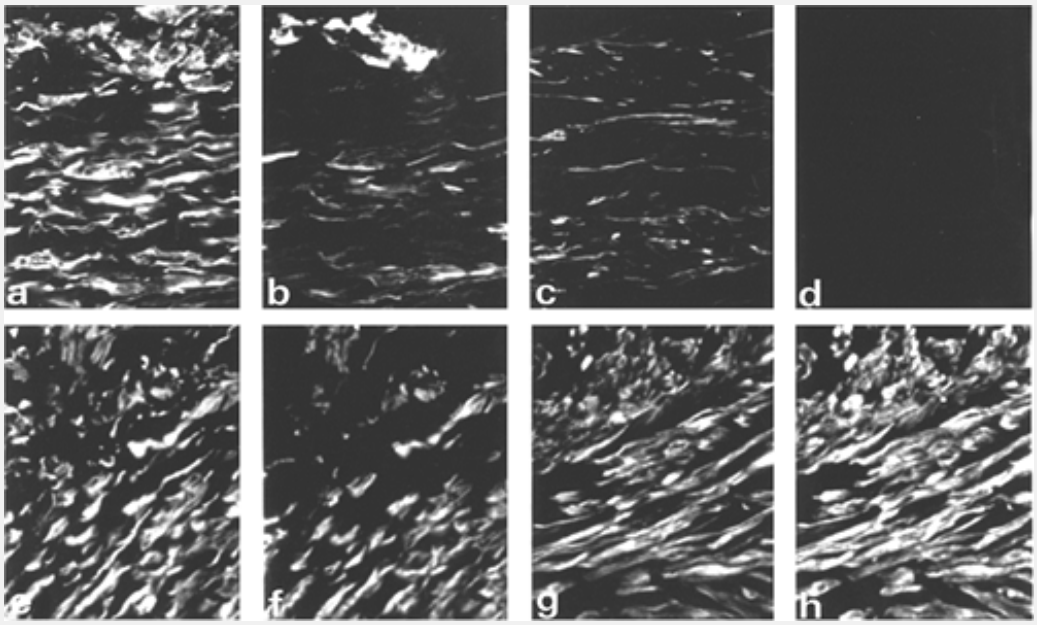

Figure 6.9 Double immunofluorescent staining of two hypertrophic scars (Aâ€“D and Eâ€“H) with antibodies to vimentin (A and E), Î±-smooth muscle actin (B and F), Î±-smooth muscle actin (C and G), and desmin (D and H). One hypertrophic scar (Aâ€“D) contains V and VA cells, and the other,

from a site of smallpox vaccination (Eâ€“H), contains mainly VAD cells. Note that most small blood vessels are positive for vimentin and Î±-smooth muscle actin. )

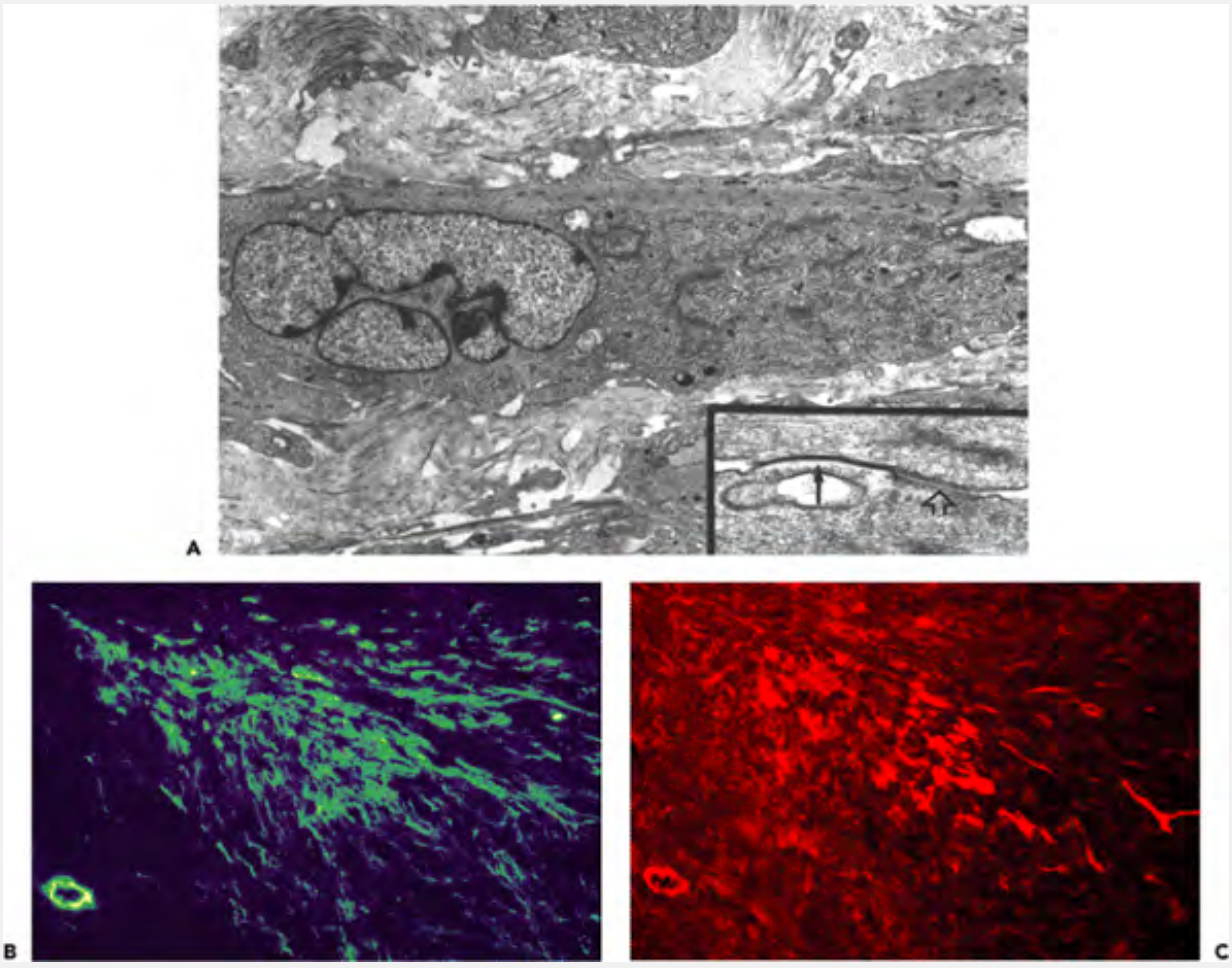

Figure 6.11 Dupuytren's disease: proliferative phase nodule. A. Transmission electron micrograph of proliferative phase nodule.

Note large typical myofibroblast with cytoplasmic extensions, well-developed rough endoplasmic reticulum and Golgi areas, and prominent cytoplasmic bundle of microfilaments with numerous dense bodies oriented parallel to the long axis of the cell. The nucleus is indented. The extracellular matrix contains few mature collagen fibers. Inset: Gap junction between two myofibroblasts (*arrow*) followed by an intermediate junction (*open arrow*). (Uranyl acetate and lead citrate: Ã—7500; inset, Ã—72,000.) B. and C. Double immunofluorescent staining for Î±-smooth muscle actin (B) and desmin (C). The majority of the proliferating cells comprising the nodule correspond to VA cells, while lesser numbers of cells express VAD and V phenotypes.

Involutional phase nodules also feature high cellularity, but the cells are smaller than those of the proliferative phase and tend to be aligned in the same direction (Figure 6.10Bâ€“C). Ultrastructurally, these nodules are composed of myofibroblasts that are also connected by gap and adherens junctions. These intercellular junctions, however, seem to be less numerous than in proliferative phase nodules. The most striking difference with proliferative phase nodules is the increased amount of collagen that envelopes myofibroblasts. By immunoelectron microscopy, Î±-smooth muscle actin is localized within bundles of microfilaments of myofibroblasts of the proliferative and involutional phase nodules.

Residual phase nodules are hypocellular and the slender and aligned cells are surrounded by thick bands of collagen, giving them a tendonlike appearance (Figure 6.10D). By ultrastructure, these nodules are composed of mature fibroblasts (Figure 6.12A), some containing discrete subplasmalemmal bundles of microfilaments without dense bodies. Occasional poorly-developed adherens-type junctions (Figure 6.12A and inset) connect the fibroblasts, but

gap junctions are no longer observed. The slender fibroblasts show

smooth, contoured nuclei and are embedded in a dense collagenous matrix formed by thick bands of tightly packed collagen fibers. In conclusion, significant ultrastructural differences exist between proliferative, involutional, and residual phase nodules in Dupuytren's disease in relation to the cells, intercellular junctions, and composition of the extracellular matrix.

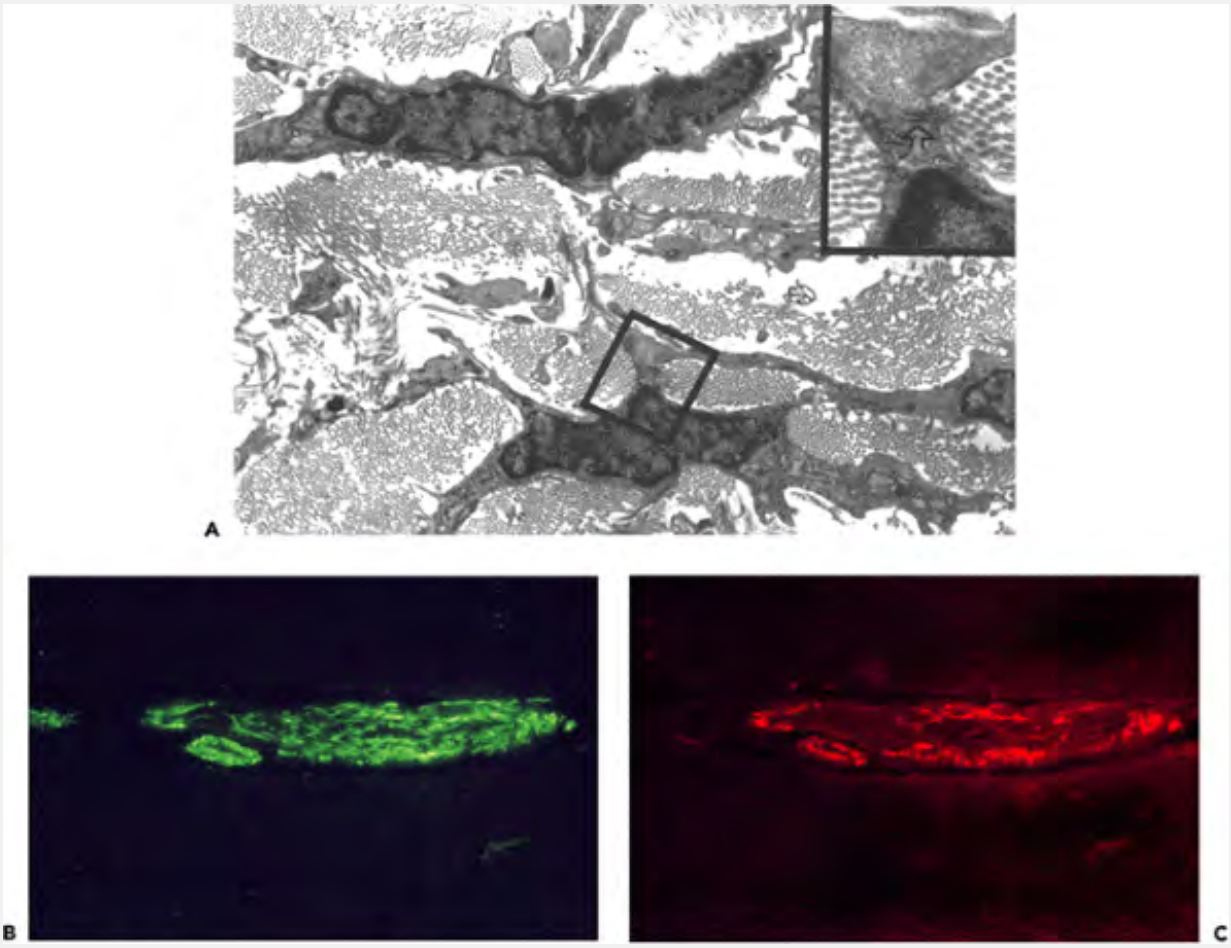

Figure 6.12 Dupuytren's disease: residual phase nodule. A. Transmission electron micrograph illustrating slender fibroblasts with smooth contoured nuclei embedded in a dense collagenous matrix and joined by poorly-differentiated junction (*open arrow,* inset) (uranyl acetate and lead citrate, Ã—12,150; inset, Ã—40,500). B. and C. Double immunofluorescent staining for Î±-

smooth muscle actin (B) and desmin (C). Cells comprising the residual phase nodule correspond to V cells. A few isolated cells express only VAD or VA phenotypes.

When the collagenous matrix of Dupuytren's disease is analyzed by immunohistochemical techniques, proliferative phase nodules reveal a predominance of type III collagen, whereas in the residual fibroblastic phase, type I collagen predominates (103). Differences between proliferative and residual phase nodules are also defined in the vascularization. In proliferative phase nodules, capillaries are numerous and feature, ultrastructurally, large and prominent pericytes that display distinct smooth muscle differentiation; whereas in residual phase nodules, capillaries are few in number and are surrounded by small and inconspicuous pericytes that are devoid of a well-developed microfilamentous apparatus (26). Analogous to wound healing, the cicatrizing process within proliferative and involutional phase nodules is centripetal, being completed within residual phase nodules.

When immunohistochemical techniques are employed to study the cellular phases of Dupuytren's disease the

following results are obtained. Cells of the proliferative phase nodules always express vimentin, which is associated in approximately 80% of the cells with Î±-smooth muscle actin (68) and in about 20 to 40% with desmin when double-labeling immunofluorescence techniques are performed (Figure 6.11Bâ€“C). Rarely, isolated cells positive for vimentin, Î±-smooth muscle actin, and smooth muscle myosin heavy chains with or without desmin are present [VA (D) M phenotype] (189). In involutional phase nodules, desmin-positive cells are less numerous or even absent, whereas Î±-smooth muscle actin-positive cells are still present, albeit in lesser numbers. In residual phase nodules few or no Î±-smooth muscle actinâ€“positive cells persist, and the remaining slender cells express

solely vimentin (Figure 6.12Bâ€“C). Accordingly, cells comprising the nodules of Dupuytren's disease express different cytoskeletal phenotypes: (a) phenotype V; (b) phenotype VAD; (c) phenotype VA; and (d) phenotype VD. In most proliferative phase nodules of Dupuytren's disease and also in the cellular areas of musculoaponeurotic fibromatoses, the number of VA cells considerably exceeds the number of VAD and VD cells (24). At the heavily collagenized interphase of involutional and residual nodules, the number of VAD and VD cells decreases progressively and is replaced by an almost pure population of V cells (24,26,257). Despite their heterogeneity in intermediate filament proteins and actin isoforms, myofibroblasts from Dupuytren's disease (69,256) express usually only nonmuscle myosins. Exceptionally, isolated cells expressing smooth muscle myosin heavy chains [VA (D) M phenotypes] are observed (189). In these tissues, the extracellular matrix around myofibroblasts is strongly stained with antibodies to fibronectin but not to laminin (256,260).

Other Quasi-Neoplastic Proliferative Conditions

A heterogeneous cytoskeletal composition is also observed in myofibroblasts of dermatofibromas, which reveal at least three cytoskeletal phenotypes: VA, VAD, and V cells, with a predominance of VA cells in cellular dermatofibromas and an almost exclusive composition of V cells in fibrous dermatofibromas (261). Whether myofibroblasts of the VA (D) M phenotype exist has not yet been determined. By ultrastructure, cellular dermatofibromas are composed of well-developed myofibroblasts, joined by gap and intermediate junctions, and admixed with variable numbers of fibroblasts and macrophages. Fibrous dermatofibromas, in contrast, are composed almost exclusively of fibroblasts and feature only small numbers of poorly developed myofibroblasts.

This heterogeneous cellular and cytoskeletal phenotypic composition

of dermatofibromas permits one to distinguish them from dermatofibrosarcoma protuberans, which represents a pure fibroblastic neoplasmâ€”both at the ultrastructural level and with regard to the cytoskeletal immunophenotype (261). Furthermore, the heterogeneous cytoskeletal composition of dermatofibroma identifies this lesion definitively as a quasineoplastic reactive and proliferative condition, whereas dermatofibrosarcoma protuberans represents a fibroblastic neoplasm (261).

Nodular and proliferative fasciitis are predominantly composed of myofibroblasts with similar cytoskeletal phenotypes of VA and rare VAD cells, the latter being more prominent in the proliferative variant (Figure 6.13Aâ€“C).

Infantile myofibromatosis reveals a predominance of VA cells with limited numbers of VAD cells. By ultrastructure, in contrast to other fibromatoses, smooth muscle differentiation appears to be more prominent than in conventional fibromatoses, although typical myofibroblasts are numerous, a feature that justifies the term *infantile myofibromatosis*. Furthermore, massive apoptosis has been documented in infantile myofibromatosis and is proposed as a putative mechanism of regression of this proliferative myofibroblastic lesion (262).

Stromal Response to Neoplasia

Legions of medical students have been taught that many invasive and metastatic carcinomas are characterized by hard consistency and retraction and are often fixed to adjacent tissues. Typical examples are invasive ductal mammary carcinomas, associated with skin and or nipple retraction (Figure 6.14A), annular stenosing colon carcinomas (Figure 6.14B), gastric linitis plastica, the so-called frozen pelvis in advanced gynecological carcinomas, the â€œwoody hardâ€• nodule of invasive prostatic carcinoma, and metastatic carcinoma in matted lymph nodes fixed to surrounding tissues and the overlying skin. The hard consistency and the retraction

phenomena are due to the desmoplastic stromal reaction and contracting myofibroblasts.

Myofibroblasts are particularly numerous within the stroma of desmoplastic and retracted primary invasive and metastatic carcinomas (6,20,21,22,23,263), and the retraction associated with such carcinomas is attributed to the contractile forces generated by stromal myofibroblasts. Myofibroblasts are usually not observed in the stroma contiguous to in situ carcinomas (Figures 6.15Aâ€“B, 6.16Aâ€“B) (6,23), suggesting that invasion beyond the basal lamina is required to evoke a myofibroblastic stromal reaction. On occasion, stromal cells expressing Î±-smooth muscle actin are observed around in situ ductal breast carcinoma (personal observation, Figure 6.15Câ€“D). By ultrastructure, the periductal stromal cells expressing Î±-smooth muscle actin may disclose the typical morphologic features of myofibroblasts with well-developed stress fibers and fibronexus. This early myofibroblastic stromal reaction around ducts of in situ carcinomas is not uniform in a given case but may change from one duct to another (Figure 6.17Aâ€“B). Myofibroblasts have also been described in squamous intra-epithelial lesions of the uterine cervix, close to the basal lamina, in increasing numbers and intensity of staining

from low-grade to high-grade variants, using immunohistochemical techniques (264).

Stromal cells with myofibroblastic features are notably absent or equivocally present within carcinomas lacking significant retraction and desmoplasia (Figure 6.18Aâ€“C) (23).

Myofibroblasts are not uniformly distributed within desmoplastic carcinomas. When their spatial relation to other components of breast carcinomas is analyzed, they are most numerous within the young mesenchymal stroma, areas corresponding to early stromal invasion, or, more consistently, in the peripheral invasive cellular front of mammary carcinomas (Figures 6.19Aâ€“F, 6.20A) (23). In the central sclerotic area of such neoplasms, myofibroblasts are poorly-developed or absent; this possibly is a reflection of apoptosis (Figures 6.19Gâ€“H, 6.20B) (23). Similarly, myofibroblasts are numerous in the cellular, edematous, and poorly collagenized stroma of other invasive and metastatic carcinomas (23).

Three types of myofibroblastic stromal reactions are observed within infiltrating ductal mammary carcinomas: (a) precocious (Figure 6.19Aâ€“B), myofibroblasts precede the carcinoma cells by some distance into adjacent tissue; (b) synchronous (Figure 6.19Câ€“D), myofibroblasts appear spatially among the carcinoma cells; and (c) late (Figure 6.19Eâ€“F), myofibroblasts are identified central to the peripheral invasive cellular front of the carcinoma cells (23). These three types of myofibroblastic stromal reactions are observed in different areas of the invading front of most infiltrating ductal carcinomas of the breast, the synchronous stromal reaction being usually predominant (23). When the collagenous matrix is analyzed, increased amounts of type III collagen are present within the young mesenchyme, areas with numerous myofibroblasts. In contrast, type I collagen is most prominent within the central sclerotic zone of breast carcinomas (106), areas in which myofibroblasts are replaced by fibroblasts (Figure 6.19Gâ€“H) (22,23).

Many pulmonary carcinomas, especially peripheral adenocarcinomas, are associated with some degree of scarring and are often associated with pleural retraction. If this process is pronounced, the term *scar carcinoma* is applied to these neoplasms. In 1962, Carroll (265) reported that the presence of elastic fibers and anthracotic pigment in scars suggested that they had been present prior to the development of the neoplasm. The more recent literature suggests that scarring represents a desmoplastic stromal reaction in response to neoplastic invasion rather than a preexistent condition. In favor of this latter interpretation is the presence of increased amounts of type III collagen within

pulmonary carcinomas with marked scarring (266), as is seen in early invasive zones of mammary carcinoma (104). In addition, the majority of stromal cells in scar carcinomas of the lung reveal ultrastructural features of myofibroblasts (267), suggesting that pulmonary carcinomas with scarring are neoplasms with a desmoplastic stromal reaction, analogous to many invasive and metastatic carcinomas elsewhere.

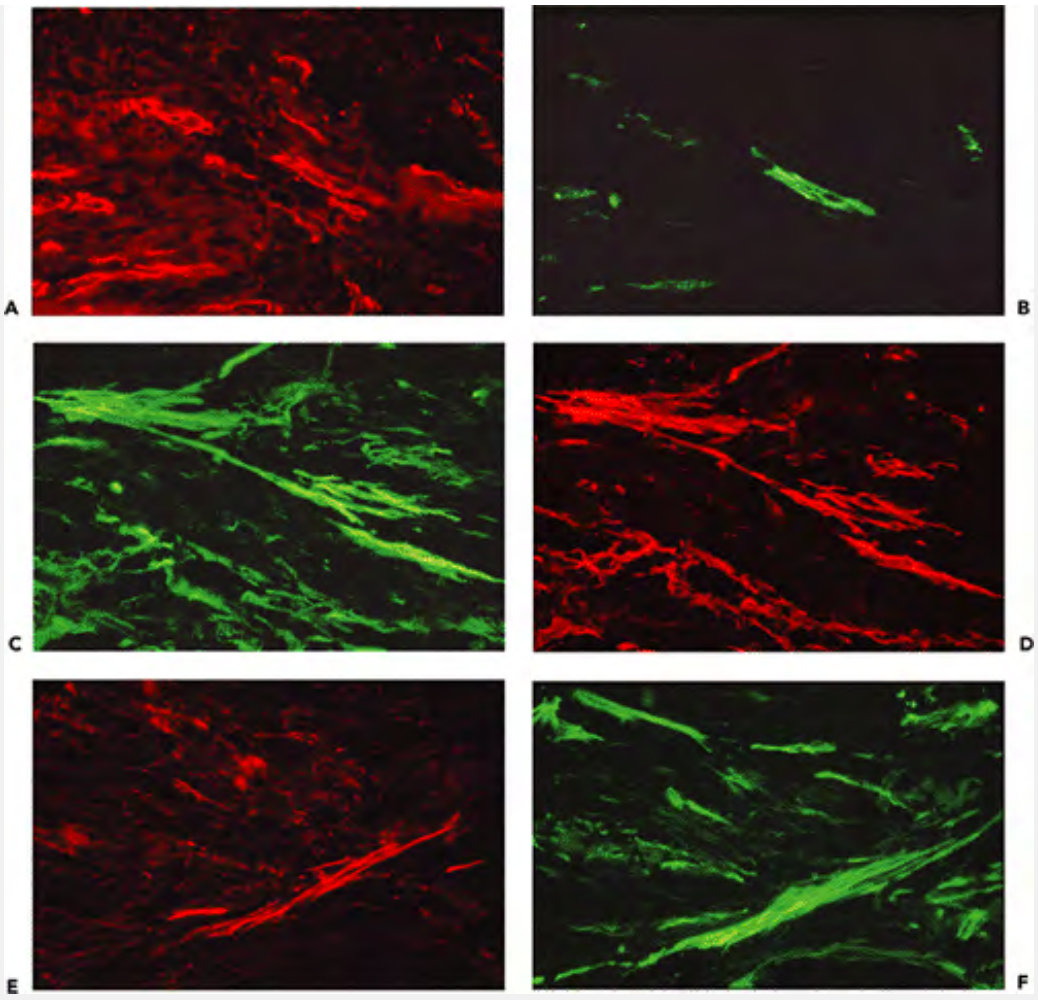

Figure 6.21 Step-sections of peripheral invasive cellular front of ductal breast carcinoma revealing V, VA, VAD, and VA (D) M myofibroblasts. A. and B. Double immunofluorescent staining for Î±-smooth muscle actin (A) and desmin (B). Stromal cells expressing Î±-smooth muscle actin (VA cells) are more numerous than those expressing Î±-smooth muscle actin and desmin (VAD cells). C. and D. Double immunofluorescent staining for Î±-smooth muscle actin (C) and smooth muscle myosin heavy chain (D). Stromal cells expressing Î±-smooth muscle actin (VA cells) are slightly more numerous than those expressing smooth muscle myosin heavy chain [VA (D) M cells]. E. and F. Double immunofluorescent staining for desmin (E) and myosin heavy chain (F). Stromal cells expressing smooth muscle myosin heavy

chain (VM cells) are far more numerous than those that express desmin [VA (D) M cells]. In conclusion, the peripheral invasive front of ductal breast carcinomas contains predominantly VA cells, followed by VA (D) M cells.

Analysis of cytoskeletal proteins, including intermediate filaments, actin isoforms, and smooth muscle myosin heavy chains reveals phenotypic heterogeneity of stromal cells in invasive and metastatic carcinomas. Areas with numerous myofibroblasts, corresponding to early stromal invasion of breast carcinomas, contain a predominance of VA cells admixed with variable numbers of VAD, VA (D) M, and V cells (Figure 6.21Aâ€“F), suggesting that certain stromal cells undergo a form of cytodifferentiation not too dissimilar from smooth muscle metaplasia (VA (D) M cells). In contrast, sclerotic areas disclose numerous V cells with occasional VA cells. No VAD and VA (D) M cells are observed (results not shown).

Myofibroblasts have also been described in sarcomas where they generally constitute a small fraction of the cell population (268,269,270). They were identified in all cases of malignant fibrous histiocytomas and well-differentiated sclerosing liposarcomas (270). Though most numerous in areas of desmoplasia, in no instance did myofibroblasts constitute the dominant cellular constituent of either neoplasm (Figure 6.22) (270). Myofibroblasts have been identified with lesser frequency and in smaller numbers in fibrosarcoma, synovial sarcoma, malignant hemangiopericytoma, and neuroblastoma. No myofibroblasts were observed in a wide assortment of diverse sarcomas in which desmoplasia was not a feature.

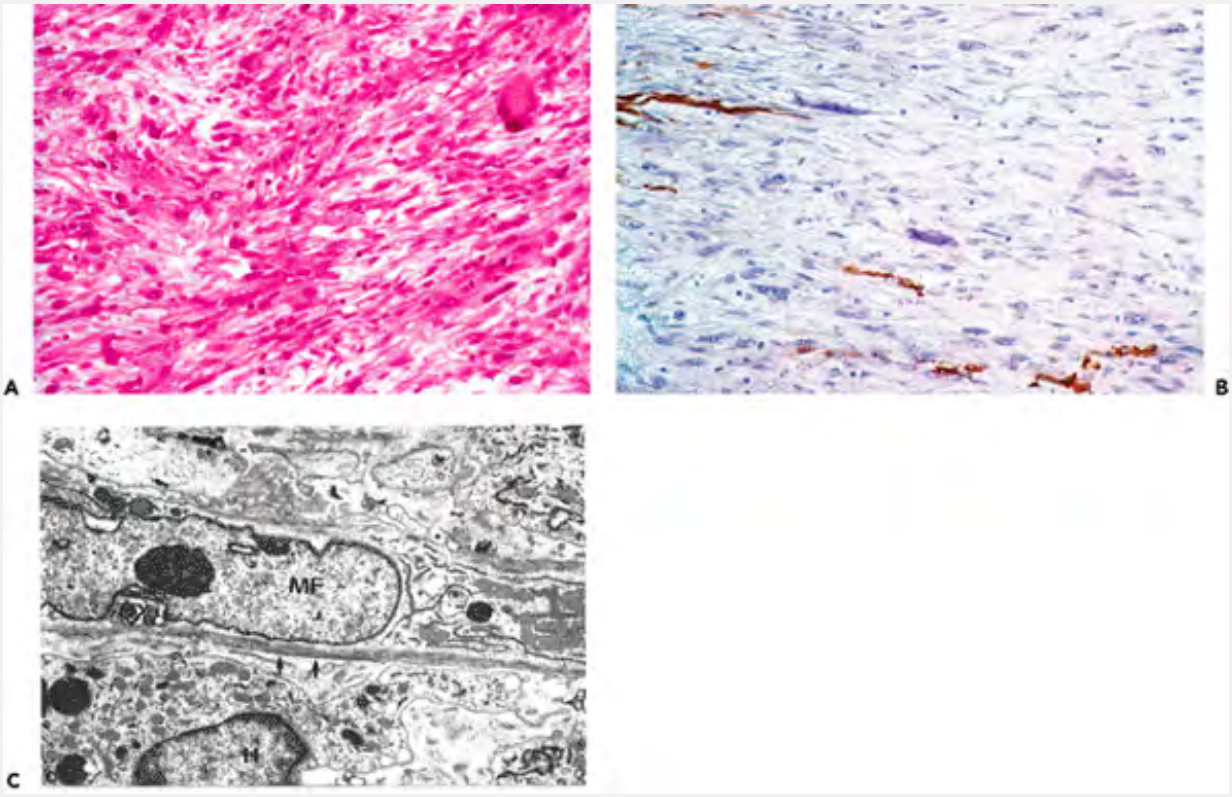

Figure 6.22 Malignant fibrous histiocytoma (storiform-pleomorphic type). A. Histological aspect illustrating spindle cell tumor with storiform pattern and isolated pleomorphic cells (hematoxylin-phloxine-saffron). B. Few spindle cells disclose immunostaining for Î±-smooth muscle actin (avidin-biotin-complex-peroxidase). C. Transmission electron micrograph illustrating a typical myofibroblast *(MF)* with cytoplasmic bundle of microfilaments; the cell is partly enveloped by a basal lamina (*arrows*) (uranyl acetate and lead citrate, Ã—25,000).

Myofibroblasts have been identified in nodular sclerosing Hodgkin's disease at the nodule-stromal interphase, which is usually heavily collagenized (271). These areas contain numerous VA and V cells with very occasional VAD cells (Figure 6.23). Whether this contributes to the relatively favorable prognosis of this variant of

Hodgkin's disease is an open question.

Neoplasms of Myofibroblasts: Benign and Malignant

Finally, several reports describe myofibroblastic neoplasms. In our opinion, neoplastic transformation of the myofibroblast, in the extreme is possible (272) but certainly remains an uncommon event. The plethora of articles related to this matter, particularly in the mid- and late-1990s, stems from the criteria employed to define this cell. The

myofibroblast is presently defined solely at the ultrastructural level; its definition at the light microscopic and immunohistochemical levels is less precise and, on occasion, imprecise. A significant number of reports describe myofibroblastic neoplasms; some were considered as sarcomas (273,274,275,276,277,278,279), and many more were described as benign myofibroblastomas or tumors of similar character with an assortment of designations (280,281,282,283,284,285,286,287,288,289,290,291).

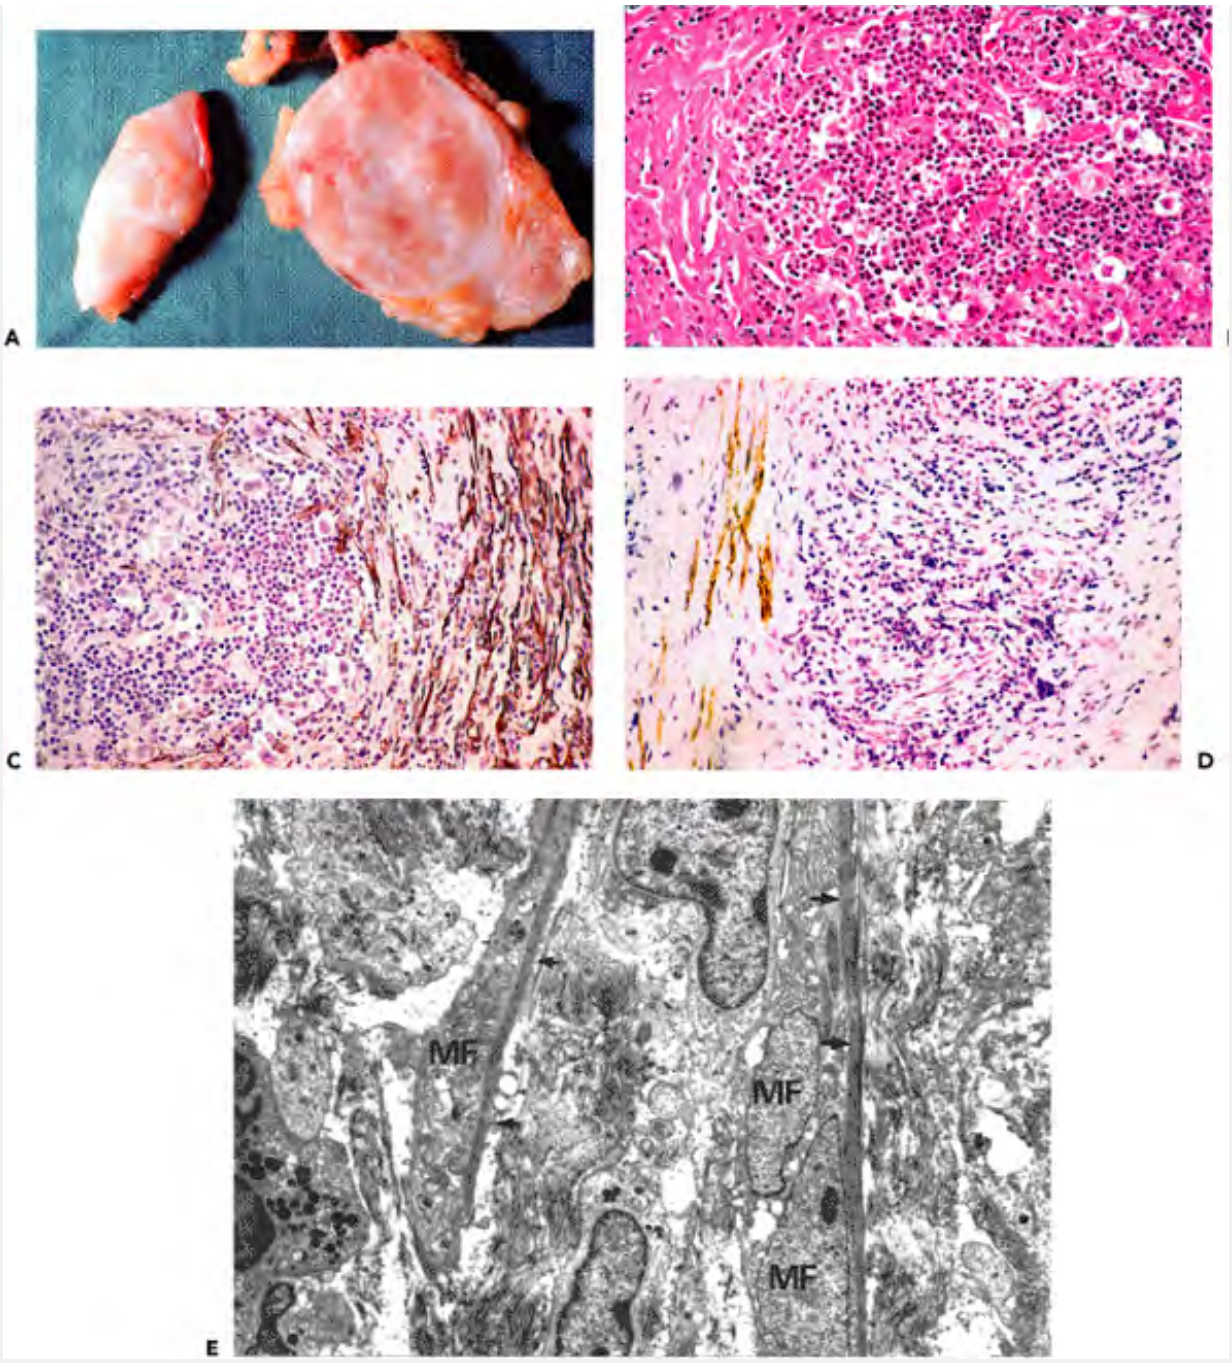

Figure 6.23 Nodular sclerosing Hodgkin's disease. A. Gross aspect of cut surface of lymph node demonstrating nodules surrounded by thick connective tissue septa (lymph node cirrhosis). (Courtesy of Dr. Roger Gareau, Department of Pathology, HÃ´tel-Dieu Hospital, University of Montreal,

Montreal, Quebec, Canada.) B. Histologic aspect illustrating nodules of atypical lymphoid nodules with some lacunar cells. The nodules are enveloped by dense collagenous containing numerous spindle cells (hematoxylin-phloxine-saffron). C. Several spindle cells around the nodule express Î±-smooth muscle actin (VA cells). D. Few spindle cells express desmin (VAD cells). All internodular stromal cells express antivimentin (results not shown). E. Transmission electron micrograph from internodular stroma illustrating numerous typical myofibroblasts *(MF)* with bundles of cytoplasmic microfilaments and dense bodies (*arrows*). (Uranyl acetate and lead citrate, Ã—5000.)

The benign myofibroblastic proliferations are generally well-circumscribed lesions, contrary to the poorly circumscribed and often infiltrating quality of reactive and quasineoplastic proliferative conditions; for example, fibromatoses, nodular and proliferative fasciitis, and proliferative myositis, lesions replete with myofibroblasts. Although thought to be composed of myofibroblasts, most of the benign myofibroblastomas were not evaluated ultrastructurally; in the few cases for which this technique was employed, typical myofibroblasts were not found. For similar reasons one might cast a jaundiced eye on the presence of myofibroblasts in mammary myofibroblastomas (289,290), the palisaded myofibroblastoma, the intranodal hemorrhagic spindle-cell tumors with amianthoid fibers of lymph nodes (288,291), soft tissue myofibroblastomas (284), angiomyofibroblastomas of the vulva (281,282), angiomyofibroblastoma-like tumors of the male genital tract (285), meningeal myofibroblastomas (287), and pulmonary myofibroblastic tumors (280). Immunohistochemically, the proliferating cells composing the so-called myofibroblastomas and related neoplasms disclose heterogeneous cytoskeletal phenotypes, such as positive reaction for Î±-smooth muscle actin and absence of reactivity for desmin in the palisaded myofibroblastoma (291) and

intranodal hemorrhagic spindle-cell tumors of lymph nodes (288) and staining for desmin associated with a negative reaction for Î±-smooth muscle actin in angiomyofibroblastoma of the vulva (281). The so-called myofibroblastomas and all other related neoplasms most likely represent myogenic stromal tumors, a designation proposed by BÃ©gin (292), possibly derived from myogenic stromal cells that have variable degrees of smooth muscle differentiation (rather than myofibroblastic neoplasms) because myofibroblasts, using strict ultrastructural criteria, either were not identified or were rare (Figure 6.24).

Sarcomas composed entirely or partially of cells that disclose some degree of morphologic or immunohistochemical features of myofibroblasts but lack the typical ultrastructural traits of myofibroblasts could well belong to the group of myogenic sarcomas (63). One has to remember that for a cell to be classified as a myofibroblast it need not express Î±-smooth muscle actin (134). In fact, whether or not a cell expresses Î±-smooth muscle actin has no bearing on whether or not it is a myofibroblast. In our opinion, while myofibroblastic sarcomas may exist, they are rare and their identification requires electron microscopy (57,58). Finally, to conclude this controversial issue, it might be well to cite Juan Rosai (59):

> Cells with myofibroblastic (myoid) features can be found in a large number of benign and malignant soft tissue lesions, which means that we are in danger of creating a waste-basket category, just as large if not larger than that of malignant fibrous histiocytoma. Therefore, if there is to be a category of myofibroblastic tumors, it would be wise to reserve it for lesions that are composed almost entirely of cells having the hybrid features of myofibroblasts and which do not fit the criteria of already established entities.

Now, a few words concerning inflammatory myofibroblastic tumor (IMT). In the 2002 World Health Organization (WHO) classification of soft tissue tumors, IMT is presented as a clinical/pathologic entity, albeit one that is genetically heterogeneous. Its synonyms are numerous: plasma cell granuloma, plasma cell pseudotumor, inflammatory myofibrohistiocytic proliferation, omental mesenteric myxoid hamartoma, inflammatory pseudotumor, and inflammatory fibrosarcoma. The entity appears to have emerged in a manner reminiscent of malignant fibrous histiocytoma (293). That this tumor discloses predominant myofibroblastic differentiation is questionable. Classically, these tumors present in the lung, mesentery, and omentum of children or adolescents and may be accompanied by fever, weight loss, fatigue, anemia, thrombocytosis, polyclonal hyperglobulinemia, and an elevated erythrocyte sedimentation rate (294). Histologic sections reveal a polymorphous mixture of cells, including spindle cells, plasma cells, lymphocytes, eosinophils, and occasional ganglion-like cells. The spindle cells in 50% of the tumors express cytoplasmic ALK protein, and this correlates with rearrangments of the ALK receptor tyrosine kinase gene at 2p23, as detected by fluorescent in situ hybridization (FISH). This genetic aberration is most commonly seen in pediatric IMT tumors but is not specific for the condition. In addition to anaplastic lymphoma kinase (ALK) expression, p80 is consistently expressed in IMT (295). Most of the tumors are biologically benign; however, up to 25% of the nonpulmonary tumors may recur and, in rare instances, the tumor may metastasize.

Thus, in our opinion, most of the described myofibroblastic sarcomas described are not unequivocally composed of myofibroblasts. That said, we have to admit that a few conditions (particularly malignant neoplasms) composed of spindle cells disclosing ultrastructural features of myofibroblasts have been described, but they are rare (57,296). As for IMT, whether or not this is a specific entity in which the myofibroblast is the principal cell is an open question.

Multiple Origins of the Myofibroblast

Considering the many conditions in which myofibroblasts occur, their heterogeneous cytoskeletal composition, and

the various functions attributed to them, it seems difficult at first glance to assume a common origin for these cells. In 1867, Cohnheim (297) proposed the vascular theory, which states that leukocytes are transformed into fibroblasts during the process of wound healing. Several subsequent studies, however, provided evidence that granulation tissue fibroblasts arise rather from local connective tissue cells (298,299,300,301). As we shall see below, circulating leukocytes and resident tissue fibroblasts are now recognized as precursors to the myofibroblasts found in granulation tissue.

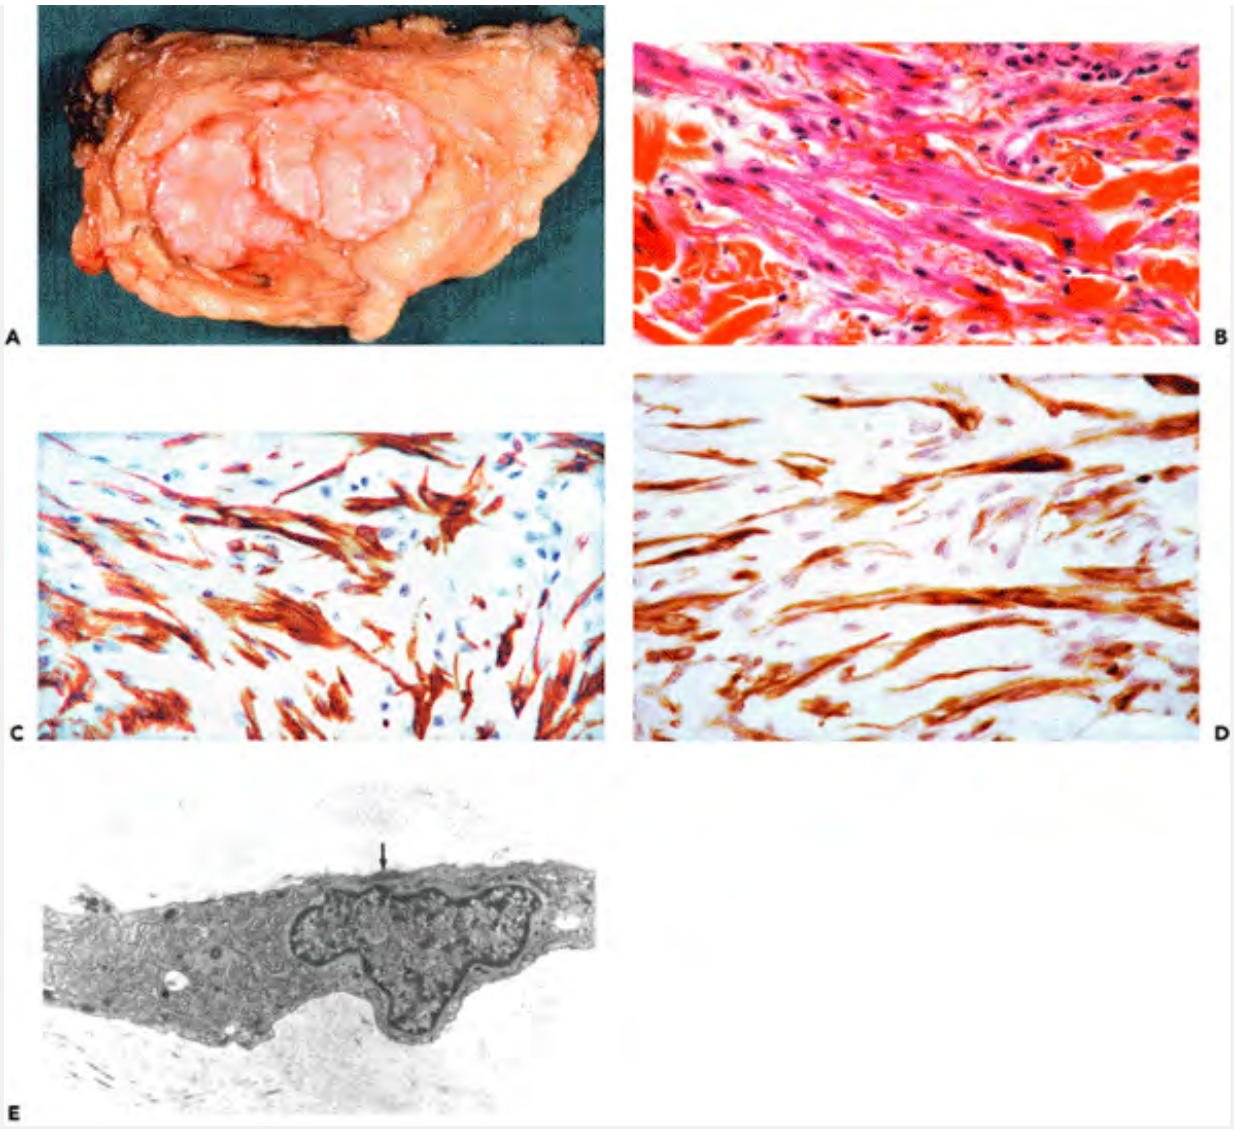

Figure 6.24 Myofibroblastoma of a male breast. A. Gross appearance disclosing well-circumscribed bilobar tumor. B. Histologic aspect illustrating spindle cells with acidophilic cytoplasm and bland nuclei (hematoxylin-phloxine-saffron). C. and D. Intense immunostaining for Î±-smooth muscle actin and desmin. E. Ultrastructural aspect disclosing discrete smooth muscle differentiation. Short bundle of microfilaments and segment of basal lamina (*arrow*). (Uranyl acetate and lead citrate, Ã—17,750.)

Amongst connective tissue cells that could transform into myofibroblasts, any mesenchymal cell is a potential candidate: foremost is the fibroblast, followed by the pericyte and the smooth muscle cell (302). With the accumulated knowledge of cytoskeletal proteins and actin isoforms in these three cell types, both in vivo and in vitro, all of these cells could be considered as possible progenitors of myofibroblasts.

Granulation tissue myofibroblasts are principally derived from local fibroblasts (25,260,303). Within experimental and human granulation tissues, myofibroblasts temporarily express a marker of smooth muscle differentiation, Î±-smooth muscle actin, which disappears after wound closure (25). This suggests that differentiation of myofibroblasts toward smooth muscle cells is only partial, at least during normal wound healing, because myofibroblasts

in this condition never express desmin or smooth muscle myosin heavy chain isoforms.

Recently, the cytoskeletal features of myofibroblasts during wound healing, Dupuytren's disease, and the stroma of mammary carcinomas were investigated. In these three conditions, myofibroblasts disclosed a progressive differentiation toward the smooth muscle phenotype (189). Whereas myofibroblasts during wound healing express only Î±-smooth muscle actin, myofibroblasts in Dupuytren's disease express smooth muscle myosin heavy chains, at least in some cases. An important proportion of myofibroblasts within the stroma of all cases of mammary carcinomas express, in addition to Î±-smooth muscle actin, desmin and smooth muscle myosin heavy chain isoforms. This suggests that fibroblastic cells are capable of proceeding well along the lines of smooth muscle cell differentiation. However myofibroblasts have not been shown to express smoothelin (304,305,306), a terminal smooth muscle cell differentiation marker, in any of the pathologic states examined (305). Hence, smoothelin expression may be used as a discrimination

marker between the two cells.

Ultrastructural data provide evidence that during pathologic or culture conditions, fibroblasts and smooth muscle cells acquire morphologic features resembling myofibroblasts (87,307,308,309,310,311), suggesting that both cell types might be progenitors of myofibroblasts. Indeed, an extensive study on the modulation of mesenchymal cells within the mammary gland stroma when placed in culture in a microenvironment mimicking conditions observed in vivo indicates that although most myofibroblasts are derived from fibroblasts, a certain proportion are derived from vascular smooth muscle cells and a lesser proportion from pericytes (312). With the caveat that it is difficult to extrapolate in vitro data to in vivo situations, this work supports the concept of a heterogeneous origin of myofibroblastic cells.

A vascular origin of the myofibroblast was also proposed on the basis of morphologic observations. It was suggested that desmin-positive cells migrate from the wall of vessels to the tissue (257). A possible source of myofibroblasts expressing vimentin and desmin also are the stromal cells of various organs positive for desmin but negative for Î±-smooth muscle actin (67,183,184,313). The possibility that myofibroblasts arise from specialized mesenchymal cells of certain organs has found a convincing confirmation in recent years. An abundant clinical and experimental literature has shown that, during the onset of experimental and human hepatic fibrosis and cirrhosis, perisinusoidal stellate cells of the liver are the most likely source of myofibroblastic cells (32,314,315,316). The conditions facilitating the modulation of perisinusoidal stellate cells into myofibroblasts have been studied, and extracellular matrix components and cytokines have been suggested as possible initiators (317,318,319,320,149). Similarly, glomerular mesangial cells have been shown to acquire myofibroblastic features, including the expression of Î±-smooth muscle actin and collagen, in several experimental and human pathologic situations (33,229,321,322). Lung septal fibroblasts, which normally possess contractile features

without expressing Î±-smooth muscle actin (323), can be induced to express this protein and collagen type I mRNA upon pathologic stimuli, such as bleomycin treatment (324,29).

Recently, advances have been made demonstrating that myofibroblasts can originate from circulating precursors and also be the product of epithelial-mesenchymal transitions. Buccala et al. (36) have identified a leukocyte subpopulation, named fibrocyte, with fibroblast-like properties. Peripheral blood fibrocytes can rapidly enter the site of injury at the same time as circulating inflammatory cells. It has been suggested that circulating fibrocytes may represent an important source of myofibroblasts during healing of extensive burn wounds, where it may be difficult for fibroblasts to migrate from the wound edge (37). This study has also shown that fibrocyte development is systematically elevated in burn patients. Furthermore, TGF-Î²1, which is elevated in the serum of burn patients (325), stimulates the modulation of peripheral blood mononuclear cells into collagen-producing cells, underlying the well-known role of this cytokine in the differentiation of the myofibroblast (326,27). It has been also shown that bone marrowâ€“derived myofibroblasts contribute to the stroma reaction, at least in experimental situations (325). Another location in which fibrocytes contribute to myofibroblast population is the bronchial submucosa during the development of asthma (327). Epithelial-mesenchymal transition plays an important role in myofibroblast accumulation taking place in kidney interstitial fibrosis, the source of myofibroblasts being tubular epithelial cells, (34) and in dialysis-induced peritoneal fibrosis, the source of myofibroblasts being mesothelial cells (35).

Thus, it appears that several cells, including fibroblasts, vascular smooth muscle cells, pericytes, perisinusoidal stellate cells in the liver, renal tubular epithelial cells, mesangial cells, bloodborne cells (fibrocytes), and mesothelial cells, can modulate (upon appropriate stimulation) into a myofibroblastic phenotype. It should be stressed, however, that the major source of myofibroblasts in whatever setting

they appear is the resident fibroblast.

Mechanisms of Myofibroblast Regression

Granulation tissue formation involves the replication and migration of fibroblasts from normal tissues to the area of inflammation and the modulation of at least a proportion of them to the myofibroblastic phenotype. Angiogenesis takes place in a coordinated way, and granulation tissue acquires its typical features. When the wound closes, a gradual evolution toward scar tissue takes place that involves

the disappearance of vascular cells and myofibroblasts with a proportional increase of extracellular matrix components. This phenomenon, which ends with the establishment of a scar, is more or less rapid according to the species, the location of granulation tissue, and the type of inflammation (7). When granulation tissue cells are not eliminated, there is the development of pathologic scarring (i.e., hypertrophic scars and keloids), which are distinct clinical and pathologic conditions (232), both characterized by a relative high degree of cellularity.

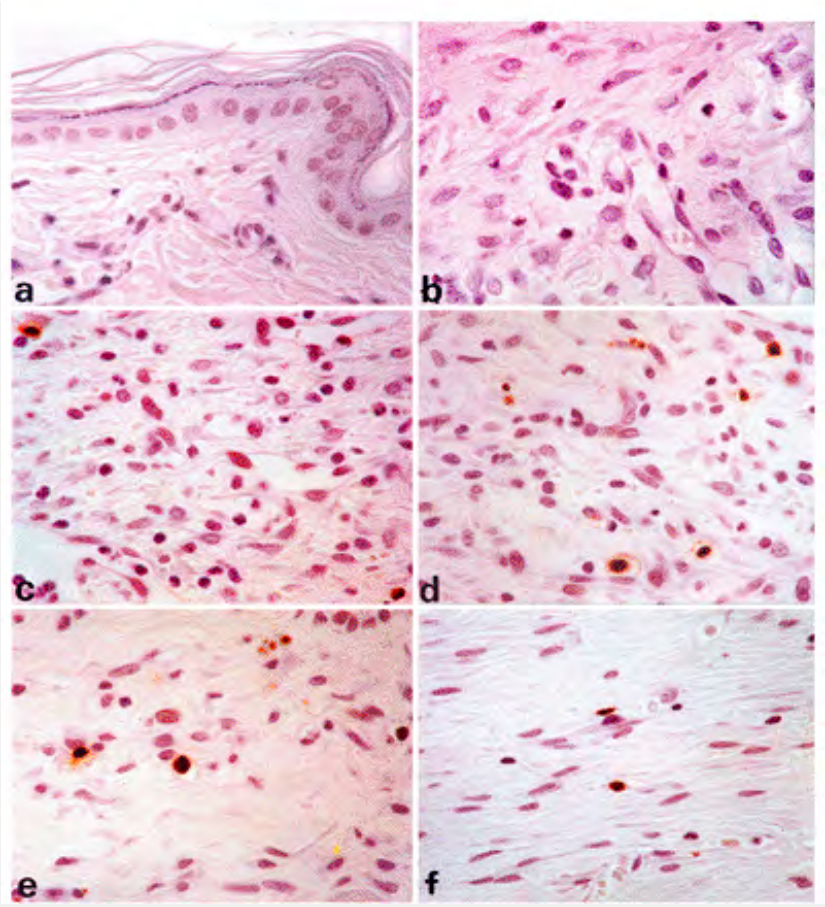

Figure 6.25 Identification of apoptotic cells in rat tissues by in situ end labeling of fragmented DNA. A. Normal rat skin, no apoptotic cells are detected. B. Twelve-day-old wound tissue. C. Sixteen-day-old wound tissue. D. Twenty-day-old wound tissue. E. Twenty-five-day-old wound tissue. F. Thirty-day-old wound tissue. At 12 days, when Î±-smooth muscle actin expression is maximal, there is no nuclear staining for apoptotic cells; after this, the number of labeled cells increases, with a maximum at 20 days (D). Thereafter (E and F), the number of labeled cells decreases. (Aâ€“F, Ã—1000.)

Recently, using several morphologic and biochemical techniques, it has been shown that the reduction in cell number (myofibroblasts

and vascular cells) observed during the transition between granulation tissue and scar formation is achieved to a great extent through apoptosis (Figure 6.25) (31); whether the lack of apoptosis plays a role in the establishment of hypertrophic scar and keloid remains to be explored. It appears that apoptosis of granulation tissue cells takes place essentially after wound closure and affects myofibroblasts and vascular cells over a

period of time, rather than occurring as a single and massive wave of cellular apoptosis. This observation is in line with the gradual resorption of granulation tissue after wound closure and with the observation that dead cells are digested by macrophages and surrounding cells. It appears that granulation tissue cell apoptosis can be accelerated significantly by the application of a viable cutaneous flap (328). This observation underlines the importance of cell communication between normal connective tissue and granulation tissue. These reports suggest that, at least during normal wound healing, the process of myofibroblast differentiation generally ends with cell death; thus, myofibroblasts can be considered terminally differentiated cells.

The question that remains to be answered is the stimulus that leads to apoptosis during wound healing. The loss of mechanical stress seems to be an important signal for differentiated myofibroblasts to de-differentiate and/or disappear. At the end of normal wound healing the extracellular matrix is reconstituted and assumes the mechanical load, thereby releasing embedded myofibroblasts from stress. Myofibroblast apoptosis has been induced by the stress-release of wound granulation tissue after removal of a flap coverage with splinting characteristics in vivo (329) and by the relaxation of attached collagen gels (330,331) in vitro. Fibroblasts in mechanically unrestrained floating versus anchored collagen matrices also show differences in cell proliferation and DNA synthesis. After contraction of floating collagen matrices there is a marked decline in DNA synthesis; the cell cycle becomes arrested and cell regression begins.

In contrast, fibroblastic cells in anchored matrices continue to proliferate and to synthesize DNA.

Recently gene products regulating cell death have been identified (332,333,334,335,336,337). In fibroblasts, the c-myc protein (338) and interleukin-1â€“converting enzyme, the mammalian homologue of the *Caenorhabditis elegans* gene *ced-3* (339), have been shown to induce apoptosis. In turn, it has been shown that the bcl-2 protein is capable of blocking apoptosis (340); however, fibroblasts lack bcl-2 expression, as assessed by antibody staining. A possible mechanism for apoptosis induction could be via the direct action and/or withdrawal of cytokines or growth factors (341,342,343). Several factors have been shown to increase the rate of wound healing, including platelet-derived growth factor (PDGF) (344), TGF-Î² (344,345,346), and tumor necrosis factor (TNF) (347). These factors may be present in the normal healing wound, released by platelets and inflammatory cells (348,349). It is probable that, as the wound heals and resolves, there is a decrease in the level of these factors. A possible explanation for the death of at least a subpopulation of myofibroblasts and vascular cells could be that they are growth-factor dependent. Alternatively, factors selectively causing the death of myofibroblasts and vascular cells might be liberated after epithelialization has been completed. Additional work is necessary to identify these hypothetical factors, but it appears that apoptosis is the mechanism through which vascular and myofibroblastic cells are gradually eliminated from normally healing granulation tissue.

Concluding Remarks

For this third edition, every section has been updated. In addition, several new topics have been added to reflect recent developments; additional photographs have been submitted; the reference list has been expanded.

Since the 1971 discovery of the myofibroblast in granulating wounds, one cannot help but be fascinated with the subject as the body of

knowledge related to this pivotal cell expands, largely through the contributions of cellular and molecular biology.

It would appear that following induction of a large skin wound, resting fibroblasts are triggered through the effects of mechanical forces and possibly yet unknown cytokines released at the wound site to assume a protomyofibroblastic phenotype characterized by the presence of stress fibers that contain cytoplasmic actin isoforms. These cells continue to modulate and eventually assume a myofibroblastic phenotype characterized by Î±-smooth muscle actin incorporation into stress fibers and the formation of specialized â€œsupermatureâ€• focal adhesions. This process is regulated by TGF-Î²1 and ED-A cellular fibronectin and results in connective tissue remodeling with an increase of extracellular matrix synthesis, collagen type III in particular, and tissue retraction (i.e., wound contraction). Recent studies strongly indicate that the forces generated by myofibroblast stress fibers produce isometric tension; this is different from the reversible contraction taking place in smooth muscle cells and involves the Rho/Rho-kinase pathway, as well as regulated activity of myosin phosphatase.

As wound healing approachs completion, genes that encode for apoptotic proteins are expressed to initiate myofibroblastic cell death; the formerly cellular wound is then converted into a poorly cellular scar. Commensurate with this, there is a shift from collagen type III to collagen type I gene expression and synthesis, resulting in the deposition of type I collagen that provides strength to the developing scar. Furthermore, cytokines that stimulate extracellular matrix synthesis early on are repressed once wound closure is completed and a functional basement membrane has been synthesized; this suggests the existence of a feedback loop (350). It is likely that deviations from this finely orchestrated process contribute to the development of hypertrophic scars and keloids.

Regarding the diverse assortment of quasineoplastic myofibroblastic proliferative processes, the cellular/molecular mechanisms central to

their pathogenesis remain essentially unexplored.

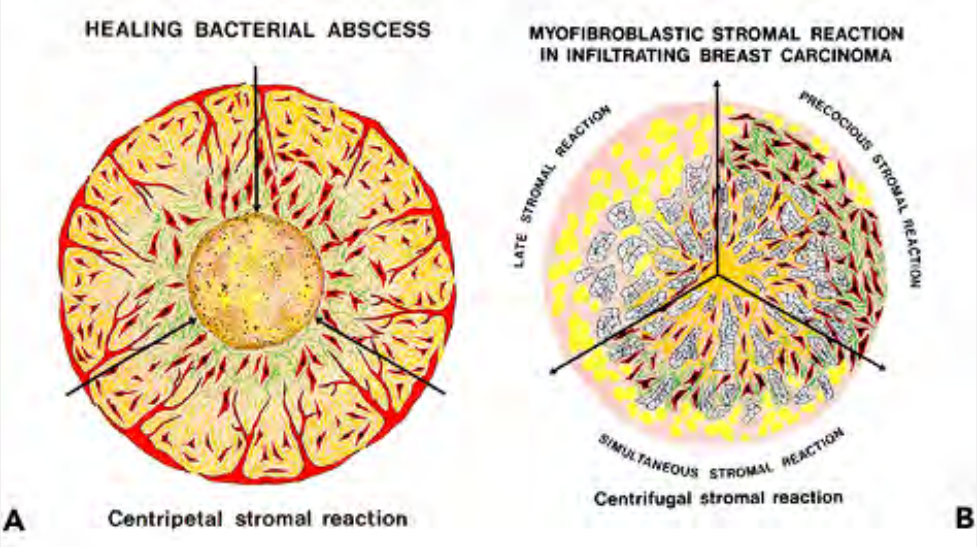

Figure 6.26 Schematic illustration of the stromal reaction. A. In a healing bacterial abscess, the cicatrizing layer is at the periphery, and the two layers containing myofibroblasts (exudativo-productive and exudative, respectively) are developing toward the center. B. In infiltrating ductal breast carcinoma, the cicatrizing area is in the center and myofibroblasts are disposed variably in the peripheral invasive cellular front of the carcinoma; precocious (preceding the invasive carcinoma cells), simultaneous (amongst the invasive carcinoma cells), and late (following the invasive carcinoma cells). In normal wound healing the stromal reaction is centripetal; whereas in invasive ductal breast carcinomas, the stromal reaction is centrifugal, indicating that cancers are wounds that do not heal.

Turning to the myofibroblastic response associated with diverse invasive and metastatic carcinomas, it was originally proposed that

this represented an expression of host response to the cancer. The hypothesis appears valid today, although one could posit whether this is beneficial since many of these cancers, despite the attending desmoplasia, continue to exact lives. Yet, death, in these settings, stems largely from the ability of the neoplastic cell to enter vascular channels and disseminate. It remains possible that these myofibroblasts, while affecting contraction and elaborating collagens and other extracellular matrix components, also release enzymes that permit tissue and vascular invasion. Recently, the mechanisms regulating the cross talk between tumor cells and stroma myofibroblasts have started to be clarified (351). Thus, it appears that the concomitant production of growth factors and/or cytokines (such as TGF-Î², hepatocyte growth factor, or stromal cellâ€“derived factor-1) and synthesis of extracellular matrix components (such as tenascin) by stromal myofibroblasts stimulates the invasive activity of malignant epithelial cells (352,353,354). If one considers that during development connective tissue remodeling plays an important role in epithelial morphogenesis (353), it is possible to conceive that cross talk between stroma and epithelium regulates both physiologic and pathologic epithelial organization. Clearly, future studies of human cancer should focus not only on the neoplastic cell, but also on the regulation of extracellular matrix synthesis and the cell-to-extracellular matrix interactions of tumors (i.e., the stroma).

Twenty-four years ago (22), we proposed that similarities might exist between the process of wound healing and the stromal response to neoplastic invasion. This assumption may also be extended to quasineoplastic proliferative conditions (e.g., Dupuytren's disease). During normal wound healing and within nodules of Dupuytren's disease and possibly other quasineoplastic proliferations, the myofibroblastic/fibroblastic reaction appears to be centripetal (Figure 6.26A), whereas within neoplastic invasion this reaction is centrifugal (Figure 6.26B), indicating that cancers are wounds that do not heal (355). The underlying cellular/molecular mechanisms explaining these fundamental differences, including the presence, delay, or

absence of apoptosis, remain to be explored.

Finally, we conclude, as in the 1997 edition, with a most intriguing report uncovered in a literature search of TGF-Î². It would appear that fetal skin wounds in a murine model heal without scarring; such wounds, apart from that contained in platelets, are devoid of TGF-Î² (356). Once again, one is reminded of the lessons to be learned by study of the events of early life.

Acknowledgments

This work was supported in part by the Cancer Research Society Inc., Montreal, Canada, the Swiss National Science Foundation (Grant No. #31-61.336.00 to GG and 3100A0-102150/1 to BH), and the Macdonald Stewart Foundation, Montreal, whose benefactors, Mrs. Liliane Stewart and the late David M. Stewart, have generously supported the Department of Pathology of the HÃ´tel-Dieu Hospital of Montreal over many years. We thank Mr. Som Chatterjee and Ms. Myrielle Vermette for skillful technical assistance and Mr. Jean-Jacques Dufour for the photographic work.

Adipose Tissue

John S.J. Brooks

Patricia M. Perosio

Introduction

In compiling this chapter, our intention was to provide practicing surgical pathologists with both a description of normal and abnormal adipose tissue and a reference source. We were inclusive in our approach and considered all bodily lesions containing mature fat appropriate for discussion regardless of site. The section on development should provide a deeper understanding for the diagnostician and a starting point for the researcher. Collected and detailed as a group are the fatty infiltrations of organs, the inflammations affecting fat, the hamartomas and mesenchymomas, and the lipomas and variants thereof. Up-to-date definitions are provided where necessary. Importantly, we have also summarized clinical and genetic syndromes in which fat cells may participate. Unusual but distinctive histologies are enumerated, such as may occur in starvation, pancreatic fat necrosis, and true lipodystrophy. All topics are well-referenced, hopefully providing the reader with a valuable resource. In short, we have attempted to describe

as many lesions as possible, not just primary fatty entities, but also

anything extraneous within adipose tissue or confused with it.

White Fat

Prenatal Development

The morphology of developing adipose tissue has been studied in detail. By examining serial sections obtained from 805 human fetuses of various ages, Poissonnet et al. (1) have determined that prior to the second trimester of pregnancy, adipose tissue primordia cannot be identified by light microscopy. After 14 weeks' gestation, aggregates of mesenchymal cells are seen condensed around proliferating primitive blood vessels. They refer to these findings as stage II in the development of adipose tissue (Figure 7.1). Prior to this time, future adipose tissue is characterized by loose spindle cells and ground substance (stage I). Later on, capillaries continue to proliferate into a rich network, around which preadipocytes become stellate and organized into a mesenchymal lobule (stage III). These preadipocytes do not contain lipid. With further development, fine lipid vacuoles characteristic of stage IV accumulate within cytoplasm (Figure 7.2). Continued proliferation of the components of the lobule results in the formation of densely packed aggregates of vacuolated fat cells with a rich capillary vascular network. Finally, condensation of perilobular mesenchyme at the periphery of the lobule results in formation of fibrous interlobular septa in stage V. This process occurs over the 10-week period between the 14- and 24-week gestation period. From approximately 24 to 29 weeks, the number of fat lobules is relatively constant. Continued growth occurs mainly due to proliferation of capillaries and adipocytes, causing an increase in the size of the fat lobules (Figure 7.2).

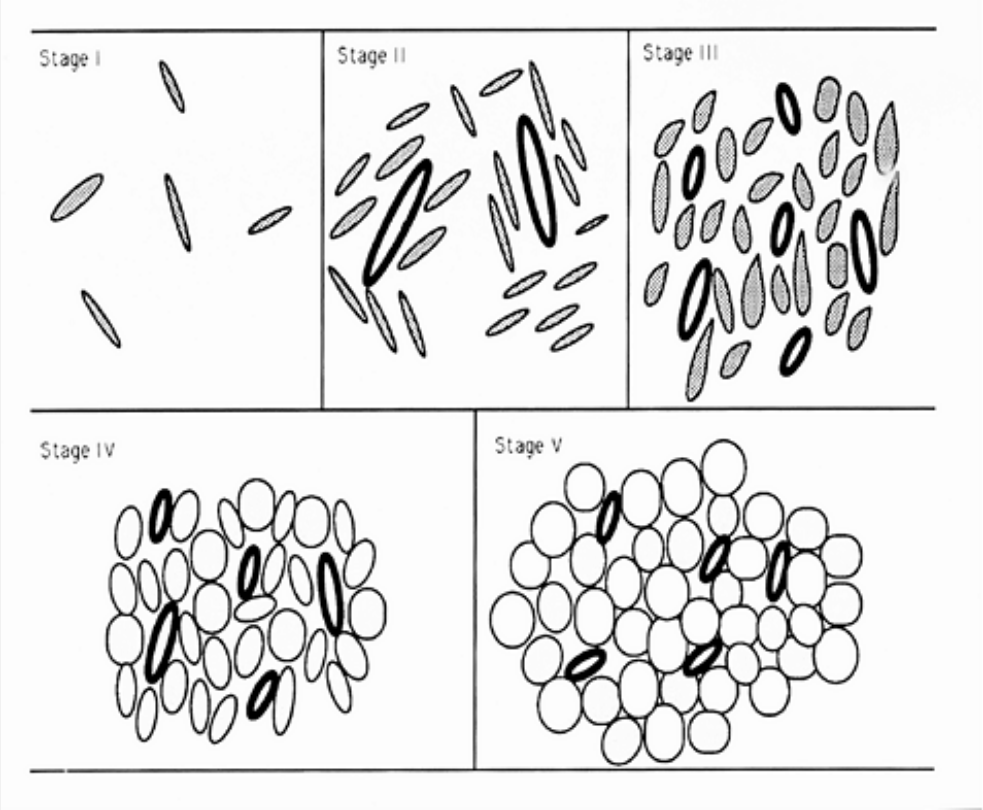

Figure 7.1 Developmental stages of adipose tissue. Stage I: Stellate cells (*stippled*) embedded in amorphous ground substance. Stage II: As angiogenesis begins, mesenchymal cells (*stippled*) condense around the blood vessels (*bold ovals*). Stage III: A rich capillary network develops from each vessel, forming a glomerulus-like network around which each lobule forms. The preadipocytes become more stellate. Stage IV: With accumulation of lipid, these adipocytes, with multiple small lipid droplets, become closely packed around the capillaries. Stage V: Further accumulation of lipid with many unilocular cells (*clear circles*) is evident. The perilobular mesenchyme condenses into interlobular septa at this stage.

The same sequence of development of adipose tissue occurs at all

sites throughout the body (2). The earliest white fat lobules appear first in the face, neck, breast, and abdominal wall at 14 weeks' gestation. By 15 weeks, they are also evident over the back and shoulders. Development in the upper and lower extremities and anterior chest begins around the sixteenth week. By the end of the twenty-third week, a layer of subcutaneous fat completely covers the extremities.

There is a very close association of adipocyte development and angiogenesis. Fat appears first in well-vascularized regions, such as the shoulder joint, before differentiation can be identified in the less well-supplied adjacent subcutaneous tissue. There is also an important physiologic significance to this close anatomic relationship. Lipoprotein lipase, the hormone responsible for transfer of triglyceride from circulating lipoproteins to adipose tissue, is synthesized by adipocytes and transferred to the luminal surface of the capillary endothelium (3). Thus, this close spatial relationship provides efficient transfer of enzyme and lipid.

Because of this close developmental association of capillaries and adipocytes, some have proposed that the adipocyte precursor, or preadipocyte, actually is derived from endothelial cells (4). Others have felt the preadipocyte may be a perivascular reticulum cell, perivascular fibroblast-like cell, or undifferentiated mesenchymal cell. The presumptive adipocyte precursor has been characterized ultrastructurally in the newborn rat (5). The preadipocyte is

a spindle cell with four to five cytoplasmic extensions along its long axis and abundant rough endoplasmic reticulum (ER). Lipid accumulates first as small droplets adjacent to the nucleus. As more lipid appears, it coalesces into a single large vacuole, and the cell takes on an oval then, finally, a round shape. The amount of rough ER decreases as the cell matures. Although cell shape and abundance of rough ER were taken as supportive evidence for the common origin of the preadipocyte and the fibroblast, which has a similar ultrastructural appearance, these similarities may have been a

coincidence. The immature adipocyte needs to synthesize and excrete lipoprotein lipaseâ€”thus the abundant rough ER. Fibroblasts synthesizing and secreting procollagen would be expected to have a similar array of organelles.

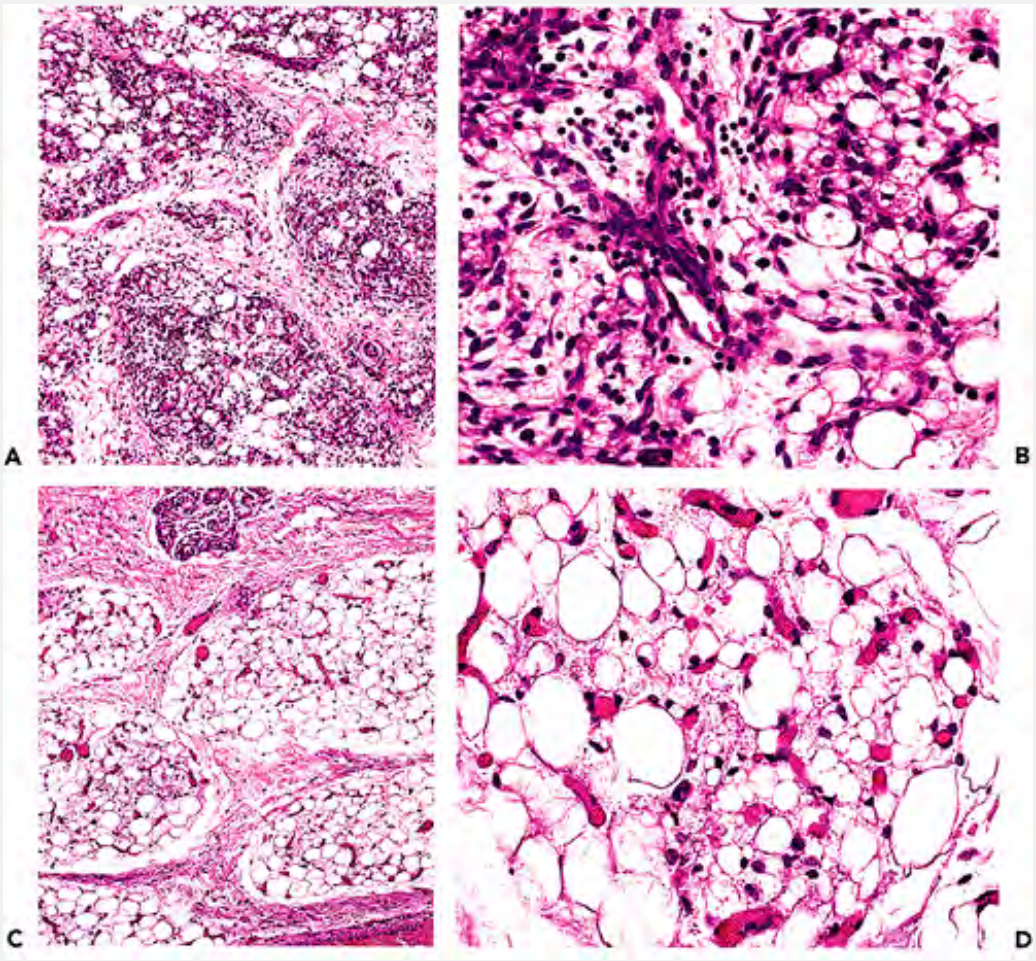

Figure 7.2 Fetal fat. A. Fat lobules from a 25-week fetus with a myxoid quality and prominent vasculature. B. At high power, both univacuolated and multivacuolated cells are noted together with small capillaries. C. and D. By 37 weeks, the lobules are more developed (C) and many of the cells are univacuolated (D).

As the preadipocyte accumulates lipid to become an adipocyte, both

multilocular and unilocular adipocytes can be seen. Multilocular adipocytes predominate at first. With further lipid accumulation, more cells assume the unilocular appearance characteristic of mature adipocytes. Thus, attempts to differentiate brown from white adipocyte tissue at the light microscopic level, which rely on the presence of multivacuolated cells to characterize and identify brown fat, are not reliable. Reliance on ultrastructural and biochemical differences helps to distinguish between these different forms of adipose tissue.

Molecular Biology

Through work on the adipocytic neoplasm known as myxoid liposarcoma (MLS), at least one gene involved in adipocytic differentiation has been identified. The translocation t(12;16)(q13;p11) of that tumor disrupts the normal function of the *CHOP* gene found at 12q13. First, the *CHOP* gene was shown to be rearranged in nearly all MLS (6), and, subsequently, the actual breakpoint was cloned (7,8). The *CHOP* gene, also known as *GADD153*, encodes a member of the CCAAT/enhancer binding protein (C/EBP) family and has a DNA binding domain. It appears to be involved in normal adipocyte differentiation because the protein it produces may be a dominant inhibitor of other C/EBP transcription factors known to be important in cell proliferation (9). Members of this C/EBP group are highly expressed in fat and are involved in the differentiation of fibroblasts into adipocytes and in the growth arrest of terminally differentiated adipocytes (6). *CHOP* itself is

induced in the differentiation of 3T3-L1 cells to adipocytes. In the neoplasm, the translocation results in a fusion gene involving *CHOP* and *TLS* (translocated in liposarcoma), an RNA binding gene with much similarity structurally and functionally to the *EWS* gene of Ewing's sarcoma. Presumably, the lack of the normal inhibitory function of an intact *CHOP* gene allows the fatty tumor to proliferate unchecked. The use of both Southern blots and fluorescent in situ

hybridation (FISH) techniques in detecting the rearranged gene will have usefulness in the diagnosis of fatty tumors. Likewise, when it becomes commercially available, antibody to the CHOP protein might be used immunohistochemically to detect such tumors.

Apoptosis, or programmed cell death, probably occurs in adipocytic tissues, but studies localizing the bcl-2 protein in human fetal tissues fail to mention its detection in fat (10).

Postnatal Development

At birth, the average-size infant has approximately 5 billion adipocytes (11). This represents only 16% of the total number of adipocytes in adults. Adipose tissue continues to grow in parallel with general growth throughout the first 10 years of life. Fat cells enlarge significantly during the first six months of life without much increase in cell number (12). Until puberty, the cell size remains fairly constant while the number of adipocytes progressively increases. At puberty, there is a substantial increase in adipocyte size and number (12). Although at the end of puberty, the total number of adipocytes is similar to the adult, new adipocytes may continue to form throughout life (13). Studies on adult rats have shown that overfeeding results in proliferation of adipocyte precursors and development of new fat cells (14). De novo adipocyte formation can be triggered by overdistension of existing fat cells and the mass of stored triglycerides (15). Loss of fat cells may also occur and has been shown in overweight women following several years of strict dietary restriction (16).

Gender Differences

The differences in body fat content noted between men and women begins in early childhood. Young girls are fatter than boys. Studies on fetuses, however, have not noted differences in the pattern of distribution or quantity of fat in prenatal life (1). The distribution of

adipose tissue, however, even in prenatal life is not homogeneous throughout the body. Gender differences in the distribution of adipose tissue following puberty are well-known and thought to be related to steroid hormone secretion (12). In humans, estrogens and progesterone induce an increase in trochanteric fat. The localization of more fat in the lower body in women results in the so-called gynecoid habitus. These same deposits are reduced by androgens in men, resulting in an android distribution of fat. The percentage of body fat also differs in men and women. Males reach a peak in body fat content during early adolescence, whereas women continue to accumulate fat relative to body weight throughout the teen years.

Functions

White adipose tissue is the body's largest energy store, and it possesses the enzymes necessary for the uptake and release of triglycerides. Briefly, triglycerides circulate in the blood in the form of chylomicrons from the intestine and very low density lipoproteins from the liver (17). Lipoprotein lipase present on the luminal surface of endothelial cells hydrolyzes the triglyceride to release free fatty acids. This enzyme is synthesized by adipocytes and transferred to the endothelial cells. Most of the free fatty acids are taken up by the fat cells and reesterified to glycerol phosphate within the adipocyte to form triacylglycerol, which is then stored within the cell's lipid droplet. The fat is mobilized through the action of hormone-sensitive lipase, which hydrolyzes stored triglycerides. The released free fatty acids may be reesterified or released to the circulation and bound to albumin for transfer to other cells.

Until recently the main endocrine function of adipose tissue was thought to be the conversion of androstenedione to estrone, the major source of estrogen in men and postmenopausal women. The aromatase action, however, has been localized to the stromal cell fraction of adipose tissue and not the adipocyte (18). More recently a dynamic role of adipose tissue has emerged with expression of

several hormones, growth factors, and cytokines identified in adipocytes, stromal cells, and macrophages that are localized to adipose tissue. These include leptin, a regulator of energy expenditure and appetite; interleukin-6, which may play a role in the metabolic syndrome; and several important regulators of glucose and lipid metabolism, the complement cascade, and the fibrinolytic system.

Leptin, the protein product of the *ob* gene, is synthesized exclusively by adipocytes and acts on the hypothalamus to increase energy expenditure and decrease appetite (19). This pathway is well-established in rats. In humans, fasting lowers serum leptin levels and increases appetite (20). Unfortunately elevated or rising levels of leptin do not show the reverse effect, and leptin has not been shown to have an anti-obesity action in humans. The majority of obese individuals have elevated serum leptin levels, proportional to the amount of adipose tissue, and it is postulated that humans are leptin resistant (21). Leptin receptors are present on most tissues, and leptin may play a role outside the adipose tissue to accelerate wound healing, increase vascular tone, and inhibit bone formation (22).

Cytokines are secreted by adipocytes, stromal cells, and resident macrophages. Interleukin-6 (IL-6) is made by adipocytes and macrophages, and adipose tissue accounts for approximately 30% of circulating IL-6 in humans (23).

Like leptin, serum IL-6 levels are highly correlated with percent body fat. The IL-6 released from intra-abdominal stores enters the portal circulation. Hepatic triglyceride secretion is stimulated by IL-6, and this may contribute to the hypertriglyceridemia seen with visceral obesity (22). Interleukin-6 also stimulates hepatic secretion of acute phase reactants, increases platelet number and activity, and increases expression of endothelial adhesion molecules. There are ongoing investigations of the role this cytokine (which is derived in large part from adipose tissue) plays in the metabolic syndrome and the risk of cardiovascular disease in obesity.

Adipocytes also secrete C3 and adipsin, the proteins of the alternate complement pathway (24). Plasminogen activator inhibitor-1 (PAI-1) is a potent inhibitor of the fibrinolytic system and favors the development of thromboemboli. Insulin induces expression of PAI-1 by adipocytes, and elevated levels are seen with obesity (25).

Regulation

White adipose tissue contains numerous receptors for hormones, cytokines, catecholamines, and lipoproteins. Catecholamines acting through Î±-2 receptors inhibit lipolysis, and a predominance of Î±-2 receptors in gluteal fat of women is thought to impact maintenance of these fat stores despite weight loss (17). Regional differences in lipoprotein lipase levels (LPL) also occur in women. Gluteal fat in premenopausal women tends to have high LPL levels, and these regions contain larger fat cells. Such regional differences disappear after menopause and are not present in obese men (26,27). This suggests that the sex steroids also play a role in adipose tissue distribution and activity. Both androgens and estrogen modulate *ob* gene expression and control adipose tissue development (28,29). Androgens are antiadipogenic and estrogens proadipogenic. These may play a role in the regional differences in fat distribution and the development of the android and gynecoid patterns of obesity.

Insulin stimulates lipogenesis and glucose uptake while inhibiting fat breakdown. Insulin and glucocorticoids stimulate DNA synthesis in cultured human adipocytes and conversion of preadipocytes to mature adipocytes. These effects are enhanced on cells obtained from obese, as compared to lean, people. Estradiol-17Î² has also been shown to stimulate division of cultured preadipocytes obtained from both men and women. Progesterone acts in vitro to stimulate both preadipocyte division and LPL activity (30). This dual role facilitates triglyceride accumulation in women. Fibroblast growth factor 1, secreted by adipose-derived microvascular endothelial cells, stimulates preadipocyte differentiation and acculumlation of

triglycerides (31).

Tumor necrosis factor alpha (TNF-Î±) and IL-6 have the opposite effect and are implicated along with leptin in the weight loss and anorexia of chronic wasting illnesses and cancer (32,33). TNF-Î± is expressed in preadipocytes and acts to block differentiation to mature adipocytes through CCAAT/enhancer binding protein alpha (C/EBP-Î±) (34). It also suppresses lipoprotein lipase and stimulates the mobilization of fatty acids. The TNF-Î± induces the release of IL-6 and leptin from adipose tissue, and the action of these cytokines is closely interrelated.

In addition to adipocyte function, fat cell size and number are also regulated. Numerous studies using tritiated thymidine incorporation as a marker for cell division in adipose tissue have been done in rats to identify mitotically active cells within fat. Mature lipid-laden adipocytes are generally considered to be incapable of cell differentiation because of the absence of mitotic figures seen histologically in normal adipose tissue. Sampling fat from rats injected with tritiated thymidine at 1 day and 3 days of age, which are then sacrificed at various times up to 5 months of age, has shown that the number of labeled cells in subcutaneous fat initially rises due to cell proliferation. The concentration of radioactivity then falls, probably as a result of a dilutional effect resulting from continued cell division (35). This study, however, failed to distinguish adipocyte from stromal labeling. Similar studies had been performed on rats in which the subcutaneous tissue is separated into stromal and adipose components. In one study, the specific radioactivity of the adipocyte fraction did not increase until two to five days after injection (36). Thus, they concluded that DNA synthesis occurs in nonlipid-laden cells or preadipocytes. As these cells accumulate lipid, labeled cells are detected within the adipocyte fraction.

Gross Aspects

Fatty tissue is typically a homogeneous, bright cadmium-like yellow,

with a glistening and greasy surface texture, and finely divided by faint septa. Any variation in color indicates a pathologic process: white to white/yellow in fat necrosis, paler yellows in many lipomas, reddish tinge to orange/yellow in angiolipoma, definite gray/white to whitish streaks in spindle cell lipoma, and white/yellow to white nodules in liposarcoma.

Histology

Microscopically, a mature white fat cell is spherical and measures up to 120 *Âμ*m in diameter (37). The cytoplasm is compressed at the perimeter of the cell, and only a thin rim of cell membrane is evident on hematoxylin-eosin (H&E)â€“stained sections. Reticulin and periodic acid-Schiff (PAS) stains highlight the adipocyte basement membrane (Figure 7.3). The cytoplasm is displaced by a single lipid vacuole, and the cells are fairly uniform in size (Figure 7.4). The nucleus, although oval, is thin and small with finely distributed chromatin; when seen in profile, a central minute clear vacuole may be seen within the nucleus (Figure 7.4). Normal subcutaneous fat is finely divided into ill-defined lobules by thin bands of collagen (Figure 7.5).

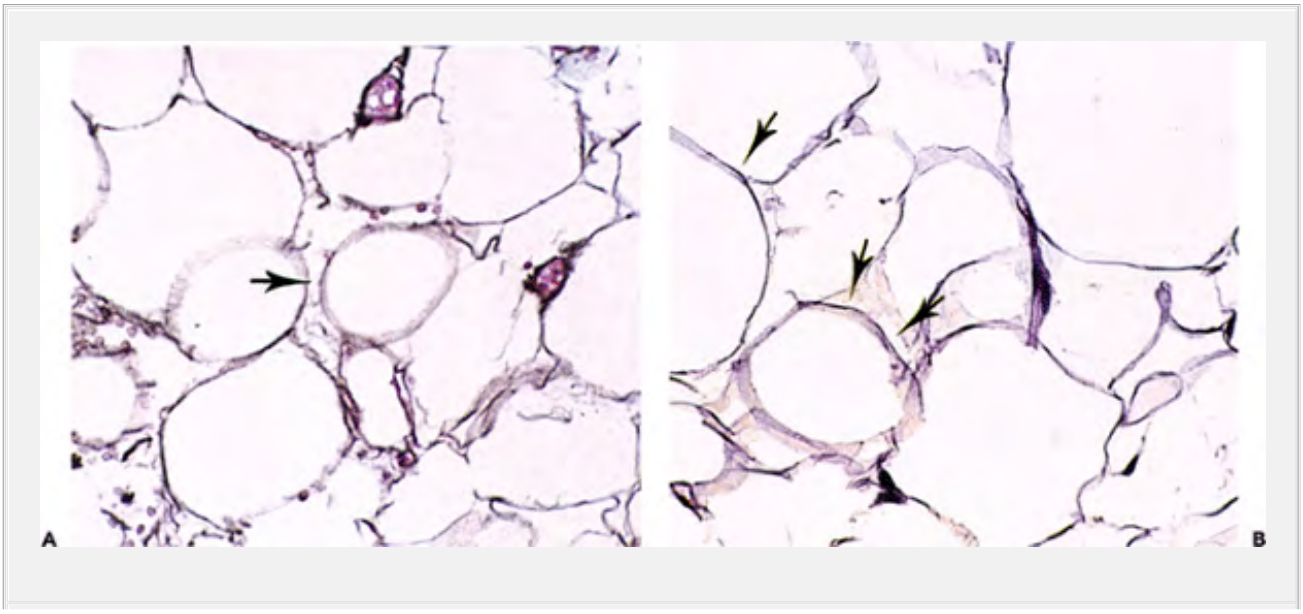

Figure 7.3 Normal adult adipocyte. A. On a reticulin stain, each adipocyte is outlined by reticulin (*arrow*), which is present outside the cytoplasm. B. The same is true on PAS stain, where the basement membrane is highlighted (*arrows*) and encompasses the pale residue of cytoplasm remaining after fixation and embedding.

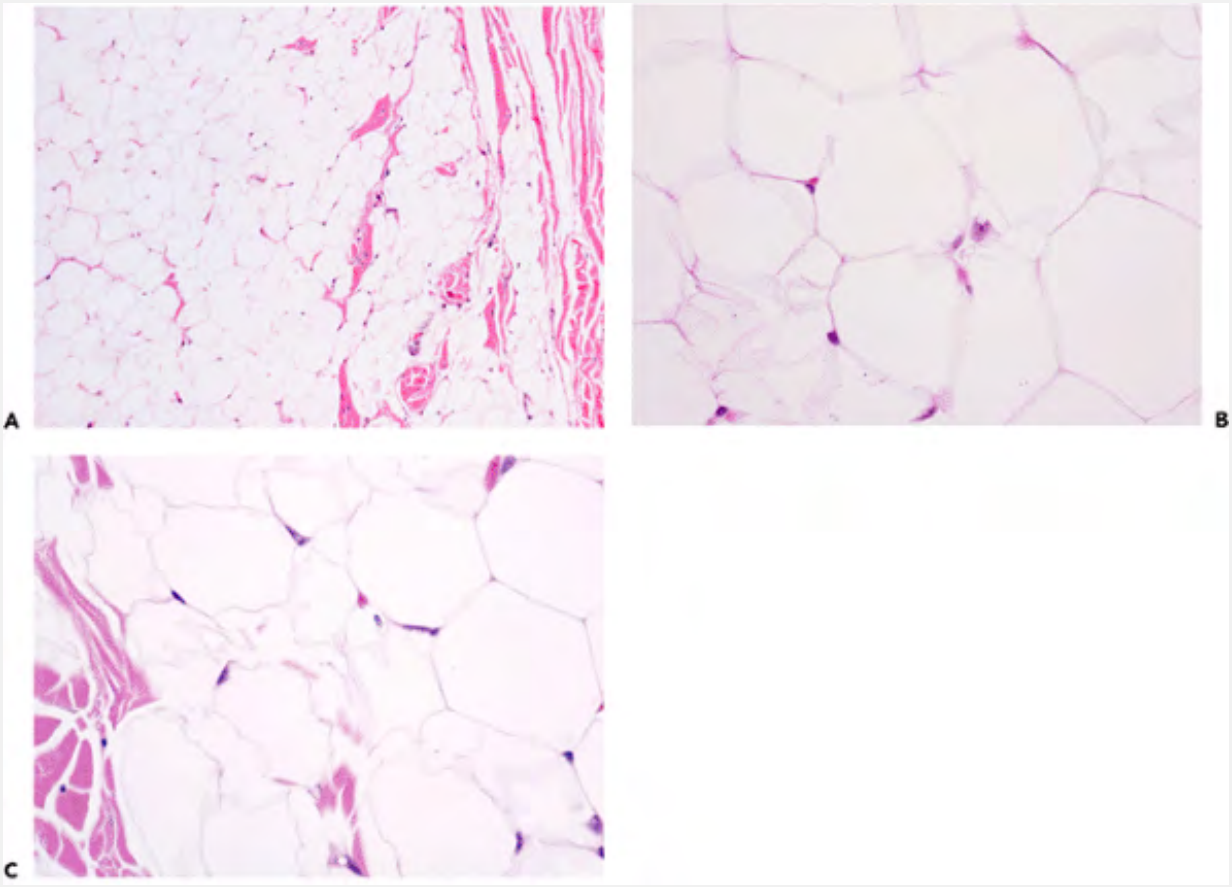

Figure 7.4 A. At medium power the size of subcutaneous adipocytes appears relatively uniform. B. At high power, pale areas represent portions of basement membrane and cytoplasm cut on the bias. Nuclei of capillary endothelial cells are present at intersections between multiple cells. C. In contrast to other

nuclei, an ideal section of an adipocyte nucleus shows a pale character due to its thin nature and the common central vacuole, or â€œLocherne.â€• The wrinkled cell outlines are an artifact occasionally seen, the result of improper fixation.

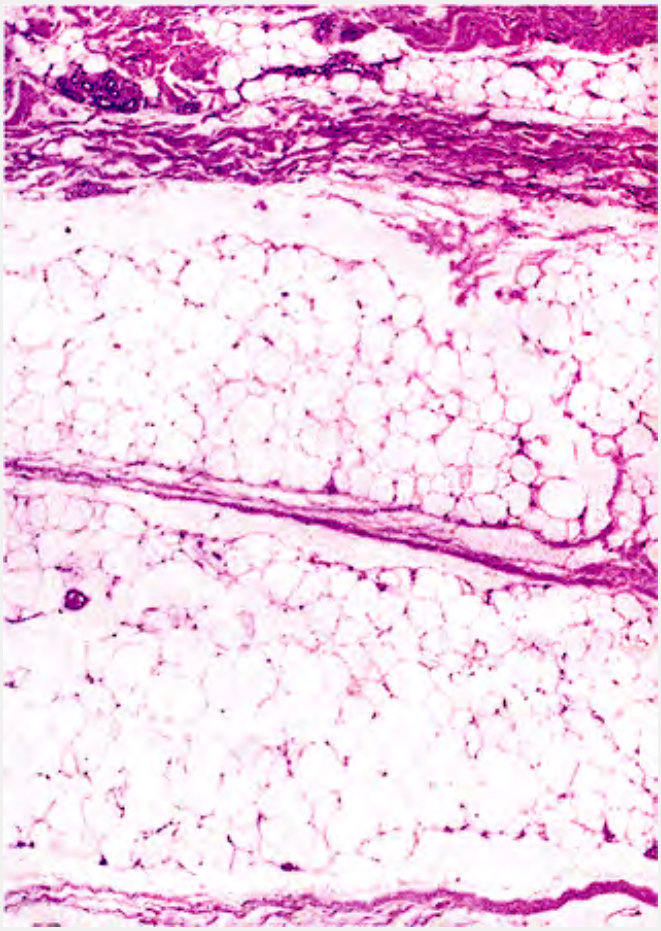

Figure 7.5 Adult subcutaneous fat lobule with associated microvasculature; note the thin and delicate fibrous tissue septa.

Ultrastructure

The ultrastructure of developing adipocytes has previously been discussed. In brief, a spindle shape with abundant endoplasmic reticulum and small spherical mitochondria characterizes preadipocytes (37). Lipid accumulates as small perinuclear inclusions that coalesce to form larger lipid droplets. The mitochondria become filamentous and the endoplasmic reticulum less prominent. In a mature adipocyte, the nucleus is flattened against the cytoplasmic membrane by a large lipid droplet. There is only a thin, tenuous rim of cytoplasm that surrounds it. Pinocytotic vesicles are seen in variable numbers but are very numerous following periods of starvation. Adjacent to the cell membrane are deposits of basement membrane. Capillaries are closely opposed to the adipocyte basement membrane. Only rarely have nerves been identified adjacent to white fat cells, although they may be seen in intercellular collagenous septa.

Brown Fat

Prenatal Development

The development of brown adipose tissue has been studied in animal models. The brown adipocyte precursors are spindle cells closely related to a network of capillaries (38). As the cells and vessels proliferate, they are organized into lobules by connective tissue septa. As the cells accumulate lipid, they initially are unilocular. However, with further lipid accumulation, multiple cytoplasmic lipid vacuoles appear. As in white fat, the close association of developing adipocytes and blood vessels has led some to speculate that adipocytes actually develop from endothelial cells. Although similar ultrastructural features are cited as supportive evidence of theory, more recent investigations have attributed these similarities to a common origin from undifferentiated mesenchyme. In fact, ultrastructural and biochemical studies that have examined developing brown adipose tissue have shown that unique features

such as large mitochondria and a unique mitochondrial protein are found early in development and distinguish brown from white fat.

Fetal necropsy studies have identified lobules of developing brown fat in the human fetus (39). The largest of these are from the posterior cervical, axillary, suprailiac, and perirenal regions. Those in the neck and axillae are closely associated with the major blood vessels of these regions in such a way that they extend along the course of the cervical blood vessels into the root of the neck. The suprailiac collections lie deep to the abdominal muscles, yet superficial to the peritoneum, and invest the anterior abdominal wall to the diaphragm. Intermediate-sized brown fat pads are seen in the interscapular paralateral trapezius and deltoid regions. Small collections are evident in the intercostal area. In this study, no difference was noted in distribution between the sexes or among the races. The amount of brown fat increases in proportion to growth throughout life. Deposits are well-established by the fifth month of gestation.

Postnatal Development

The presence of brown fat beyond the neonatal period in humans has been debated. An autopsy study by Heaton (40), however, has identified lobules of brown fat throughout life to the eighth decade. Brown fat is most widely distributed in young children and, over the next several decades, gradually disappears from most sites. In children under age 10, identifiable deposits of brown fat were identified in the interscapular region, around the neck vessels and muscles, around the structures of the mediastinum, and adjacent to the lung hila. Intra-abdominal and retroperitoneal deposits were noted around the kidneys, pancreas, spleen, mesocolon, and omentum, as well as in the anterior abdominal wall. The extremities were not sampled. Although brown fat disappeared from most areas, it was found to persist around the kidneys, adrenals, and aorta and within the mediastinum and neck throughout adult life. As in fetal life, no difference in distribution based on gender was noted.

Function

The main function of brown adipose tissue is heat production. It has been estimated that the maximal aerobic capacity per gram of tissue is almost 10 times that of skeletal muscle (41). It has been estimated that even in humans the small quantities of brown fat present are capable of raising heat production by over 20% (42). The production of heat is closely related to the active sympathetic innervation of brown fat and stimulation by norepinephrine. Release of norepinephrine results in the production of cyclic adenosine monophosphate (AMP) and lipolysis to release free fatty acids (43). These undergo oxidation within the mitochondria to produce adenosine triphosphate (ATP). Brown fat mitochondria contain a unique uncoupling protein, also known as thermogenin, which uncouples the oxidation of fatty acids from generation of ATP (44,45). The resultant energy is dissipated as heat. In small rodents and hibernating animals, brown fat is activated by cold temperatures to produce heat, resulting in what is known as nonshivering thermogenesis. Teleologically, this would be useful in those at risk for hypothermia. Thus, neonates, unable to alter the external environment in order to maintain body temperature, would be expected to have relatively more active brown fat than adults. In addition, brown fat accumulation and activation may play a role in weight regulation. Experimentally overfed rats show a compensatory increase in brown fat activation in metabolic rate, minimizing weight gain (46). Many types of obesity in laboratory mice and rats are related to defective regulation of brown adipose tissue, including that seen in ob/ob mice (47). In contrast, exaggerated leanness may be associated with excessive brown adipose tissue responsiveness to external factors, such as sympathetic stimulation. Although brown adipose tissue is present in humans, its role in weight regulation, obesity, and thermal regulation in adults remains controversial (48). Increased amounts of periadrenal brown fat in malnourished people

at autopsy suggest a compensatory increase in nonshivering thermogenesis to maintain body temperature in those with diminished subcutaneous fat and cachexia (49).

Regulation

Unlike white fat, brown fat is highly innervated and regulated by sympathetic stimulation. Nerves enter each lobe and branch within the interlobular septa, running along the vessels to terminate on the fat cells (50). Brown fat cells have numerous Î²1- and Î²2-adrenoreceptors that regulate lipolysis and thermogenesis (43). The Î±-adrenoreceptors, although present, probably do not act directly in heat production. Norepinephrine also may act to increase the number and character of brown fat cells. Using continuous infusions of norepinephrine, Mory et al. (51) have shown that such chronic sympathetic stimulation results in increased cellularity, increased protein content, and increased mitochondrial density in brown fat. Because of this close association of sympathetic activity and brown fat activity, several investigators have used pheochromocytoma as a model to study brown fat activities in humans. These studies have provided evidence supportive of early autopsy studies. Functional brown adipose tissue was identified in adults with pheochromocytomas that had similar biochemical features to the better-characterized brown adipose tissue of rodents (52).

Hormones also play a role in brown fat regulation, but it is minor in comparison to the sympathetic system. Thyroid hormone, although active in regulating metabolic rate, has little importance in diet-induced or nonshivering thermogenesis (43). Insulin stimulates glucose intake into brown adipose tissue. Both cortisol and gonadal steroid hormones inhibit thermogenesis, thus promoting energy conservation.

Histology

The term *brown fat* was applied to this tissue because of its characteristic gross appearance. It is incorrect to refer to it as â€œfetalâ€• fat because it is present throughout life. The abundant vascularity and numerous mitochondria within the cells impart a characteristic reddish-brown color to the tissue. Brown fat has a glandular lobulated appearance. This is in contrast to the more diffuse growth pattern of white fat. Histologically, brown fat is organized into lobules of cells that are made up of adipocytes, capillaries, nerves, and connective tissue. These are surrounded by a thin, fibrous capsule containing blood vessels, nerves, and scattered white adipose cells (53). The cells are polygonal in shape, with a mixture of multivacuolated and univacuolated cells (Figure 7.6). The occurrence of both cell types is emphasized, and

their presence in developing white fat initially confused studies on its origin. The multivacuolated cell, characteristic of brown fat, has a highly granular cytoplasm with numerous lipid inclusions. Its granular appearance is due to the numerous mitochondria necessary for thermogenesis. The nucleus is spherical and often centrally located, although a large lipid inclusion may displace it toward the periphery of the cell or, rarely, to the extreme perimeter (as in white fat). Small nucleoli are common. The unilobular cells are indistinguishable histologically from the mature signet-ring cellâ€“type white adipocytes but are different ultrastructurally. On average, the size of the brown fat cells is smaller than white adipocytes, approximately 25 to 40 *Âµ*m. In animals that hibernate, marked seasonal variation in cell size has been noted. Both exposure to cold and starvation result in lipid depletion, causing reduction in cell size and wrinkling of the cell membrane.

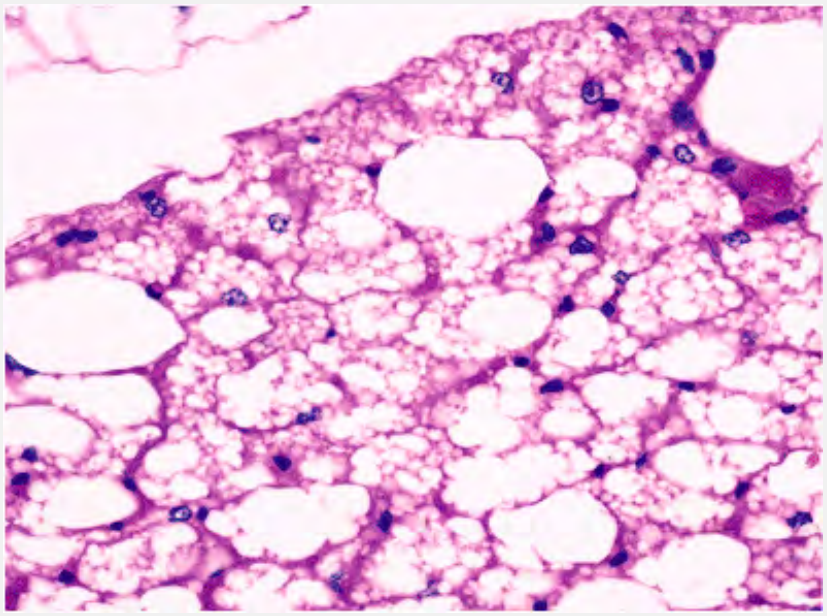

Figure 7.6 Normal adult brown fat. Nearly all cells have centrally placed nuclei and multivacuolated cytoplasm. Rare cells (*top left*) are nonvacuolated. An arborizing thin capillary network is noted.

Brown adipose cells are surrounded by a network of collagen fibers that contain numerous minute nerve axons and blood vessels. Nonmyelinated axons terminate on the fat cells, providing an avenue for direct sympathetic regulation. The vascularity is quite prominent with numerous capillaries coursing between the adipocytes. It is estimated in rats that the vascularity of brown fat is four to six times greater than that of white fat (53).

Histochemistry

Enzyme Histochemistry

In development, enzyme histochemistry within developing adipocytes is related to the stage of adipocyte differentiation. In fact, in some

systems, such as the rat, it is clear that enzymatic differentiation of adipocytes precedes morphologic differentiation (54,55). In regions destined to become adipose tissue, undifferentiated morphology is initially present without a capillary bed and without any enzymatic capacity. Subsequently, immature cells or what can be termed â€œpreadipocytesâ€• exist in the form of spindle cells within an area containing a capillary bed. These cells lack any lipid or a basal lamina and have a large complement of enzymatic activity; but they lack the capability to release fat as a result of the absence of esterase (lipase). In mature lobules, adipocytes in the form of rounded cells now contain lipid, a basal lamina, and a well-developed capillary bed; the entire complement of enzymatic activity is present, including NADH-tetrazolium reductase, ADPH-tetrazolium reductase, and glucose 6-phosphate dehydrogenase (G6PDH). Malate dehydrogenase (NADP) activity is acquired only by late-stage adipocytes (54). Hausman and Thomas (54) demonstrated the presence of such enzymatic differentiation before the assumption of an obviously rounded cell shape consistent with an adipocyte.

Lipoprotein lipase is an enzyme found at high concentration in fatty tissues. It is involved in the transport of serum triglycerides into adipocytes in the form of fatty acids. However, it can be found in other tissues such as skeletal muscles (56,57) and cardiac muscle (58), where it may be localized to endothelial cells. Concentration in fat is directly related to the serum insulin concentration.

Lipid Histochemistry

Lipids in adipose tissue are generally identified using various stains, such as oil red O and Sudan IV (59,60,61,62,63,64,65). It should be noted that lipids are lost in formaldehyde after prolonged fixation, and, thus, cases to be tested using frozen cryostat sections of fixed material should be obtained as soon as possible. Of the two time-honored lipid stains mentioned, oil red O gives the more intense stain and is more rapid to perform. Sudan black B may stain nonlipid

substances (such as coagulated proteins) nonspecifically. As a rule, neutral fats are detected using these fat stains. However, a differential staining pattern between neutral fats and fatty acid components and phospholipids can be obtained with the Nile blue sulfate stain (66); with this stain, neutral fat stains pink to red, and fatty acids and phospholipids stain bluish. The lipid composition of fatty tissues may also be investigated using new techniques such as the hot-stage polarizing-light microscopic method (67).

The normal composition of lipid in white adipose tissue consists of 99% triglyceride in the form of neutral fat and less than 1% in the form of phospholipid, cholesterol, and fatty acids (53). In less-differentiated adipocytes, such as those found in liposarcomas, there is a shift away from neutral fat to phospholipids and cholesterol (66). Unfortunately, lipid stains appear to have little use in the everyday examination of adipocyte lesions. The droplets seen on the stains may represent nonspecific staining, and a variety of other mesenchymal lesions may contain lipid (64). An exception is the distinction between lesions with artificial vacuoles, such as epithelioid smooth muscle lesions, which are negative with fat stains.

Intracellular Lipid in Nonadipocytes

Lipid may accumulate in a variety of other cell types and in nonadipocytic tumors.

Steatosis

According to *Stedman's Medical Dictionary* (68), steatosis has two main meanings: adiposis and fatty degeneration (e.g., steatosis cordis = fatty degeneration of heart). These terms (and the terms used in a variety of pathology texts) are unclear, and the distinction between intracellular lipid accumulation and adipocyte infiltration of organs is not

made. When nonadipocytes store lipid intracellularly, the phrase *lipid*

accumulation is accurate; in the liver, the term *steatosis* is used; and, in major pathology texts (69,70), the term appears to be applied solely to the hepatocyte. However, intracytoplasmic lipid can be found within other solid organs, such as the heart [in the myocardial fibers in hypoxia (69)] and the kidney [in the renal tubule in diabetes, poisonings, Reye's syndrome (71)]. Theoretically, there is no reason why these processes cannot be referred to as myocardial or renal tubular steatosis. Regardless, in referring to intracellular lipid accumulation, terms such as *lipid accumulation* or *steatosis* are preferable to unclear and archaic designations, such as *adiposis* or *fatty degeneration.* Discussion of adipocyte infiltration of organs is found later (see the section entitled Syndromes Associated With Fatty Lesions (including Lipomatosis).

Lipid accumulation may occur in the placenta after prolonged parenteral nutrition; there, it takes the form of foamy vacuoles within the syncytial and Hofbauer cells of the chorionic villi (72).

Aside from adipocytes, lipid in the form of cholesterol and cholesterol esters may be identified in cells with a steroid-producing function in organs, such as the adrenal, ovary, and testis (and tumors thereof). In addition, other types of lipid are found within a variety of tumors. In practice, it is generally thought that a lipid stain (e.g., oil red O) can aid in the differential diagnosis of certain tumors. For example, it is well-known that renal cell carcinomas typically contain lipid (73), and most pathologists have the impression that many other tumors do not. However, it is clear from studies four decades ago (74) that fat stains are positive in the majority of cancers (Table 7.1). Thus, there are problems with the use of the fat stain in the diagnosis of carcinoma, and caution should be exercised in interpretation. Furthermore, although some clear cell lesions in the differential diagnosis of renal cancer contain glycogen (benign sugar tumor of lung) (75), others such as xanthoma of bone (76) contain lipidâ€”and thus a fat stain is of no assistance.

Table 7.1 Oil Red Oâ€“Positive Carcinomas[a]

Squamous cell carcinoma	Ovarian carcinoma
Gastric carcinoma	Breast carcinoma
Lung carcinomas	Prostatic carcinoma
Renal cell carcinoma	Thyroid carcinoma
Lymphoma, large cell	Myeloma

[a] For the majority of cancer types, a high percentage of the tumors listed showed a positive reaction.

Immunohistochemistry

Currently, there is no commercially available specific immunohistochemical marker for adipose tissue. However, an adipocyte lipid-binding protein, p422 or aP2, is a protein expressed exclusively in preadipocytes late in adipogenesis. Preliminary studies with an antibody to aP2 demonstrate that it stains only lipoblasts and brown fat cells and is capable of identifying liposarcomas selectively (77). This may be quite useful diagnostically in the future.

Adipocytes and tumors thereof stain positively for vimentin; and, in our experience, adipocytic tumors have been negative for

cytokeratin, desmin, and muscle-specific actin. In 1983, Michetti et al. (78) were the first to describe S-100 immunoreactivity in adipocytes, specifically of rat origin. The S-100 protein was extracted and shown to be identical to that found in the rat brain. Ultrastructurally, S-100 reactivity was widely dispersed within adipocyte cytoplasm but was not found within mitochondria, lipid droplets, or most of the endoplasmic reticulum. In a similar ultrastructural study, Haimoto et al. (79) identified S-100 protein in the plasma membranes, in membranes of microvesicles, and within polysomes. The Golgi apparatus was negative for this marker, although some reactivity was found within the rough endoplasmic reticulum. During the process of lipolysis in fat cells, Haimoto et al. (79) noted a change in the distribution of S-100 antigen and suggested that S-100 protein molecules interact with free fatty acids, indicating that this protein may act as a carrier protein for free fatty acids.

The S-100 protein is a highly acidic calcium-binding protein of molecular weight 21,000. It consists of two polypeptide chains (Î± and Î²) and may occur as dimers in three ways: S-100a (Î±, Î²), S-100b (Î², Î²), or S-100ao (Î±, Î±) (80). When fat cells have been analyzed, they have been shown to contain only S-100b (Î² form), like Schwann cells (80,81). In the routine practice of immunohistochemistry, adipose tissue reacts in a variable fashion (Figure 7.7), accounting for some negative reactions observed by Kahn et al. (82). Although lipomas and liposarcomas are reported to be frequently positive with S-100 (83,84,85,86), in our experience, this has not been true. Regardless of fixation with formalin or Bouin's solution, very few liposarcomas have exhibited S-100 immunoreactivity.

Adipocytic lesions do not stain with antibodies to neuron-specific enolase (87).

Obesity

Human obesity is thought to be approximately 60% genetic in origin, with multiple genetic and environmental factors involved (88). The role of brown adipose tissue (BAT) was briefly alluded to earlier, and new research continues to underscore its importance. For example, in transgenic mice engineered to lack BAT, obesity develops routinely (89). In

mice, the genetics of obesity are more clear than in humans. A team at the Rockefeller University led by Dr. Friedman first reported the identification of the *ob* mouse gene and showed that mutations of it are associated with the development of obesity (90). These same researchers have located the human counterpart (*OB* gene) (90) and mapped its location to chromosome 7 (91). The human protein produced by this gene has 84% homology with the mouse protein, appears to be a hormone secreted by adipose tissue, and likely functions as part of a pathway to regulate body fat. If, indeed, a defective hormone is responsible for some forms of obesity, then there is an immediate therapy available in the form of fully intact native hormone. In 1995, several research groups (92,93,94) have shown that injection of the ob protein into mice causes the animals to lose weight and maintain their weight loss. Even obesity due to a nongenetic defect like excess diet fat is corrected by the ob protein, now called leptin.

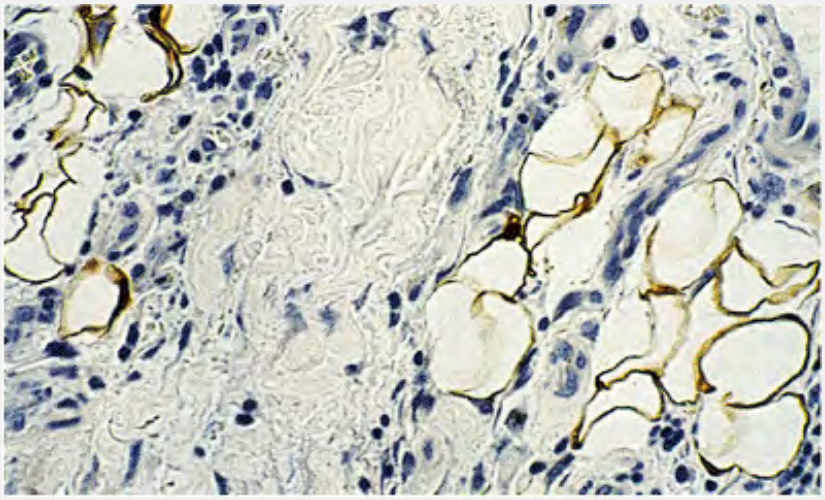

Figure 7.7 S-100 immunohistochemistry. Reactivity is seen both in the nuclei and in the cytoplasm surrounding the lipid droplets. Such S-100â€“positive results appear to vary considerably from case to case, probably reflecting fixation differences.

Finally, the receptor for this protein has been identified recently and shown to be nonfunctional in obese animals (95). Clearly, there have been major advances constituting a breakthrough in obesity research, and the fruits of this research should affect human therapy soon.

Adipocyte Lesions

Terminology

In contrast to other human tissue cell types, the terms *hypertrophy* and *hyperplasia* are not usually applied to the adipocyte. It is stressed here, however, that adipocyte hypertrophy (or increased fat cell size) is a recognized phenomenon and is found, for example, in obesity. Enlarged, or hypertrophic, fat cells (>120 *Âµ*m or so) can also be identified in neoplasia (lipoma and liposarcoma) where cells

appear to have three or four times the normal diameter (e.g., >300 Âµm). Hyperplasia (or an increased number of adipocytes), in contrast to widespread belief, is a definite occurrence. Again, it is common in obese patients, but it may also be seen in organ-based infiltrations; these are a type of site-specific adipocyte hyperplastic processes. Mature adipocytes are incapable of regeneration, and new fat cells are added through in situ mesenchymal cell differentiation recruited from primitive perivascular cells. No disease or change involving adipocytes can appropriately be termed a degeneration (as mentioned earlier), other than liquefaction with necrosis. Atrophy of adipocytes may be seen in malnutrition, starvation, or as the effect of chemotherapy (see the section entitled Atrophy). The appearance of mature fat cells as small foci in unusual places is termed *metaplasia* and is discussed in a later section. Localized new growths of either pure adipocytes or mixtures of adipocytes in other tissue constitute neoplasia and are presumably clonal entities.

Degeneration

In the condition sclerema adiposum neonatorum, the subcutaneous fat is grossly and microscopically abnormal. Rubbery plaques are due to fat necrosis and degenerative individual fat cells with intracellular needle-shaped crystals (96). This fat crystallization is brown and can be highlighted by polarization. Such crystals apparently may also be identified in up to 30% of stillbirths as a general degeneration following intrauterine demise (96). In another disease, Neu Laxova syndrome, a defect in lipid metabolism causes a lardlike appearance to the adipose tissue and is lethal.

Atrophy

The changes in fat lobules during starvation or malnutrition are particularly noticeable in the subcutaneous region or the omentum. Individual fat cells are reduced in size and fat content, and those without much lipid take on a rounded or epithelioid appearance (97).

In the extreme, lobules of these epithelioid cells can simulate tumor nodules histologically (Figure 7.8). The cytoplasm is variable in amount and is eosinophilic or granular with or without small lipid vacuoles of differing size, depending on the severity of the malnutrition. Some cells have a multivacuolated appearance. The intervening region between cells is constituted by homogeneous eosinophilic or amphophilic myxoid ground substance (Figure 7.8) that is probably an extract of serum, although stimulation of proteoglycan matrix by the process of starvation (98) is possible. As part of this involution process, lipofuscin is deposited within the shrinking cells (Figure 7.8). Importantly, each lobule retains its overall oval shape, although markedly reduced in size and considerably separated from other lobules (Figure 7.8). In extreme cachexia, only streaks of tissue remain.

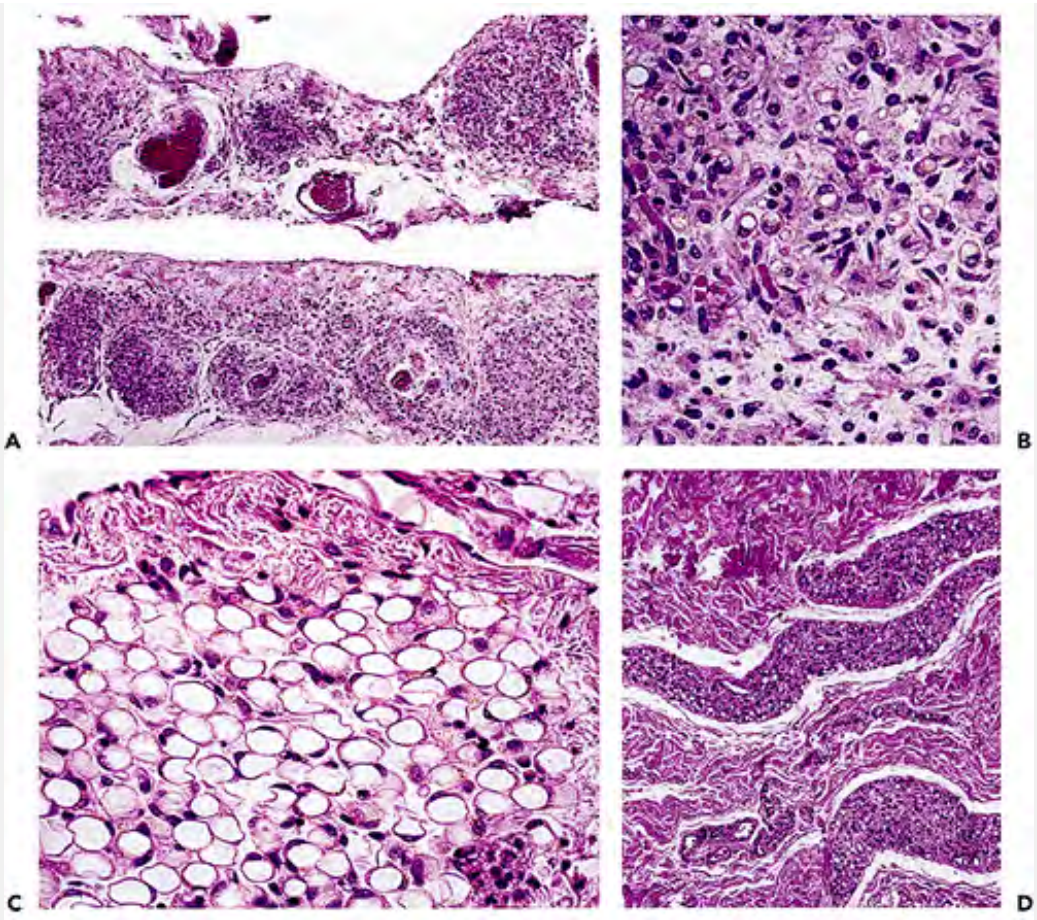

Figure 7.8 A. The extreme atrophy seen here in the omentum of a patient with anorexia nervosa may mimic tumor deposits. B. At high power, shrunken eosinophilic cells are seen with occasional vacuoles and lipofuscin pigment. C. In less severe starvation, these omental adipocytes are well-recognized, although much smaller than normal size; again, note the presence of pigment. D. In the skin, severe cachexia secondary to a cancer resulted in marked involution of the cutaneous fat lobules, which appear only as elongated streaks.

Nearly identical changes can also be seen in the white adipose tissue of fasted animals. As the cells gradually lose their lipid, the single lipid droplet breaks up into multiple vacuoles. Gradually, all lipid

disappears. These cells become small and ovoid in shape, sometimes measuring only 15 Âµm in diameter (99). There is an apparent expansion of pericellular collagen in such a way that these cells appear as clusters of mesenchymal cells in fibrous stroma. Ultrastructurally, multiple pinocytotic vesicles are seen clustered along the entire cell membrane (53). Lipid is not seen within these vesicles, and their significance is unknown.

In the bone marrow, chemotherapy causes changes referred to as serous atrophy or gelatinous transformation (100,101). The majority of the fat cells have been destroyed, leaving scattered adipocytes of varying size remaining. No lobular appearance is present in the marrow, but the interstitial compartment is composed of the same eosinophilic myxoid substance described previously, again probably consisting of serum fluid and proteins. Droplets of lipid scattered about are also found and, upon regeneration, may appear as foci of lipogranulomas.

Although the microscopic features of the starvation effect on human brown fat have not been described, animals maintained on a dextrose-thiamine diet are known to show distinct morphologic changes in brown fat (37). The mitochondria are disrupted and large, irregular electron-dense inclusions are seen within the mitochondrial matrix. The cristae may assume a mosaic pattern with compartmentalization of the material. These cells revert to normal after 24 hours of a normal diet. Similar changes in white fat mitochondria have not been seen with starvation, suggesting that the active mitochondria of brown fat are particularly labile and sensitive to dietary changes.

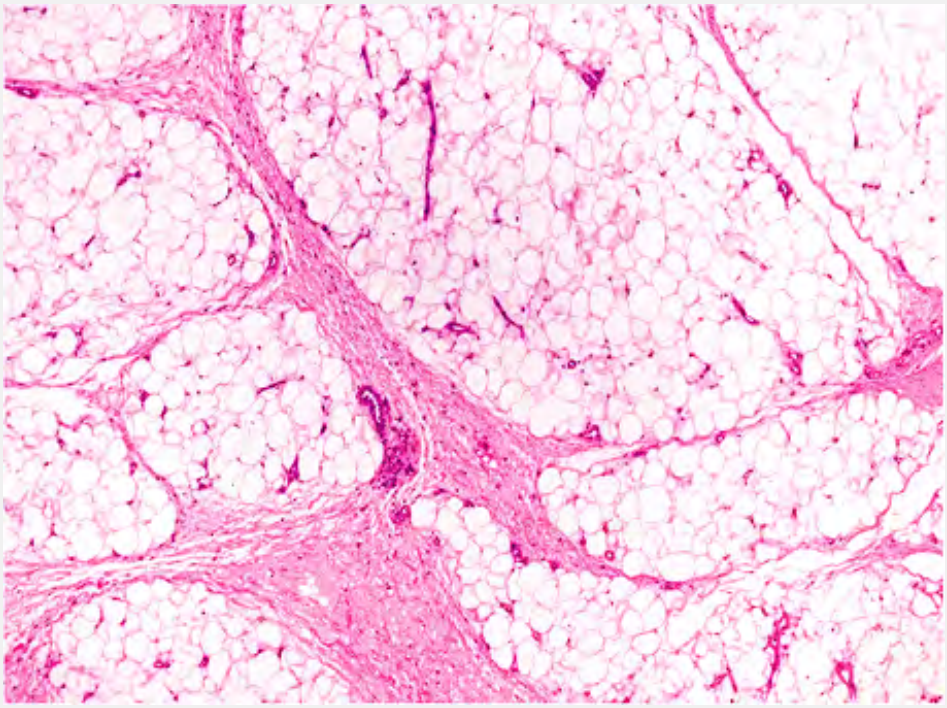

Figure 7.9 Accentuated fat lobules in ischemia of the lower extremity. Loose myxoid connective tissue widens the septa between lobules; edema and a mild inflammatory infiltrate are present.

Cellulite

The term cellulite is applied to the external skin when it exhibits linear depressed streaks (mattress phenomenon) or frank dimpling. Cellulite is typically found on the thigh and buttocks and is more common in females; it can be divided into incipient cellulite and full-blown cellulite. The former results from an uneven undersurface of the dermal-hypodermal interface, with fibrous tissue surrounding the protruding papillae adiposa; vertical fibrous strands of uneven thickness divide the hypodermal fat (102). In contrast, full-blown

cellulite consists of a delicate meshwork of collagen fibers produced by increased hypodermal pressure of fat accumulation and increasing fat volume. Scattered CD34+ fibroblasts are seen in both forms of cellulite. Unlike women, men have a more smooth, strand-free dermal interface in the thigh and buttock areas (102).

Ischemia

Little is written about the effect of ischemia on the adipocyte. We have observed changes in the subcutaneous fat of legs removed for atherosclerotic vascular disease. They consist of accentuation of the lobular architecture by thickening of the fibrous septa; wider and more myxoid in quality, the septa are edematous and also contain scattered inflammatory cells (Figure 7.9). Actual necrosis was not observed.

Metaplasia

As surgical pathologists, we most frequently encounter adipocytic metaplasia, usually calcified, in cardiac valves (Figure 7.10). There is little in the literature or textbooks on this phenomenon. The emergence of mature adipose tissue seems to parallel the appearance of osteoblasts forming bone within the calcific deposits. Once adipose tissue is present, bone marrow precursors may become resident, presumably from circulating cells, and cause hematopoiesis. Metaplasia is not limited to this site and may be encountered in calcified large vessels or elsewhere, such as in laryngeal cartilage undergoing ossification. We have even seen it in small ossified bronchioles. A similar phenomenon of hematopoiesis without adipose tissue and bone has been reported within acoustic neuromas (103).

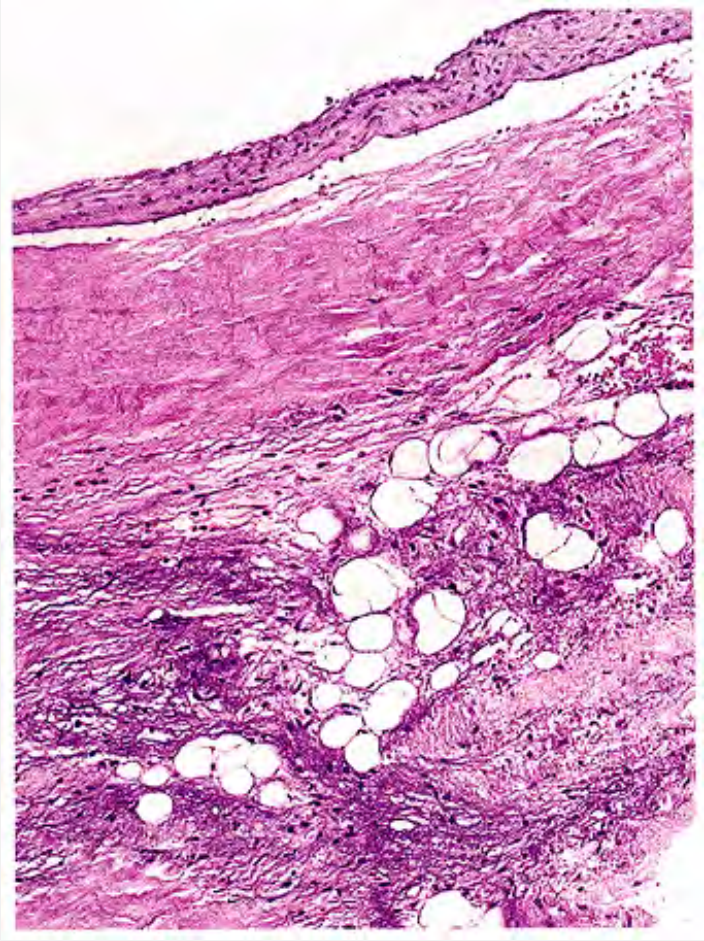

Figure 7.10 Fatty metaplasia of cardiac valve. Mature adipocytes are found in a myxoid background but are more commonly seen in association with calcification or ossification.

Lipodystrophy

Although there are several different entities referred to in the past under this name, some (idiopathic intestinal lipodystrophy, or Whipple's disease) are infectious and others (mesenteric lipodystrophy; see section entitled Mesenteritis) are inflammatory

disorders without fundamental changes in the fat cells themselves. The one example of a true lipodystrophy is called membranous lipodystrophy, a relatively new clinical entity characterized by abnormal fat cells, bone cysts with pathologic fractures, and leukodystrophy of the brain (104,105,106). The marrow fat is particularly affected (104), but the â€œmembranocysticâ€• lesions are also present to a lesser degree in the subcutaneous adipose tissue (106). The characteristic and pathognomonic finding is the highly shrivelled, undulating outline of individual fat cell membranes, giving them hyalin eosinophilic convolutions or â€œarabesque profiles.â€• Multiple small cysts are found, apparently formed by fusion of ruptured adipocytes. Young adults are affected in Japan and Finland primarily, but five cases have been seen in the United States (105). Its etiology and pathogenesis are unknown; it is probably related to an enzyme deficiency (104). A secondary form of membranous lipodystrophy has been described in association with lupus erythematosus and morphea profunda (107). Interestingly, the membranous changes in fat characteristic of lipodystrophy can also be seen in normal fat affected by radiation therapy (108).

Adipocytes in Organs

Fatty Infiltration

As distinct from lipid accumulation or steatosis (see section entitled Steatosis), fatty infiltration is defined as the presence of mature adipose tissue in sites not normally containing fat. This is a disorder or condition relating to adipocyte cell growth and, therefore, the term *fatty degeneration* is a misnomer and incorrect. In some situations, such as within extremity muscle groups, the process of fatty infiltration is often related to atrophy of the involved site (109). This association between fatty infiltration and atrophy or involution is also noted in other organs [thymus (110), bone marrow (111), and kidney (112)], and apparently signifies the propensity for adipocytes

to fill a vacuum, in a sense, left by atrophic processes (97). Whatever the stimulus may be, the adipocytes probably arise from pleuripotent mesenchymal cells adjacent to blood vessels (97). The reversal of this relationship is found in the parathyroid gland, where there is an inverse relationship between parenchymal cells and adipocytes, to the point where no adipocytes are present in complete parathyroid hyperplasia.

Nonatrophic organs can also accumulate fat cells (lipomatosis), and the classic examples are the heart and pancreas (69). In these locations, no parenchymal damage is discerned, and the process is a type of accidental lipogenesis (97). In the case of the pancreas, normal parenchymal histology and function are present even though the pancreas may be nearly invisible grossly (69,113). This type of pancreatic lipomatosis is correlated with age and obesity and also occurs in diabetics (113). The amount of pancreatic tissue is thought to be either completely normal (69) or partially depleted (113). However, true pancreatic atrophy with resultant lipomatosis also exists as a rare condition known as Schwachman syndrome (113) [see Table 7.2 in section entitled Syndromes Associated with Fatty Lesions (Including Lipomatosis)]. Fatty infiltration of the heart is most often an innocuous condition with no effect on the myocardial fiber or cardiac function (69). However, there are rare exceptions in which severe adipocity has resulted in cardiac rupture (97). Another clinically important lesion is termed *lipomatous hypertrophy of the interatrial septum* (114), a focal enlargement that may cause sudden death, arrhythmias, or congestive failure (115,116). Be mindful that the occasional appearance of fat in endocardial biopsies in no way indicates cardiac perforation (117).

Isolated fat cells can be found within lymph nodes in childhood, but enlarged nodes with prominent fatty infiltration mainly occur in adults, particularly in obesity (118). Common in the abdomen and retroperitoneum, such â€œlipolymph nodesâ€• can be mistaken for lipomas (118) or be interpreted as positive in a lymphangiogram for lymphoma or Hodgkin's disease (personal observation), mimicking

lymphoma relapse (119). Rarely, a lipoma or angiomyolipoma occurs in the liver (120), but those lesions should not be confused with the hepatic pseudolipoma (121). This pseudolipoma is often found as a bulge on the surface of the liver and probably represents capture of previously detached appendices epiploicae. In the mouth, fat is one of the components contributing to macroglossia in certain conditions (122).

The Ito cells of the liver are fat-containing cells along the sinuses and are a variation on normal histology (123); they may become prominent in the condition known as lipopeliosis (124) and may be involved in the benign neoplasm called spongiotic pericytoma (125).

Fat Biopsy for Amyloid

It is becoming increasingly popular to perform a subcutaneous fat biopsy for the diagnosis of amyloidosis. In such instances, the Congo red stain may reveal amyloid around blood vessels and, occasionally, between adipocytes (126,127,128). This procedure is at least as sensitive as the rectal biopsy (128), can identify up to 84% of cases (127), can be combined with other studies to determine amyloid type (126), and is a safe and innocuous way to make the diagnosis (127).

Biopsy analysis of adipose tissue may become important in the future, to assess a given individual's storage content of toxic chemicals. A variety of industrial and environmental hydrocarbons are stored predominantly in fat, and subcutaneous adipose tissue deposits may be analyzed and results correlated with the development of diseases such as neoplasia.

Inflammations

Fat Necrosis

Three histologically distinct types of fat necrosis exist: the ordinary

variety secondary to trauma and other inflammation, that associated with pancreatitis, and infarction of fat. Histologically, ordinary fat necrosis is typified by the presence of epithelioid histiocytes, foamy macrophages, and giant cells in adipose tissue, often surrounding and isolating individual adipocytes (Figure 7.11). Lymphocytes and plasma cells are also found in small numbers. Occasionally, unusual crystalloids may be seen (129). Fat cells become destroyed, and the released lipid may fuse to result in a single droplet larger than the average cell or in minute droplets. This process may resolve with mild fibrosis or, if extensive, may cause cyst formation with eventual dense fibrosis and even calcification at the periphery. Such cysts with central liquefaction may be located on the buttocks and be the final result of trauma, secondary to an injection. Just beneath the cyst wall, necrotic outlines of adipocytes are usually present, signifying the origin of the end-stage cyst in fat necrosis.

An unusual type of fat necrosis forming cystic spaces has been designated *membranous fat necrosis* by Poppiti et al. (130). In this example, actual cysts are formed that contain pseudopapillary structures and central debris. Although the fat cell outlines are normal in appearance, the formation of these cysts resembles that seen in membranous lipodystrophy. Membranous fat necrosis can also occur secondary to radiation therapy (108).

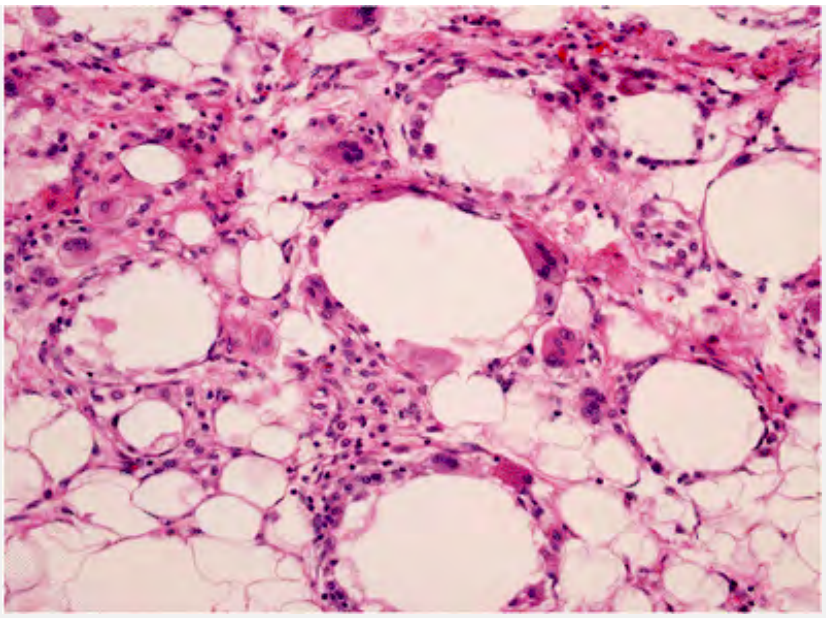

Figure 7.11 Fat necrosis, ordinary type. Multinucleated histiocytic giant cells surround a large lipid vacuole formed by fusion of destroyed adipocytes. Scattered lymphocytes and monocytes occupy expanded spaces between cells at top.

Figure 7.12 Fat necrosis, pancreatic type. In contrast to regular fat necrosis, numerous neutrophils are found, together with central liquefaction. The central material may give either an eosinophilic or basophilic appearance, and disrupted cell membranes can be appreciated.

Fat necrosis secondary to acute pancreatitis is histologically distinctive (Figure 7.12). Rather than consisting of a histiocytic infiltrate, the pancreatic fat necrosis is accompanied by an infiltrate of neutrophils predominantly, and liquefaction of fat is apparent (131,132). In the center of the lesion, the infarctlike outlines of fat cells can be seen, and fat cell membranes are ruptured, releasing

their contents into a central eosinophilic or basophilic material. The entire region is bordered by an acute inflammatory infiltrate. The process is thought to be secondary to the action of pancreatic lipolytic enzymes in the serum acting on susceptible foci.

The infarction type of fat necrosis, in which eosinophilic outlines of fat cells without nuclei or inflammation are present histologically, may be seen in lipomas and in detached peritoneal tissue originating from appendices epiploicae. The lipomas containing infarction may be pedunculated with twisting, causing compromise of blood flow.

Calciphylaxis

Another disorder that often manifests itself as skin and subcutaneous fat necrosis is called calciphylaxis; here, the characteristic vascular necrosis with calcium precipitation will aid in the diagnosis (133). It is a painful and often lethal complication of dialysis and renal failure (134). Small vessels (including arterioles in the fat) show mural calcification and necrosis, along with thrombosis and necrosis of surrounding tissues. In some cases, an association with primary hyperparathyroidism has been reported (135).

Panniculitis

Numerous diseases and conditions may cause an inflammatory infiltrate of the subcutaneous adipose tissue, namely, a panniculitis; readers are referred to a variety of textbooks on skin pathology for an in-depth enumeration of these. Only a few relevant points are made here. First, the condition called Weber-Christian disease, or febrile nodular nonsuppurative panniculitis of the subcutaneous fat, was described early in this century and is consistently referred to in discussions of this topic. However, it became clear in the 1960s and 1970s that this disease was not a clinically distinct entity, but rather had many separate etiologies, including steroid withdrawal, diabetes

mellitus, tuberculosis, pancreatic disease, and systemic lupus erythematosus (136). Thus, it is generally agreed today that Weber-Christian â€œdiseaseâ€• was a clinical description of a presentation for numerous diseases and is a term to be avoided (137).

Panniculitis, as a rule, can be divided into those that are septal and those that involve the lobules of adipose tissue (137). The character of the infiltrate is important, and note should be made of the presence of eosinophils (138), neutrophils and granulomas (139), histiocytes with lymphophagocytosis (140), or other specific changes (141). Autoimmune diseases such as scleroderma (142) and lupus (143) may be causative, indicating the importance of historical detail. Unusual causes, such as Î± 1-antitrypsin deficiency (137), have a characteristic histology, as does pancreatic fat necrosis (described in other texts). Even withdrawal from steroids may cause a panniculitis (144).

Mesenteritis

Inflammation of the mesenteric fat is a recognizable clinical entity that has more recently been termed *mesenteric panniculitis* to signify the active inflammatory stage and *retractile mesenteritis* to signify the fibrotic stage (145). Other terms complicate the literature, but it is generally held that they all refer to the same disease process and spectrum: liposclerotic mesenteritis, sclerosing mesenteritis, mesenteric lipodystrophy (ML), and Weber-Christian disease of the mesentery [see recent review by Kelly and Hwang (146)].

The process consists of a chronic inflammatory infiltrate of lymphocytes, plasma cells, foamy histiocytes, and giant cells, along with recognizable fat necrosis, edema, and a variable amount of fibrosis and calcification. Myofibroblasts proliferate and are directly involved in the pathogenesis of the retractile disease (146). While it most often thickens the mesentery (type 1 ML), it can appear as a single tumefaction at the mesenteric base (type 2 ML) or as multiple discrete nodules (type 3 ML) (147). Other space-occupying lesions,

such as inflammatory pseudotumors, xanthogranulomatosis (see below), and fibromatosis, are in the differential diagnosis (119). Affected patients are usually middle-aged and predominantly male, and they complain of vague abdominal discomfort and weight loss, with over one-half presenting with fever. Nearly one-half of them are, oddly enough, asymptomatic (146). Rare cases have been fatal, but the prognosis is generally excellent. Mass lesions regress within 2 years in about two-thirds of the patients, and any pain disappears in three-quarters of them (145). Steroids are commonly given to treat the disease, but it is unclear whether the course of the disease or the progression to fibrosis is changed (145).

Retroperitoneal xanthogranulomatosis can be due to a primary inflammatory process of the kidney, or it can represent involvement of the retroperitoneum by the mesenteritis. Many foamy histiocytes and lymphocytes are seen. Rarely, it can be associated with Erdheim-Chester disease (multisystem fibroxanthomas with bone pain and sclerotic bone lesions) (148).

Lipogranuloma

Small collections of epithelioid histiocytes with lipid droplets are commonly encountered in lymph nodes, draining the gastrointestinal tract (mesenteric, porta hepatis, retroperitoneal), and in the liver, spleen, and bone marrow. They do not imply a pancreatitis (in which necrosis should be present) or other pathologic process and are completely incidental.

Tumors and Tumorlike Lesions

Brown Fat Lesions

Hibernoma

The only pathologic lesion of brown fat known to date is the

hibernoma, the neoplastic counterpart given its name by Gery (149). Although many of the cells in the hibernoma are multivacuolated, some cells lack vacuoles completely and are eosinophilic and granular in appearance. Both of these cell types have a centrally placed nucleus. Importantly, univacuolated cells with peripherally placed nuclei

resembling white adipocytes can be identified, as they can in normal brown fat (149,150). The red-brown color of a hibernoma is the result of the increased vascularity in numerous mitochondria. The ultrastructure of hibernoma is similar to brown fat (151); and, indeed, when cellular organelles are compared, the ultrastructure suggested to a number of authors (149,150) is that brown fat and white fat are two distinct tissues, with different ultrastructural features.

Concerning location, many hibernomas arise in sites corresponding to the distribution of normal brown fatâ€”interscapular area, neck, mediastinum, and axilla (149); other cases have been reported in the abdominal wall, thigh, and popliteal space (149), all sites considered devoid of brown fat (152). Generally medium-sized tumors (5 to 10 cm), hibernomas may obtain a huge dimension [23 cm (153)] and are often present for years prior to excision. The tumors typically occur in young adults with a median age of 26 years, much younger than patients with ordinary lipoma (149). Interestingly, endocrine activity has been noted within these tumors, with steroid hormones (including cortisol and testosterone) detected (154). Hibernomas do not recur, but whether malignant hibernomas exist has been a controversial topic. A case having atypical mitoses and bizarre nuclei was reported by Enterline et al. (155), and a similar case with ultrastructural features was documented by Teplitz et al. (156).

White Fat Lesions

Adipose Tissue within Nonfatty Lesions

Almost any malignant tumor may invade and incorporate mature fat cells. Occasionally, however, the presence of fat cells within mesenchymal proliferation can be confusing. For example, nodular fasciitis may incorporate individual fat cells that can appear smaller than normal, mimicking lipoblasts (136). Likewise, a very prominent component of adipose tissue accompanies intramuscular angiomatosis and lymphangiomatosis of the extremities (152). Benign teratomas of the ovary (157) and lung (158,159) occasionally contain mature adipose tissue as an incidental finding. So-called fibrous polyps of the esophagus (160) also contain adipose tissue. Other nonlipomatous tumors that may contain fat include the pleomorphic adenoma of the salivary gland and the benign spindle cell breast tumor described by Toker et al. (161). This lesion may be what has been described recently as a myofibroblastoma (162) with the incorporation of adipose tissue.

Perhaps by a process of cellular metaplasia, fat may also be found occasionally in the endometrium (163) or in epithelial tumors of various types (see below).

Ectopic Adipose Tissue

Ectopic fat either in cardiac valves or within organs was discussed earlier in the Metaplasia and Fatty Infiltration sections. Oddly enough, ectopic fat may occur in the dermis, where it causes a pedunculated appearance; this has been termed *nevus lipomatosis superficialis* or, more recently, *pedunculated lipofibroma* (164).

Hamartomas Containing Fat Cells

Many of us are aware that the benign pulmonary â€œchondroma,â€• or â€œhamartoma,â€• may contain fat (158). In fact, approximately 75% of these lesions do (165), and the presence of such a tissue foreign to the lung parenchyma supports the concept that these

lesions are benign mesenchymomas (158,165). Occasionally, the lipomatous component may be so dominant as to suggest a lipoma (165,166).

Amazingly, adipose tissue can be a component of many other unusual lesions. It may be coupled with vascular, fibrous, and myofibroblastic components in multiple congenital mesenchymal hamartomas [multiple sites (167)]; with undifferentiated spindle cells and fibroblasts in the fibrous hamartoma of infancy [mainly in shoulder and axillary regions (168,169,170)]; with fibrous tissue and mature nerve in the sometimes congenital fibrolipomatous hamartoma of nerve with or without macrodactyly [palm, wrist, or fingers (171,172,173)]; or with smooth muscle and vessels in the angiomyolipoma (174,175). These hamartomatous lesions of tuberous sclerosis will be discussed further. In another oddity, adipose tissue is one component of human tails and pseudotails (176), along with skin and other tissues.

Massive Localized Lymphedema

In morbidly obese patients, huge subcutaneous masses as large as 50 cm may form, clinically mimicking liposarcoma (177,178). Pedunculated masses of adipose tissue show dilated lymphatics and edema and thus this condition is known as massive localized lymphedema (MLL). Grossly, the fat is marbled in appearance secondary to coarse bands of fibrous tissue intersecting fat lobules. Microscopically, the adipose tissue is dissected by fibrosis simulating sclerosing liposarcoma; however, the lesion is superficial, and there are no atypical stromal cells nor lipoblasts. In the edematous septa, scattered myofibroblasts are noted. Aside from the often postsurgical abdominal sites reported initially, MLL may also occur in the thigh, scrotum, and inguinal regions and be associated with hypothyroidism (178).

Mesenchymomas

Adipose tissue is a nearly constant component of benign mesenchymomasâ€”growth that should be redefined as having more than two mesenchymal elements. LeBer and Stout (179) required the presence of at least two different mesenchymal elements to make a diagnosis of mesenchymoma. However, we believe the trend has evolved in favor of more than two elements, and those lesions with only two

elements currently appear to be designated separately as chondrolipoma, fibrolipoma, and so on (152,180). This seems appropriate since the secondary element, usually in a lipoma, is frequently a very focal finding (as it may be in a liposarcoma). Thus, aside from lesions with focal â€œmetaplasia,â€• lesions with three or more elements can be designated true mesenchymomas. For instance, a description of a trigeminal neurilemmoma (181) was really a mesenchymoma with cartilage, bone, hemangioma, schwannoma, and adipose tissue. Also, a thoracic tumor with smooth muscle, angiomatoid spaces, fibrous tissue, and adipose tissue is another mesenchymoma, reported in association with hemihypertrophy (182). Angiomyolipoma is another example of a benign mesenchymoma and is frequently found in the kidney, where approximately 40% are associated with tuberous sclerosis (175). Although the fat seen here is practically always mature, rarely lipoblast-like cells may be seen in these (152,183). Angiomyolipomas have also been reported in other sites, such as lymph nodes (184).

Lipomas

The distinction between adipose tissue lobules and true lipoma occasionally arises in the practice of surgical pathology, necessitating a strict definition of lipoma. Although lipoma is well described in two major texts (152,180), definitions are concise without detail. Lipoma is herein defined as a superficial or deep-circumscribed and expansile benign neoplasm composed of mature adipose tissue, which is commonly (but need not be) encapsulated. Such a definition

emphasizes its well-differentiated and clonal nature (see following) and serves to distinguish most lipomas from normal fat and prominent posttraumatic skin folds, or â€œfat fracturesâ€• (185). As Allen (180) emphasizes, the capsule may be quite thin and poorly defined. Nonetheless, it is a crucial requirement for superficial tumors; deep lesions, on the contrary, are often nonencapsulated. When a subcutaneous lipoma is excised in a piecemeal fashion, the lesion may be diagnosed by noting the presence of portions of capsular fibrous tissue in the form of a circular arc of collagen of varying width at the edge of tissue fragments. In the absence of a clear-cut capsule or fragments thereof, a diagnosis of a superficial lipoma cannot be made.

Clinically, the majority of lipomas seen in surgical pathology are subcutaneous tumors typically in the middle-aged to elderly patient. Males and females are probably equally affected, and there are no racial differences. Most tumors are located on the trunk or upper extremities; if other sites are encountered, consideration should be given to one of the lipoma subtypes (e.g., forearm for angiolipoma, neck for spindle and pleomorphic types). Lipomas probably outnumber all other soft tissue tumors combined (152). Interesting facts about lipomas include (a) a nearly static size after the initial growth period (152); (b) the relative rarity of lesions on the hands, feet, face, and lower leg despite the presence of fat (152); (c) hardness after the application of ice, a diagnostic sign (152); (d) the lack of size reduction in starvation (152,180); (e) a definite, but low, recurrence rate [1 to 4% (152,180)]; (f) an unknown etiology; (g) a possible relation to potassium intake (186); and (h) a possible association with an increased incidence of cancer [46% (187)].

Many lesions of the subcutaneous region come to surgical pathology labeled as lipomas; and, not uncommonly, a portion of these actually turn out to be something else that is frequently more interesting.

When one views normal fat histologically, the size of fat cells appears to vary somewhat due to the sectioning plane; however, the variation

is relatively small [80 to 120 Âµm (personal observation); Figure 7.4]. In lipomas [including atypical lipoma (188)], there is a tendency for cell size to vary more widely, with larger cells (e.g., >300 Âµm) being apparent. Practically, this means that a medium-power view will often disclose a two- to fivefold size range (Figure 7.13). Normal fat has a netlike structure of fibrous tissue, wherein such dispersed fibrous bands or septa dissect the adipose tissue randomly. The fibrous tissue is thicker in quality in bodily regions exposed to pressure, such as the hands, feet, and buttocks (97). This netlike fibrous tissue arrangement is recapitulated within lipomas (Figure 7.14), particularly at the periphery where small lobules are often found. A high degree of vascularity is a feature associated with lipogenic malignancy, but we should be aware that this refers to a visible network of capillaries, often in strings and branching arrays. However, normal adipose tissue and lipomas are likewise highly vascular, except the capillary vascular bed is more difficult to visualize. A PAS stain of a lipoma, for example, can highlight the minute but diffuse capillaries, particularly at the junctions between cells, where they are made more difficult to see due to compression. A delicate reticulin

network is also present in lipomas, contributed to by the basement membranes of both lipocytes and capillaries; each lipocyte is completely encircled by reticulin in a manner similar to normal fat cells (Figure 7.3). Normally, lipomas have a low degree of cellularity and no nuclear atypia; the presence of either is cause for concern. Sometimes increased cellularity is due to a diffuse low-grade form of fat necrosis (Figure 7.15). The ultrastructure of lipoma recapitulates that of its normal counterpart (189).

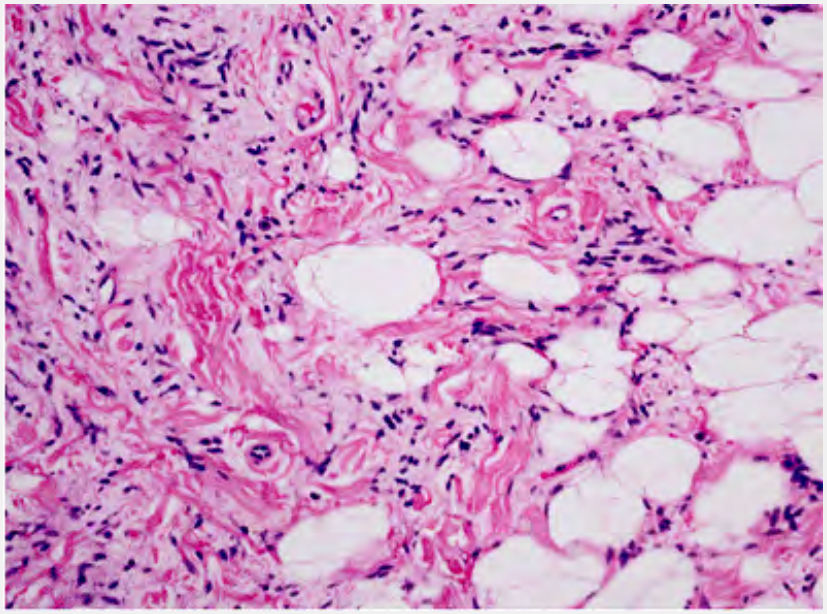

Figure 7.13 Variation in fat cell size in spindle cell lipoma. Some adipocytes are three to five times the size of a normal adipocyte; compare with Figure 7.4. Increased numbers of spindle cells together with collagen bands characterize this lipoma subtype, although the size variation seems to be present in all unusual types of lipoma.

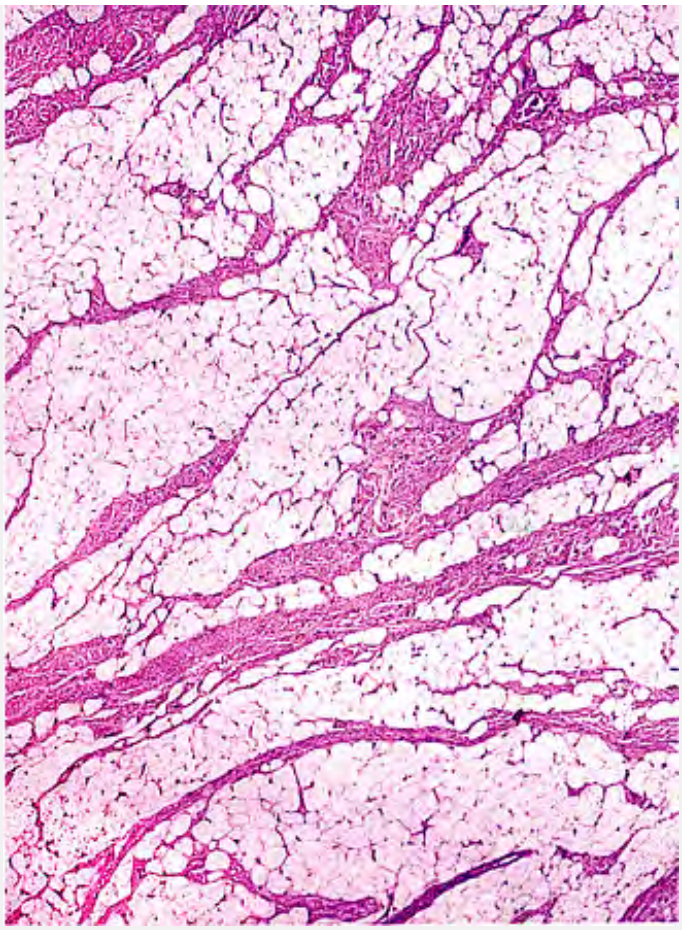

Figure 7.14 Lipoma with accentuated lobulation. In certain sites such as the buttock, foot, and hand (*depicted here*), thick fibrous septa are noted throughout; these correspond to the thicker septa within the normal adipose tissue in these regions.

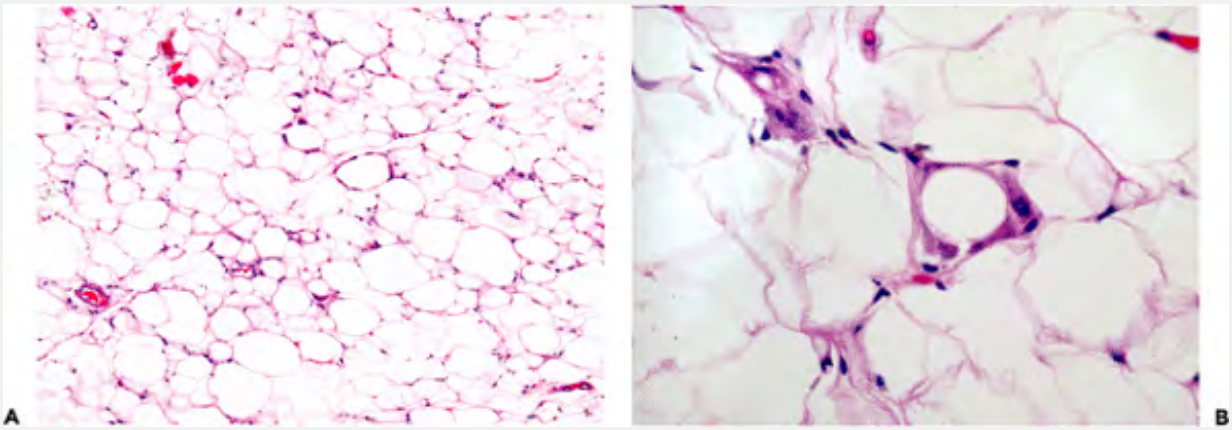

Figure 7.15 Lipoma. A. In some tumors, an increased cellularity at medium power may cause concern, but it is frequently due to a mild but diffuse fat necrosis. B. The lipocytes are falsely enlarged by the histiocytes without much other inflammation.

Myxoid Change

In rare lipomas, the mature fat cells are separated by varying amounts of a loose basophilic ground substance, probably proteoglycan (Figure 7.16). When prominent, the lesion may be designated a *myxolipoma* or *myxoid lipoma* (152,180). The myxoid quality often raises the possibility of a myxoid liposarcoma. However, these areas contain only widely scattered bland cells and are never hypercellular. Furthermore, the plexiform capillary network so typical of the malignant tumor is absent, as are lipoblasts. As Enzinger and Weiss (152) observed, rare cells may be vacuolated but contain bluish mucoid material.

Intramuscular Lipoma

Deep lipomas may be either intermuscular or intramuscular, with the latter unencapsulated tumors being the more common. Intramuscular

lipomas (190), also known as infiltrating lipomas, involve the large muscles of the extremities (particularly the thigh, shoulder, and upper arm) or the paraspinal muscles. For extremity lesions, an inapparent mass may become visible upon voluntary contraction. Microscopically, the lipocytes are typically mature, and mitoses or atypical nuclei are not found. Muscle fibers are widely dispersed throughout the lesion (Figure 7.17). Any unusual features should raise the suspicion of a well-differentiated liposarcoma (191). Often, intramuscular lipomas extend beyond the muscle fascia to involve the intervening connective tissue space. Therefore, it is often difficult to completely excise such lesions, and the recurrence rate is higher than that for ordinary subcutaneous lipoma. This has been particularly true for paraspinal intramuscular lipomas.

Intramuscular angiolipomas are lesions considered to be intramuscular hemangiomas with a variable fat content (152).

Lipoma arborescens is a special type of lipoma occurring in a joint: it has a characteristic villiform gross appearance,

and the patients typically have a highly painful knee (180). The mere presence of adipose tissue on a synovial biopsy is not synonymous with this entity.

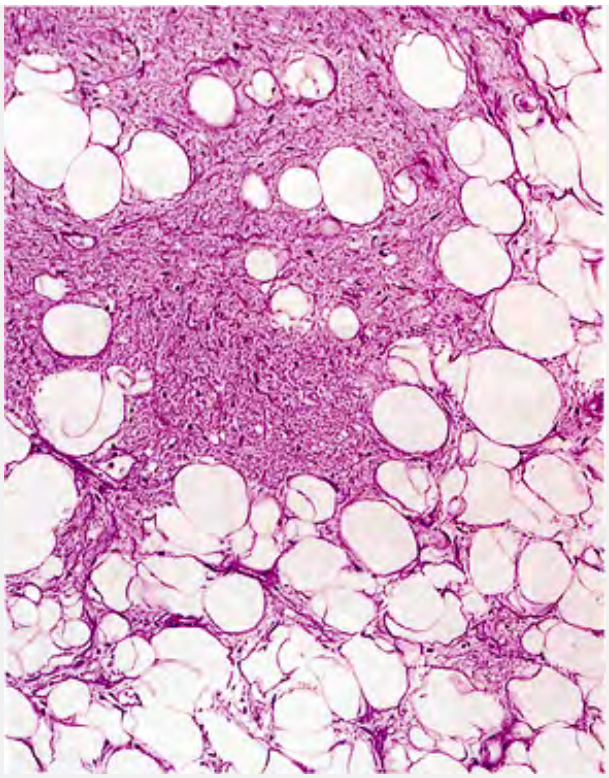

Figure 7.16 Lipoma with myxoid change. Features that differentiate this from myxoid liposarcoma are the lack of branching capillary vessels and significant cellularity in the myxoid component.

Other Elements in Lipomas

Aside from the ordinary lipoma, extraneous elements of various types can be associated with an adipose tissue benign proliferation, including combinations with epithelial or other mesenchymal components.

Mesenchymal Components

Perhaps the most common mesenchymal component associated with the lipoma is, as surgical pathologists are aware, benign

cartilaginous metaplasia (Figure 7.18). So-called chondrolipomas may occur in almost any site of the body, including the breast (192) and mediastinum (193). Although the term *benign mesenchymoma* has been applied to such lesions, the chondroid metaplasia is practically always an extremely minor component in the form of very small isolated islands of cartilage; therefore, the designation of mesenchymoma appears to be an exaggeration (as it is when cartilaginous metaplasia occurs in liposarcoma). Allen (194) also prefers to avoid the term *mesenchymoma*.

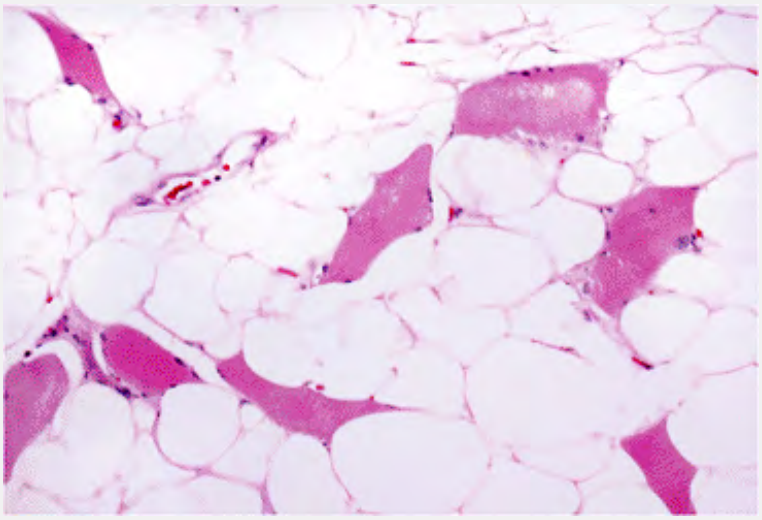

Figure 7.17 Lipoma, intramuscular type. The light fat cells proliferate between dark individual skeletal muscle fibers in this commonly unencapsulated tumor (trichrome stain).

Lipochondromatosis is a recently reported entity that involves the tendons and synovium of the ankle region as a mass lesion (195). Rarely benign osteoid is also found in lipomas, either solely or coupled with cartilage (196). Some of these osteolipomas are in contact with periosteum and may be termed *periosteal lipoma* (196). Smooth muscle lesions, particularly of the uterus, may be combined with adipose tissue to produce lipoleiomyomas (197) and

lipoleiomyomatosis (198). Prominent blood vessels are a frequent component of superficial small subcutaneous tumors called angiolipomas (152). These lesions are interesting, as they may be multiple, cause pain due to frequent microthrombi, and give rise to the differential diagnosis of Kaposi's sarcoma when the angiomatoid component completely overcomes the lipocytic component (Figure 7.19). These fat-poor variants are designated cellular angiolipomas (199). In such instances, the diagnosis is made by finding rare-to-scattered mature fat cells, usually at the periphery of the lesion.

Some lipomas contain an increased content of fibrous tissue. These usually superficial tumors have been called fibrolipomas. However, it is likely that the amount of fibrous

tissue in a lipoma is directly related to its anatomic site of origin (Figure 7.14). Dense thicker fibrous tissue is typically found in lipomas of the pressure-bearing regions of the body such as the hands, feet, and buttocks; the lobular architecture accentuated by such fibrous bands may be apparent grossly.

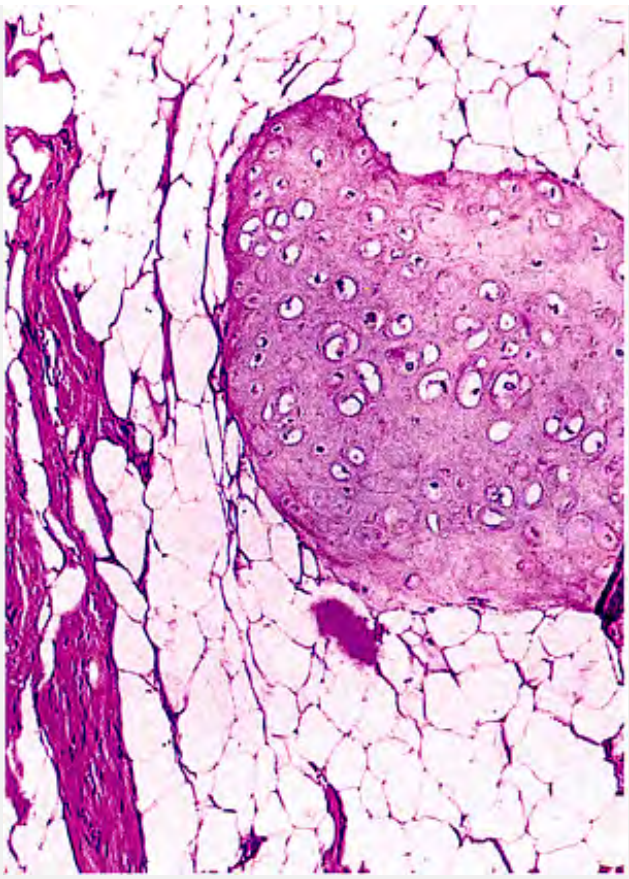

Figure 7.18 Chondrolipoma. Small nodules of mature cartilage are present, often very focally; this combination alone should not be labeled a mesenchymoma.

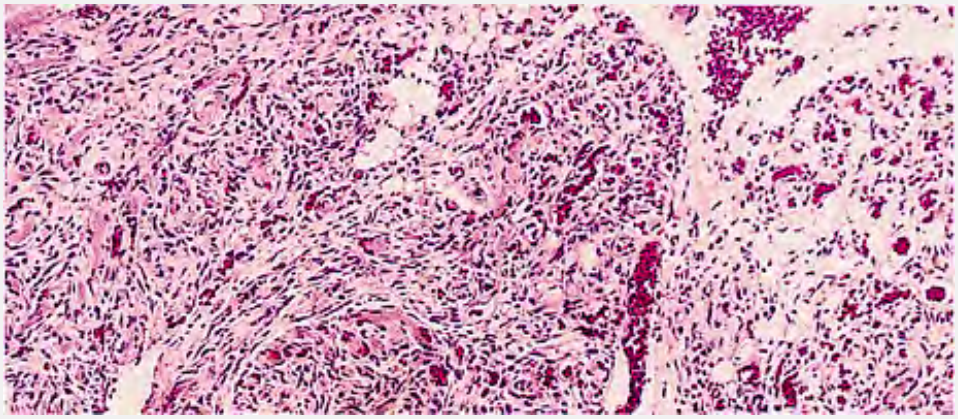

Figure 7.19 Angiolipoma. In this unusual example, the rarity of adipocytes (*top middle*) makes the tumor resemble a deep Kaposi's-like lesion; the location, circumscription, frequent microthrombi (*center*), and isolated islands of fat cells at the periphery aid in the diagnosis.

Epithelial Components

In some superficial lipomas, eccrine glands may be incorporated into the lesion. Eccrine glands may be found at the junction of dermal collagen; the subcutaneous fat and lipomas arising in this region can cause displacement of these glands, well within the substance of the lipoma. This phenomenon has been noted in locations such as the hand and buttock (personal observation).

Adipose tissue may accompany adenomas (i.e., lipoadenomas) of the thyroid (200) and parathyroid (201). Aside from lipoadenomas, other lesions of the thyroid gland may contain fatâ€”including colloid nodules, lymphocytic thyroiditis, and papillary carcinomas (202,203). Another unusual phenomenon is the formation of the thymolipoma (204). As listed in Table 7.2 [see section entitled Syndromes Associated with Fatty Lesions (Including Lipomatosis)], an unusual lipomatous syndrome is described that consists of thyrolipoma,

thymolipoma, and pharyngeal lipoma (205).

Lymphocytes in Lipomas

Occasionally, one may observe a dense perivascular lymphocytic infiltrate in scattered vessels within and outside ordinary lipomas. Although not generally described, the authors have observed this phenomenon several times and investigated the patients; they have not exhibited evidence of chronic lymphocytic leukemia or autoimmune disease. Perhaps this may represent a localized host reaction to the proliferation.

Special Lipoma Types

In the spindle cell (206,207,208) and pleomorphic (209,210) lipomas, the fat cells appear variable in size at low power. In spindle cell lipoma (Figure 7.13), the spindle cell content may vary from scanty to abundant, and the nuclei of the spindle cells are wavy, resembling nerve sheath lesions. Dense fibrous tissue is also found sometimes with a keloidal quality. Similar cells may be seen in pleomorphic lipoma, which has, in addition, characteristic floret tumor giant cells (Figure 7.20). Both of these lesions are encapsulated and have characteristic locations commonly limited to the head and neck of elderly males. They may be related entities (211). Interestingly, immunoreactivity for androgen receptor has recently been demonstrated in the fibroblast-like spindle cells of spindle cell lipoma (Brooks, personal data).

The chondroid lipoma is a well-circumscribed lesion with two elements: mature adipose tissue and focal or prominent areas containing strands and nests of eosinophilic vacuolated cells resembling chondroblasts or lipoblasts. A hyalinized myxoid matrix is also seen. This tumor is S-100 protein, vimentin, and CD68-positive, and may be cytokeratin-positive. It occurs mainly in women in the superficial soft tissues or skeletal muscle of extremities, head, and neck. While worrisome in appearance, the lesion does not recur or

metastasize (212,213).

Finally, an unusual fatty tumor of the mediastinum with elastic tissue has been described as elastofibrolipoma (214).

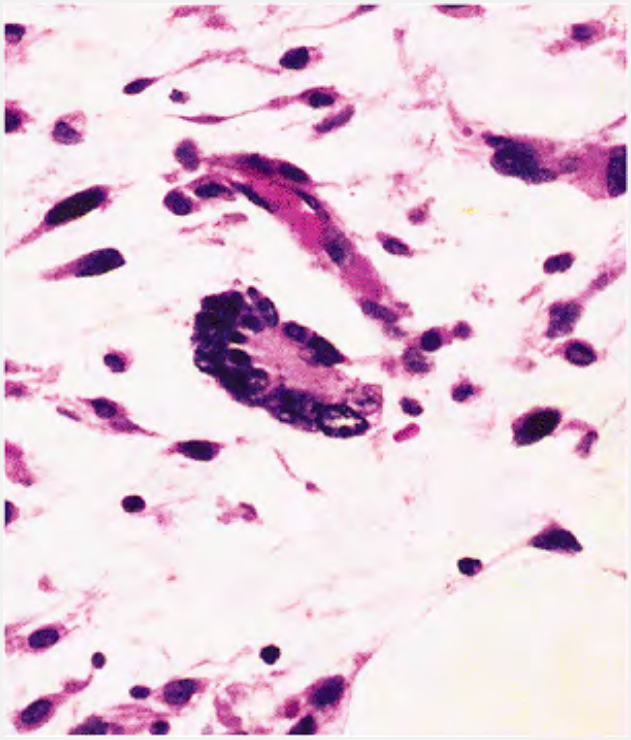

Figure 7.20 Floret cell. The wreath of nuclei at the periphery characterizes this cell, which is classically present in pleomorphic lipoma but may occur in some liposarcomas.

Lipoblastoma

Frequently a congenital lesion, the lipoblastoma (215,216,217,218,219,220,221) is a benign solitary proliferation of fat, retaining the lobular architecture of developing fetal white adipose tissue. Nearly 90% of these superficial lesions occur before

the age of 3 (152). Interestingly, lesions tend to mature with the age of the patient. Tumors may be predominantly myxoid with spindle cells, predominantly lipocytic, or mixed; all types have a prominent capillary bed and are often encapsulated. When mature fat cells are present, they are typically in the central portion of the lobules, in turn surrounded by collagen. In contrast, the presence of maturing adipocytes in myxoid liposarcoma is frequently found at the periphery of the lobule (220). Thus, while these tumors bear a resemblance to myxoid liposarcoma, there are clear differences, and the lobular accentuation with collagen is quite typical (Figure 7.21), as is the age at presentation. Rare cells resembling brown fat or hibernoma cells have been identified in lipoblastoma (219). If these lesions are single, they should be termed *lipoblastoma* (216) and not *lipoblastomatosis* (218,221); that was the original designation given appropriately by Vellios et al. in 1958 for a diffuse form (215).

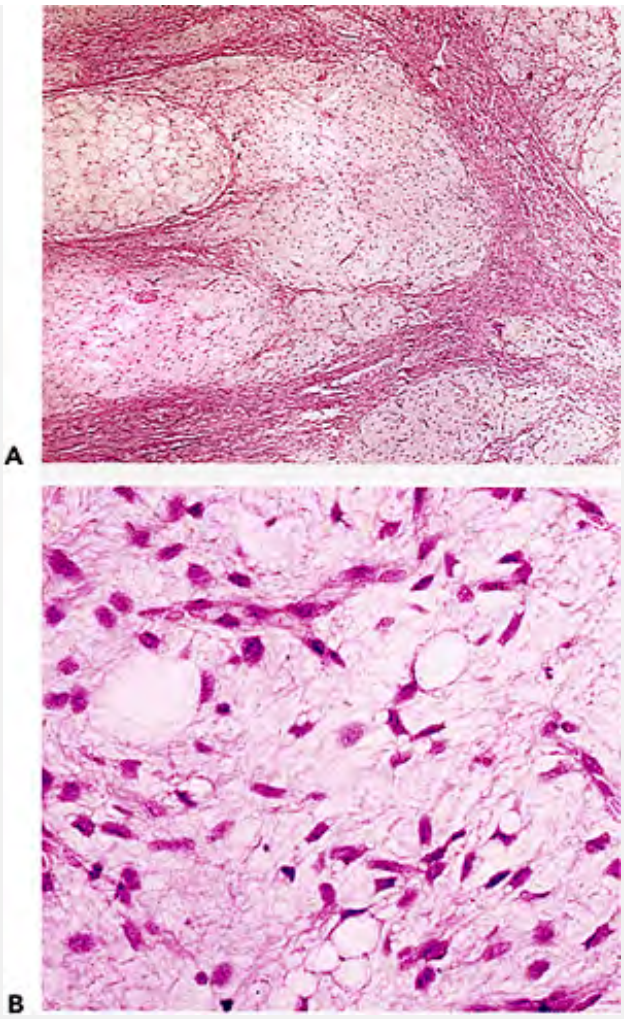

Figure 7.21 Lipoblastoma. A. At low power, a distinctly lobulated appearance can be observed. In some lobules, differentiation has started in the center. B. Within the myxoid lobules, small lipoblasts and spindle cells are found. The spindle cells are similar to those in developing fat (see Figure 7.2B).

Lipoblastomatosis

Lipoblastomatosis is the proper designation for the less common diffuse form of lipoblastoma. About one-third of the patients have diffuse tumors, which (in contrast to the solitary form) are usually

deeply situated, more poorly circumscribed, infiltrating muscle, and with a higher tendency to recur (216).

Cytogenetics of Lipomas

Chromosomal karyotypes of lipomas have been studied (222,223,224,225,226,227,228,229) and reveal nonrandom changes involving chromosomes 3 and 12, indicative of clonality. The balanced translocation t(3;12) is a common finding (224,225), with breakpoints described at probably identical locationsâ€”q27;q13 (223) and q28;q14 (222). The breakpoint on chromosome 12 is very close to the one described in the t(12;16) translocation in myxoid liposarcomas (224). This balanced translocation involving chromosome 12 is seen in roughly 50% of lipomas (225) and may involve other chromosomes such as 21 and 7 (225). Another one-third of lipomas show a ring chromosome (225) originally described by Heim et al. (226) as a possible rearrangement of chromosome 3; this may be a marker for lipogenic tumors. Rarely, chromosome 6 has shown an abnormality (229). Interestingly, subgroups of lipomas may show different cytogenic changes (227).

Likewise, clonal chromosomal changes are noted in lipoblastoma with the abnormality at 8q11-q13 (230).

Syndromes Associated with Fatty Lesions (Including Lipomatosis)

The word *lipomatosis* may appropriately refer to two separate conditions: the presence of multiple subcutaneous lipomas and the infiltration of organs or sites such as the pelvis (231,232) by adipose tissue. The bilateral multiple symmetrical lipomatosis (MSL) syndrome [Madelung's disease (233,234,235,236,237)] is said to be frequently accompanied by a high intake of alcohol (180). However, there is increasing evidence that there is no association of MSL with alcohol abuse (238), that there may be a constitutional mitochondrial

dysfunction (239), that mitochondral DNA may be abnormal (240), that patients have plasma lipid anomalies (241), and that the cells involved may be distorted brown fat cells supportive of a neoplastic nature to MSL (242).

Lipomatosis may involve a single portion of the body, such as the face (243), the spinal epidural area (244,245,246,247), the mesentery (248), the mediastinum and abdomen (249), the mediastinum alone (250), the brain (251,252), and the

kidney (253), as well as subcutaneous tissue (254). Syndromes relating to many of these are delineated in Table 7.2.

Lipomas, either as single or multiple tumors, may be part of a variety of syndromes (Table 7.2), some of which are autosomal dominant [Gardner's syndrome (255,256), MEA type 1 (257,258), Bannayan's syndrome (259), or tuberous sclerosis (260)]. Pathologists may find it interesting to note that lipomatous lesions may also occur in Cowden's disease (261), Beckwith's hemihypertrophy (180), and as fat within a pulmonary â€œhamartomaâ€• in Carney's syndrome (262,263).

Furthermore, adipose tissue lesions may be found in association with other clinical syndromes as well (264,265,269). The listing in Table 7.2 is meant to be as complete as possible for informational purposes. The lipodystrophies (membranous and intestinal or mesenteric) were discussed earlier.

Table 7.2 Syndromes Associated with Fatty Processes

Syndrome	Description
Diffuse mammary steatonecrosis	Fat necrosis with infarction and lipogranulomatous reaction; found in

	patients with large pendulous breasts (97)
Acute pancreatitis	Disseminated focal areas of fat necrosis in the subcutis; may also occur with pancreatic carcinoma (97)
Retractile mesenteritis	Fibrosis and retraction of mesentary with distortion of intestinal loops; the outcome of mesentary panniculitis/isolated mesenteric lipodystrophy (97,146)
Weber-Christian disease (avoid term)	Historic term for a clinical syndrome with chronic inflammation, fat necrosis, and scattered acute inflammatory cells in the subcutisâ€” â€œnonsuppurative panniculitisâ€• with recurrent lesions and febrile illness; this is now known to be due to a variety of separate diseases and is a term to be avoided (136,137)
Beradinelli's lipodystrophy	A minor part of a complex disorder including gigantism, hyperlipidemia, fatty cirrhosis of liver, muscular hypertrophy, and hyperpigmentation; familial (97)
Dercum's disease	Multiple lipomas with pain and tenderness (79,97,152,180)
FrÃ¶hlich's	Sexual infantilism with obesity and

syndrome	symmetrical or asymmetrical lipomas (a form of hypopituitarism)
Madelung's disease	Symmetrical lipomatosis; associated with alcohol intake (180,233,234,235,236,237)
Gardner's syndrome	Familial intestinal polyposis; subcutaneous lipomas may occur (255,256)
Multiple endocrine adenomotosis I (MEA 1)	Subcutaneous lipomas occur (257); a case of liposarcoma reported (258)
Schwachman syndrome	Lipomatous atrophy of the pancreas with prominent lipomatosis, maldigestion, neutropenia, and growth retardation (113)
Trite's syndrome	A combination of thymolipoma, thyrolipoma, and pharyngeal lipoma (205)
Carney's syndrome	Pulmonary hamartomas (which often contain fat), gastric smooth muscle tumors, and paraganglioma (262,263)
Tuberous sclerosis	Angiomyolipomas of kidney, other tumors, and hamartomas; occasionally diffuse lipomatosis (260)

Beckwith's hemihypertrophy	Congenital asymmetry, some with associated Wilms' tumor, occasional benign mesenchymoma with adipose tissue (182)
Familial multiple lipomas	Multiple subcutaneous lipomas (268)
Bannayan's syndrome	Autosomal dominant disorder with macrocephaly, lipomas, hemangiomas, and intracranial tumors (259)
Laurence-Moon-Biedl syndrome	Congenital optic nerve atrophy, polydactyly, mental defect, and occasional adrenal lipomas (267)
Carpal tunnel syndrome	Occasionally caused by tendon sheath lipoma (264)
Fishman's syndrome	Encephalocraniocutaneous lipomatosis (251,252)
Goldenhar-Gorlin syndrome	Oculoauriculo-vertebral dysplasia with CNS lipomas (266)
Cowden's disease	GI polyposis with orocutaneous hamartomas; angiolipomas have been observed (260)
Spinal epidural lipomatosis	Fatty infiltration of epidural space (244,247); occasionally secondary to

	steroids (247)
Membranous lipodystrophy	Abnormal subcutaneous and bony fat with bone cysts, pathologic fractures, and leukodystrophy of brain (104,105,106)

Mimics of Fat Cells

Mature Fat Cells

Pathologists visualize adipocytes as clear cells or â€œwhite holesâ€• on routine sections. Therefore, other cells or processes with this white hole appearance may be confused with them. Some lesions are fairly obviousâ€”like the vacuolated lymphadenopathy of lymphangiogram effect.

Dilated superficial lymphatics if closely clustered, as they may be in a nasal polyp, remind one of adipocytes at medium power. The submucosal cystic spaces of pneumatosis cystoides intestinalis (270) are composed of gas with a lining of inflammatory cells, histiocytes, and giant cells. Cysts very similar in histology are occasionally noted within ovarian teratomas; here, it is probably a reaction to internal rupture. Likewise, small gaseous cysts without any lining in the intestinal mucosa truly mimic lipocytes in an entity termed *pseudolipomatosis* (270). Similar clear but artifactual vacuoles in the skin have been called pseudolipomatosis cutis (271). Termed *villous edema* in placental texts, this artifact of chorionic villi gives them a pseudolipomatous appearance. Lipid-filled sinusoidal Ito cells in the liver simulate small adipocytes in vitamin A toxicity (272).

Lipoblasts

The response to the lipidlike substance silicone after the rupture of a breast implant can cause concern: when the response to the silicone is marked with sheets of histiocytes containing a single dominant vacuole, the cells resemble lipoblasts and the lesion may be mistaken for liposarcoma.

Tumors with vacuoles also cause the pathologist to consider a lipocytic origin. Metastases to the skin or subcutaneous region of signet-ring carcinoma or signet-ring melanoma (273) (Figure 7.22) may resemble lipoblasts, and other helpful features such as nesting or spindling are not always present. Lymphomas of both B- and T-cell origin exhibiting a vacuolated or signet-ring appearance have recently been described (274,275,276,277,278), may mimic liposarcoma (278), and should be in the differential diagnosis of cutaneous, nodal, or retroperitoneal tumors.

Mesenchymal tumors such as epithelioid smooth muscle lesions and fibrohistiocytic neoplasms (Figure 7.23) can be vacuolated as well, due to an artifact and proteoglycan material, respectively. These two tumor groups, particularly in the form of gastrointestinal (GI) stromal malignancies (leiomyosarcomas) and myxoid malignant fibrous histiocytoma, probably account for the largest number of lesions mistaken for liposarcoma. In the GI tumors, the perinuclear vacuole coupled with a cellular epithelioid morphology can closely mimic the round cell or cellular myxoid liposarcoma. In myxoid fibrohistiocytic tumors of various types, vacuolated cells superficially simulate the lipoblast, but closer inspection reveals a delicate basophilic substance in the cytoplasm, apparently due to matrix production by the tumor cells (Figure 7.23). Unusual paragangliomas with vacuoles (279,280) may also be puzzling. Other lesions most often simulating lipocytes are those of endothelial origin because a true and often large vacuole is produced. Such cells may be identified in the histiocytoid hemangioma (281), in other epithelioid angiomas (282,283), in the spindle cell hemangioendothelioma (Figure 7.24) (284), in epithelioid hemangioendothelioma (285), and in some poorly differentiated angiosarcomas (Figure 7.25). In

contrast to most large lipoblasts, the large vacuoles in endothelial tumors show a central septation. Chordomas, particularly with a sacral presentation, may be confused with a lipocytic tumor due to the prominent

vacuolization of the physaliphorous cells. Mesotheliomas may also be vacuoled mimicking liposarcoma (286).

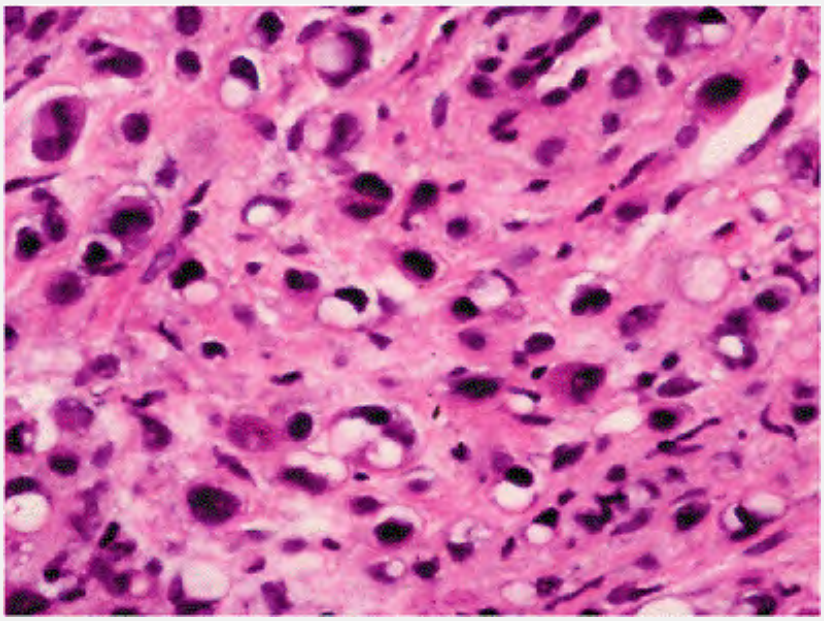

Figure 7.22 Adipocyte mimic. Subcutaneous metastases from either signet-ring carcinoma or melanoma (*seen here*) may rarely imitate a lipocytic tumor.

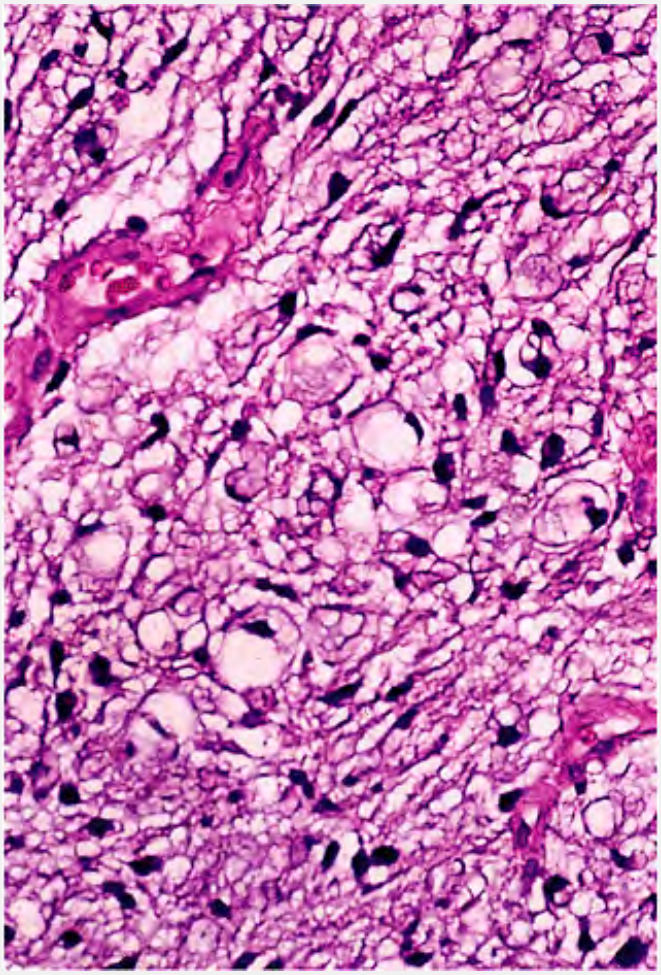

Figure 7.23 Lipoblast mimic. In fibrohistiocytic tumors like myxoid dermatofibrosarcoma and myxoid malignant fibrous histiocytoma, cells with a vacuolated appearance may be confused with lipoblasts; however, the vacuole contains a wispy bluish coloration due to the presence of proteoglycan matrix.

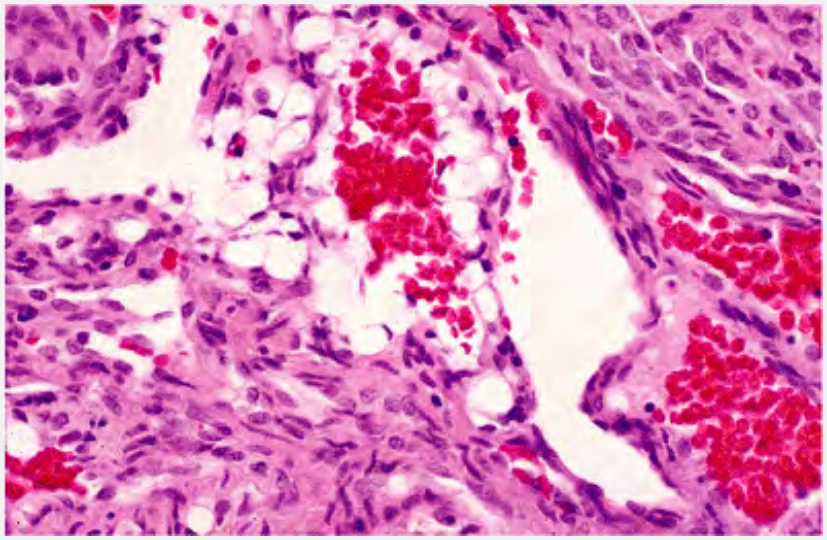

Figure 7.24 Adipocyte mimic. Large vacuolated cells can be found in the spindle cell hemangioma, but they are endothelial in nature and often line vascular spaces as seen here.

The best defense against a misdiagnosis of another tumor as a lipocytic one is strict adherence to the definition of a lipoblast: a cell, occasionally large but usually small, with a vacuole or vacuoles indenting the nucleus. The requirement for nuclear indentation assures an intracellular/cytoplasmic location for the vacuole and also excludes the semicircular nuclei around small vascular channels. Extracellular vacuoles are a common phenomenon, particularly in lesions with areas of mucoid matrix, and are often mistaken for a true intracellular finding; however, the nucleus is never affected since the substance is noncytoplasmic.

True liposarcomatous differentiation may be rarely identified in nonfatty malignancies such as medulloblastoma (287), cystosarcoma phyllodes (288), and even mesothelioma (289).

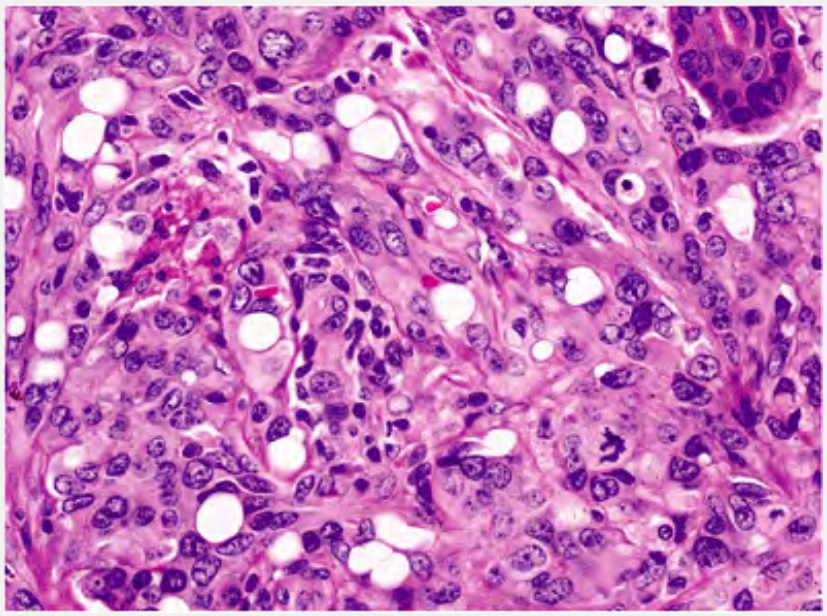

Figure 7.25 Adipocyte mimic. In some poorly differentiated angiosarcomas, vacuolated endothelial cells also resemble fat cells; however, note the presence of occasional septated vacuoles (*center*), a feature typical for proliferating endothelial cells and unlike adipocytes.

Skeletal Muscle

Reid R. Heffner Jr.
Lucia L. Balos

Introduction

Skeletal muscle is the largest organ in the body by weight and volume. There are hundreds of individual muscles comprising the skeletal musculature. The functions of these muscles encompass not only the movement of skeletal components, but also swallowing, respiration, and maintaining posture. The variation in the gross anatomy of these muscles is considerable. More to the point for our purposes are the histologic characteristics of muscle in general and the site-specific variations such as fiber size and fiber-type proportions. Since the anatomic pathologist is increasingly called upon to interpret microscopic findings in muscle as they relate to disease, a familiarity with the histology of normal muscle is the basis of any accurate assessment of this kind. Today, an understanding of muscle histology in a modern context depends upon some knowledge of developmental biology and molecular biology.

Embryology

The development of skeletal muscle is orchestrated in the unborn baby by a host of genes, many of which are yet unknown. These genes have the function of regulating the transformation of mesenchyme into muscle tissue and of reorganizing previously formed tissue through processes like apoptosis. We will have more to say about the molecular biology of muscle development after a discussion of some basic embryology. Skeletal muscle develops embryologically from somatic mesodermal tissue. The paraxial mesoderm is first apparent on day 17 and is the origin of the somites that are completely formed by day 30. At this time, a series of 42 to 44 pairs of rounded somites can be found adjacent to the notochord in the midline. By the fourth week, the mesodermal somites separate into the dermatomes and segmental myotomes. The latter give rise to the muscles of the body wall. The dorsal division of myotomes, the epimeres, represent the origin of the back muscles, while the ventral division hypomeres differentiate into the lateral and ventral muscles of the body wall, including the intercostals, abdominal obliques, and strap muscles of the neck. The muscles of the extremities arise from the limb buds that form from the lateral plate mesoderm that is also the origin of the bone, tendon, ligaments, and blood vessels. In the human embryo the mesenchyme of the limb buds appears at about the fourth week of gestation and is subject to induction by the somites. At the end

of the eighth week, the primordia of individual muscles can be appreciated. Muscle tissue is not derived directly from the lateral plate mesoderm (as was previously thought) but from somitic mesoderm, which invades the limb bud in week 5 (1). Differentiation of the limb musculature follows a cephalocaudad and proximal-to-distal progression. In each limb, the somitic mesenchyme subdivides into a dorsal and ventral mass with respect to the skeletal elements. The extensor, abductor, and supinator muscles are derived from the dorsal mass, whereas the

flexor, adductor, and pronator muscles originate from the ventral mass (2).

The most immature muscle cells are myoblasts. These are small, round, mononucleate cells with prominent nucleoli and evidence of mitotic activity. Myoblast cytoplasm contains no microscopically detectable filaments, but ribosomes can be identified. Masses of proliferating myoblasts represent the source of myotubes, the next step in myogenesis (3). Myotubes appear to arise as a result of fusion of the more primitive myoblasts (4). Myoblast fusion has been shown to depend upon a plasma membrane glycoprotein with a molecular weight of 38 KDa (5). This surface marker presumably allows fusing myoblasts to recognize each other. The 38-KDa membrane protein is also found on immature myotubes and satellite cells. Ultrastructurally, myoblasts are seen to have contact with each other through filopodia. Adjacent myoblasts are often joined by gap junctions (6). Fusing myoblasts become longitudinally oriented, a process which requires fibronectin (7). At this stage of myogenesis, groups of primitive muscle cells, including myoblasts and myotubes, are enclosed by a common basement membrane. In each cluster, there is usually one larger primary myotube. Between groups of cells are aggregates of interstitial cells (8).

Myotubes differ from myoblasts by the presence of multiple nuclei and cytoplasmic filaments. Filaments first form at the peripheral portions of the sarcoplasm and consist of 10 nm fibroblast-like fibrils that disappear during maturation (9). Immunohistochemical techniques also demonstrate the presence of desmin and vimentin within myotubes. More mature secondary myotubes have a larger diameter, increased numbers of nuclei that are central in cross sections, and more prominent myofilaments (Figure 8.1). These cells also begin to show evidence of contractile activity. Secondary myotubes eventually give rise to muscle fibers. As they approach this stage of development, secondary myotubes cease fusing and develop acetylcholine receptor protein on the cell surface. At first

receptor protein is diffusely distributed on the cell surface, but it later becomes focused into so-called hot spots where motor endplates will develop (10).

Muscle fibers differ from myotubes in that their nuclei are peripheral and their filaments are organized into sarcomeres. Muscle fibers also develop a sarcotubular system, and in time they become innervated. Immature muscle fibers often acquire multiple innervation sites, all but one of which eventually disappears.

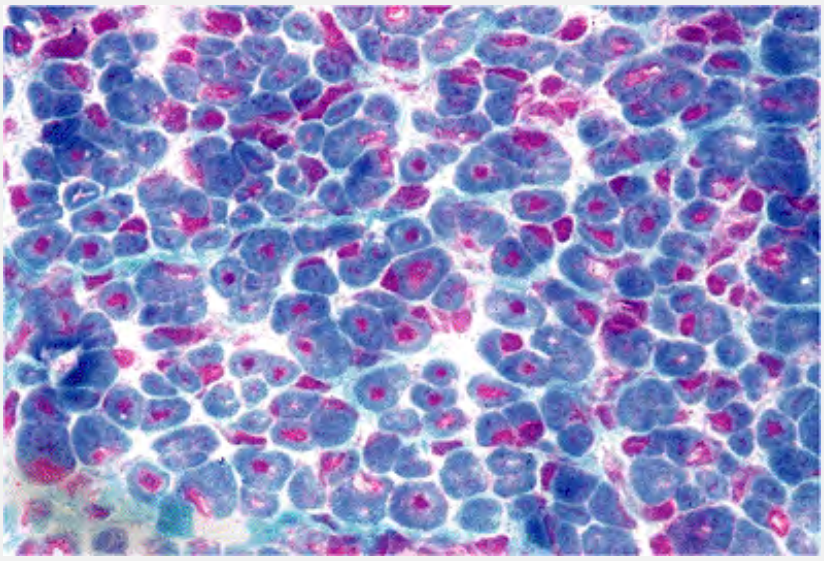

Figure 8.1 Myotube stage of muscle development. Myotubes typically have large central nuclei (trichrome).

The number of myotubes continues to decline after the twenty-first week of gestation so that at the time of birth myotubes are no longer conspicuous histologically. As myotubes become fewer in number, the muscle fibers undergo histochemical differentiation, which begins in the fifth month of development. Between fifteen and twenty weeks of gestation, a primitive progenitor of the checkerboard pattern emerges in which all myotubes and

myofibers have high ATPase and oxidative enzyme activity (11). By twenty weeks gestation, approximately 10% of fibers are larger in diameter, with both high oxidative enzyme activity and reduced ATPase activity. These fibers, which are basophilic in H&E stains, are the so-called Wohlfart B fibers and are the earliest example of type 1 fibers to be detected in developing muscle (12). The remaining 90% of fibers (Wohlfart type A) correspond to type 2 fibers with enhanced ATPase activity. Although type 2A and 2B fibers are not yet visible, a few type 2C fibers that stain dark in both acid and alkaline ATPase reactions are apparent. These fibers typically immunostain with antibodies to both fast and slow myosin. The more mature checkerboard histochemical pattern, which is stimulated by the innervation of fibers, is almost completed between 26 and 30 weeks of gestation (13). At birth the histochemical mosaic begins to resemble that of mature adult muscle. Approximately 80% of fibers are clearly identified as type 1 or type 2. The remaining 20% are undifferentiated fibers that have both abundant oxidative enzyme activity and stain darkly in routine ATPase reactions. A few Wohlfart type B fibers remain at birth. Type 2C fibers are not encountered.

As mentioned earlier, the development of skeletal muscle is under the control of several categories of genes and their products (14). Among these categories are transcription factors and signaling molecules such as growth factors and their receptors. A comprehensive discussion of this subject would not be appropriate, but a few illustrative examples will be given in recognition of the fact that these

molecular events in the embryo will soon be relevant in the understanding and diagnosis of muscle disease, especially the congenital myopathies and dystrophies.

One of the important influences in the early stages of segmentation when the segmental identity of the somites is established is the expression of *Hox* genes, a family of homeobox

genes that act as transcription factors involved in craniocaudal segmentation of the body. Myogenesis originates with a population of mesenchymal cells that become devoted to a lineage of myogenic cells. The molecular basis of this transition rests with an array of myogenic regulatory factors, MyoD, myogenin, Myf-5, and MRF-4, which are basic helix-loop-helix proteins. Both Myf-5 and another transcription factor, Pax-3, activate MyoD (myogenic determining factor), which leads to the formation of mononuclear myoblasts. Meanwhile, myoblasts in the myotome of the somite continue to replicate and are kept in the cell cycle by growth factors such as fibroblast growth factor (FGF-8). Myogenin expression is controlled by Myf-5 and MyoD; along with myoblast recognition and adherence mechanisms that rely on adhesion molecules like M-cadherin, myogenin expression promotes myotube fusion. In turn, MRF-4 is responsible for differentiation into myofibers.

Postnatal and Developmental Changes

During the prenatal period and childhood, muscle fibers continue to increase in length until full growth is attained. Muscle fibers lengthen in response to growth of the skeleton by virtue of two fundamental changes in the sarcomeres. Existing sarcomeres lengthen, producing longitudinal fiber growth (15). This mechanism may account for up to a 25% increase in fiber length and indicates that there is a relative â€œexcessâ€• of sarcomeres that may elongate during periods of rapid growth of the skeleton. Muscle fibers also undergo real longitudinal growth with the addition of new sarcomeres, which involves the synthesis of contractile proteins (16). New sarcomeres are known to be added at the end of fibers, usually at the myotendinous junctions (17). There is also evidence to suggest that new sarcomeres are not only added at the end of fibers, but within internal segments as well. Whether the actual number of muscle fibers is augmented after birth is the subject of a current debate. Until recently the

myofiber population was thought to be relatively stable after birth and throughout adult life (18). The studies of Adams and DeReuck (19) and others, however, seem to suggest a gradual rise in the number of fibers between birth and the end of the fifth decade. In some muscles, the total increase in fibers may reach 80 to 100% of the neonatal level. The mechanism accounting for an increase in the fiber population probably involves a population of dividing stem cells that subsequently undergo fusion to produce new mature fibers. A major aspect of growth of muscle fibers after birth relates to an increase in transverse dimension. In general, between birth and adulthood there is a five-fold increase in muscle fiber diameters (20). For example, in the leg muscles, the average diameter of mature fibers is 45 Âµm as compared to 7 Âµm at birth. The enlargement in fiber diameters does not proceed at an even rate from birth to early adulthood, when fibers obtain a maximum diameter. Instead, fiber diameters increase at a relatively slow rate until puberty, when a burst of growth occurs. As an example, in the gastrocnemius, fibers more than triple in size from age 12 (average 19 Âµm) to age 21 (average 62 Âµm) years.

A major revision in the histochemical profile of muscle occurs after birth. In the term infant, a checkerboard staining pattern is clearly evident in alkaline ATPase reactions. However, fiber typing is often not distinct in oxidative enzyme reactions (Figure 8.2). The emergence of type 1, 2A, and 2B fibers in oxidative preparations occurs during infancy. Undifferentiated fibers having both abundant oxidative enzyme and ATPase activity represent approximately 20% of fibers at birth. These gradually differentiate into type 1 and type 2 fibers during the first year of life. The fate of Wohlfart B fibers, comprising about 1% of myofibers at birth, is unknown. They are not seen in biopsies of children past the age of 12 months.

The connective tissue elements of muscle are much more prominent at birth, particularly the perimysial components.

Immediately after birth the perimysium may account for up to 20% of the cross-sectional area of muscle tissue. During early childhood, the perimysium and other connective tissue components rapidly shrink to less than 5% of the cross-sectional area, in part because of the enlargement of the muscle fibers. In the immediate postnatal period, blood vessels (especially arteries) appear excessively thickened as a result of the presence of abundant smooth muscle elements.

Expansion of the luminal diameter of blood vessels in the first year of life gives the vascular elements an adult appearance. The noncontractile, supporting connective tissue contains abundant collagen and scattered fibroblasts. Foci of hematopoiesis remain after birth, containing stem cells, erythroblasts, and myelocytes. These foci are more likely to be seen in the distal muscles of the extremities. They disappear within one month after birth.

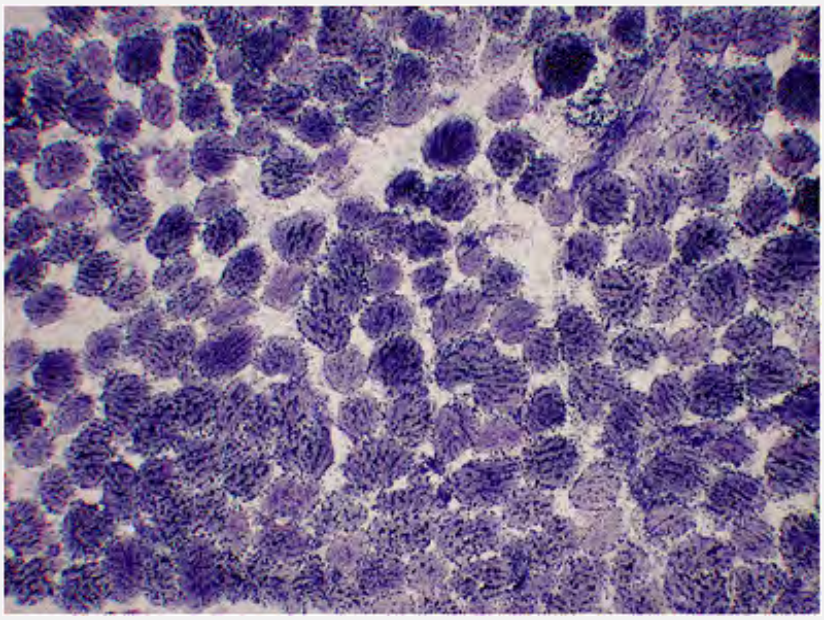

Figure 8.2 Newborn muscle. Indistinct fiber typing is evident in oxidative enzyme reactions (NADH-TR).

Apoptosis

Our scientific knowledge of apoptosis in skeletal muscle is at a rudimentary stage, but the medical literature is beginning to address apoptosis as a regulatory process in the normal development of muscle and in its relationship to selected pathologic conditions (21).

During embryologic life, both neurons and skeletal muscle are affected by the process of apoptosis. A great deal more is known about programmed cell death in nerve cells, including motor neurons, than in muscle. A review of the earlier literature discussing natural neuronal death has been published by Hamburger (22). A recent article by Sohal (23) addresses the subject of embryonic development of motor neurons and muscles, culminating in the establishment of mature nerve-muscle relationships. During embryogenesis, a necessary remodeling of muscles occurs through apoptosis, which removes â€œunwantedâ€• cells or structures to make room for further maturation. In the chick embryo, programmed cell death clearly occurs as the myofibers are developing. The large diameter primary myotubes are preferentially affected. The cytological features suggesting apoptosis include misshapen nuclei and irregular chromatin condensations along the nuclear envelope (24). It has been shown that, in rat embryos, macrophages play an important role in the removal of dead fibers (25). In human fetal muscle, the programmed cell death of both primary and mature myotubes occurs between 10 and 16 weeks of gestation (26).

A body of information regarding apoptotic events in postnatal and

adult muscle is beginning to accumulate. Such diverse conditions as disuse, exercise, ischemia, aging, and certain myopathies are being examined. Skeletal muscle apoptosis differs from most other tissues in several ways. Muscle cells are multinucleated, and their mitochondrial composition varies with fiber type and other factors such as exercise. Muscle cells contain two separate mitochondrial populations, subsarcolemmal and intermyofibrillar. It is unclear at the moment whether the expression of pro- and antiapoptotic agents differ in the two populations. Because it is a multinucleated cell, the muscle fiber does not always undergo apoptosis in same fashion as other cell types. Damage limited to individual myonuclei seems to be more common than death of the entire cell. In denervation, myonuclear loss leads to fiber atrophy instead of cell death. Finally, the elevated expression of endogenous caspase inhibitors in muscle seems to confer relatively greater resistance to apoptosis.

Anatomy

There are 434 voluntary muscles in the human body (27). They comprise 25% of the total body weight at birth and 40 to 50% of the total weight in adults. Not surprisingly, a greater muscle mass is encountered in males than in females. Individual muscles vary greatly in size. For example, the smallest muscle in the body, the stapedius, measures only 2 mm in length. On the other hand, the sartorius and other large muscles of the extremities measure up to 2 feet in length (61 cm). Skeletal muscles are composed of varying numbers of muscle fibers (e.g., 10,000 in lumbricals and 1,000,000 in gastrocnemius) (28). These are connected at both ends to tendons or the epimysium.

Because the fibers work in conjunction with each other, they are aligned in the same direction. Few skeletal muscles are modeled after the lumbricals, where all the fibers are arranged in a fusiform structure that tapers at either end at the site of tendinous

insertion (29). The more familiar unit is a parallelogram composed of muscle fibers that insert at both ends on a flat tendon composed of dense collagen. In a parallel muscle, the fascicles are parallel to the longitudinal axis of the muscle, as in the thyrohyoid. In oblique muscles, a tendon typically runs within the muscle or on its surface, and the muscle fibers insert obliquely on the tendon. Oblique muscles are most often pennate or featherlike. Some are bipennate, much like a feather in which there is a central shaft from which a series of barbs radiate on either side. Such muscles have a central tendinous structure from which two sets of parallel muscle fibers radiate (e.g., peroneus longus). Other muscles are simple pennate, in which only one set of parallel muscle fibers attaches obliquely on a shaftlike tendon (e.g., extensor digitorum longus). Muscles are designated as complex pennate when the muscle consists of multiple parallelograms attaching to several tendons in the muscle mass. Not all skeletal muscles follow precisely the model of parallel or pennate design. They may be triangular like the pectoralis minor or spiral in structure like the forearm supinators. Although most muscles are attached to and are involved in moving bony skeletal structures, some voluntary muscles (such as those of the larynx and esophagus) do not have attachments to bone.

The blood supply to individual skeletal muscles has not been extensively studied and is therefore incompletely understood. It is known that the arterial supply to muscles varies somewhat with the individual. In general, the skeletal muscles are subserved by several rather than a single artery, which renders them rather resistant to ischemia from an embolus or from disease of a single vessel. Much of our understanding regarding the pattern of vascularization in human muscle is derived from studies performed by Blomfield (30).

The vascular supply to skeletal muscle falls into one of five categories.

- The blood supply is derived from a single nutrient artery that divides in a longitudinal fashion within the muscle itself. The gastrocnemius is an example of such a system.
- The muscle is supplied by several separate arteries entering the muscle along its length. Anastomoses are formed within the muscle between the territories of each artery. This pattern is typical of the soleus.
- The blood supply arises from a single main artery that enters the belly of the muscle and subsequently forms a radiating pattern of collaterals, as in the biceps brachii.
- In muscles like the tibialis anterior, a pattern of anastomosing arcades is derived from a series of penetrating arteries. This vascular pattern is considered to be the most efficient form of vascularization.
- A less efficient form of the anastomosing arcade pattern is the rectangular pattern of anastomoses formed by a series of penetrating arteries. This so-called quadrilateral pattern is seen in the extensor hallucis longus muscle.

Once a main artery enters the muscle substance, it branches into a number of primary intramuscular arteries that ramify in the epimysium and perimysium. The primary arteries, with a diameter which ranges from 80 to 360 Âµm, give rise to numerous secondary arterioles that run parallel to the direction of the muscle fibers. The secondary arterioles often connect to primary arteries, forming artery-to-artery anastomoses. The secondary arterioles, which range in diameter from 50 to 100 Âµm, typically have a thin adventitia composed of fibroblasts and collagen. The smooth muscle coat is much thinner than that of the primary arteries, usually having only two to three layers of cells. The internal elastica is prominent and continuous. The secondary arterioles branch to form terminal arterioles, which measure 15 to

50 Âµm in diameter. Their smooth muscle coat is usually only one layer of cells. The internal elastica becomes discontinuous and is lost in smaller vessels. The distal portions of the terminal arterioles have precapillary sphincters, which are formed from the smooth muscle cells of the media. These sphincters are found in blood vessels with an inner diameter of less than 15 Âµm. Footlike processes between the smooth muscle cells and the endothelium may be seen in the region of the sphincters.

As in other tissues, the arterioles end in an elaborate system of capillaries. In contrast to most other organs, in muscle a relatively small number of capillaries are open at rest (31). During muscle activity there is a considerable increase in the number of open capillaries. A marked difference in capillary density is observed in different muscles, as well as in trained versus untrained subjects. Studies of capillary density reveal that the average single muscle fiber is surrounded by 1.7 capillaries (32). Capillary density may also be expressed as the number of capillaries per fiber, which on average in cross sections is 0.7.

The density of capillaries also reflects oxygen consumption within muscle. Therefore increased numbers of capillaries are evident where larger numbers of type 1 fibers are present. This phenomenon is less evident in humans than in animals such as the cat, in which muscles are composed chiefly or totally of one fiber type. Thus in the cat soleus muscle, which is composed almost entirely of type 1 fibers, the density of capillaries is 1,600 per mm^2. In the gastrocnemius, a muscle with far fewer type 1 fibers, the capillary density is 600 per mm^2 (33). The capillaries within skeletal muscle travel primarily in a longitudinal direction, although they are frequently linked by short transverse branches.

Ultrastructurally, capillaries are composed of endothelial cells surrounded by a basement lamina. Occasional pericytes are encountered outside the basement membrane. Endothelial cells typically contain numerous pinocytotic vesicles. Where endothelial

cells are joined, they lack tight junctions. Hence the capillary endothelium is freely permeable to tracers such as horseradish peroxidase. The capillary pericytes are essentially smooth muscle cells that contain large numbers of filaments. The pericytes are innervated by small-diameter unmyelinated nerve fibers. The basement membrane (which lies between the endothelium and pericytes) measures 20 to 30 nm, although some thickening and reduplication of the basal lamina occurs in older patients.

The nerve supply to individual skeletal muscles often enters the surface of the muscle at the belly and is accompanied by one or more major penetrating arteries. Within the main nerve trunk are myelinated and unmyelinated axons. Contributions to the nerve are made from myelinated efferent motor fibers that innervate the muscle fibers; somatic afferent sensory fibers from muscle spindles, Golgi tendon organs, and Pacinian corpuscles; and unmyelinated autonomic efferent fibers. At least 50% of the fibers are sensory in function. The motor fibers that innervate the myofibers demonstrate a bimodal size distribution. The large diameter Î± fibers innervate fast motor units, while the Î² fibers are distributed to slow motor units and some intrafusal fibers of the muscle spindle. The very small diameter Î³ fibers supply the remainder of the muscle spindle fibers. The large motor fibers are relatively uniform in diameter, measuring between 10 and 15 Âµm. The small motor fibers vary from 2 to 7 Âµm in diameter.

As the distal motor axon approaches the muscle fiber, it is transformed into the terminal axon, which represents the proximal portion of the neuromuscular junction, or motor endplate (MEP). The neuromuscular junction, measuring about 50 Âµm in diameter, is composed of the presynaptic (PRS) portion or terminal axon and the postsynaptic (POS) portion, which is formed by a unique region in the muscle fiber (Figure 8.3). The PRS and POS domains are separated by a specialized, 50-nm wide intercellular space, the synaptic cleft.

The myelinated motor nerve terminates at the PRS region as an unmyelinated axonal segment that is enveloped

by the teloglia, the distal projections of Schwann cells. The terminal axon and teloglia are covered by a layer of endoneurium, the sheath of Henle, which becomes continuous with the endomysium of the muscle fiber in the area of MEP. Numerous synaptic vesicles, each 45 to 50 nm in diameter, are found in the terminal axon. The vesicles are most plentiful around thickened zones of increased electron density at the presynaptic membrane. Studies utilizing freeze-fracture electron microscopy have demonstrated that parallel pairs of double rows of intramembranous particles, measuring 10 nm in diameter, are located at these electron dense zones (34). The particles are considered to represent voltage-sensitive calcium channels known as active zones.

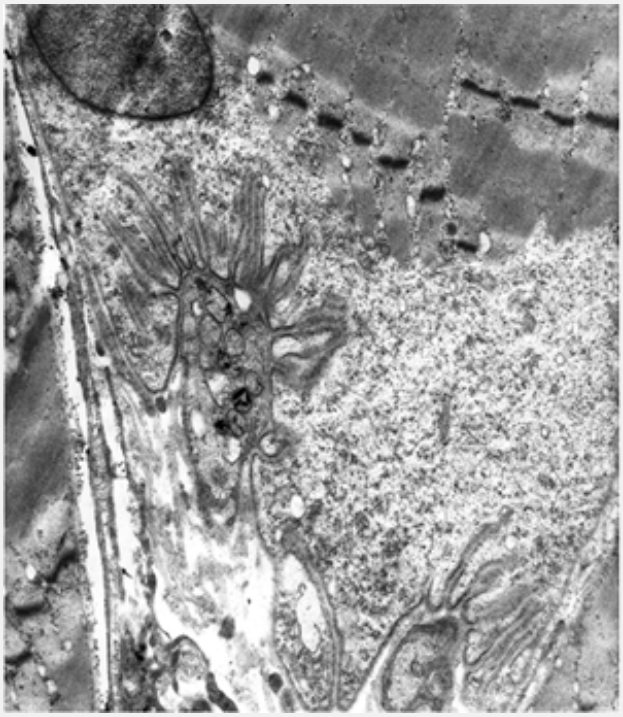

Figure 8.3 Electron micrograph of motor endplate (MEP).

Ultrastructurally, the MEP consists of a terminal axon and a postsynaptic region formed by a specialized portion of the muscle fiber. The surface of the fiber is undulating, representing the postjunctional folds.

At the POS region of the muscle fiber, the cell surface is elevated to form the hillock of DoyÃ¨re, or sole plate. Within the sole plate, the sarcoplasm is granular, and a cluster of sarcolemmal nuclei is often seen. Nuclei in this location are plump and vesicular. The terminal axon ramifies in the sole plate as a series of branches called telodendria, which indent the surface of the fiber, producing gutters or troughs. The surface of the fiber at the MEP is undulating and redundant, creating the complex of postjunctional folds that can be demonstrated by supravital staining as the subneural apparatus of Couteaux. The spaces between the folds denote the secondary synaptic clefts. As a result of the formation of these clefts, the surface area of the POS membrane is increased to approximately 10 times the surface area of the PRS. The postsynaptic membrane of the folds is thicker and more densely stained at the crests than in the depths of the clefts. By electron microscopy, the juxtaneural membrane at the crests of the folds contains irregularly spaced densities measuring 11 to 14 nm in diameter. In freeze-fracture preparations, on the P face of the membrane, the crests are studded with rows of particles that are similar in size to these densities (about 10 nm) (35). These large intramembranous particles are considered to represent the acetylcholine receptor, a pentameric 275 KDa glycoprotein (36).

Light Microscopy

Familiarity with the normal structure of skeletal muscle provides a useful background for the pathologist in the evaluation of muscle biopsies. Other sources offering a more comprehensive discussion of the light microscopy, histochemistry, and electron microscopy of

normal muscle than is possible here are found in the literature (37,38,39,40,41,42,43,44,45,46,47,48). The muscle fiber is a multinucleated, syncytial-like unit shaped like a long, narrow cylinder. The normal adult myocyte is not perfectly round but is polygonal, producing a multi-faceted profile in cross section. The nuclei are usually located subsarcolemmally, numbering four to six per cell when sectioned transversely. For each millimeter of fiber length, there are approximately 30 nuclei (49). In routine sections the sarcolemmal nuclei are slender and flat, with an orientation that is parallel to the long axis of the fiber. These nuclei measure 5 to 12 Âµm in length and 1 to 3 Âµm in width. Their chromatin is fine and dustlike. The nucleoli are small and not visible in many fibers. In paraffin sections stained with H&E, the sarcoplasm is light pink and textured in cross sections (Figure 8.4). In frozen sections that are often routine in biopsies submitted for diagnosis, muscle tissue is stained with Gomori's rapid trichrome (RTC). Here the fibers and connective tissue stain green while nuclei are blue-black. In some cases the mitochondria can be identified, especially in

type 1 fibers, as tiny red granules within the sarcoplasm (Figure 8.5A). The cross-striations must be viewed in longitudinal sections and are difficult to see in any detail without special stains. They are best demonstrated in PAS and PTAH stains or in resin-embedded material where alternating dark and light bands are evident (Figure 8.6). The diameter of fibers is determined by several factors (see the section entitled Gender, Training, and Aging).

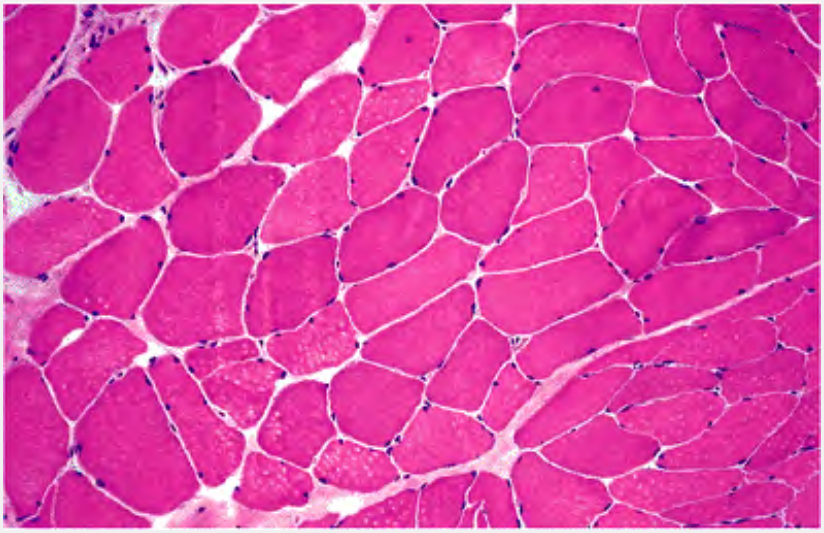

Figure 8.4 Cross section of muscle. The sarcoplasm is textured and the sarcolemmal nuclei are peripheral in location (H&E).

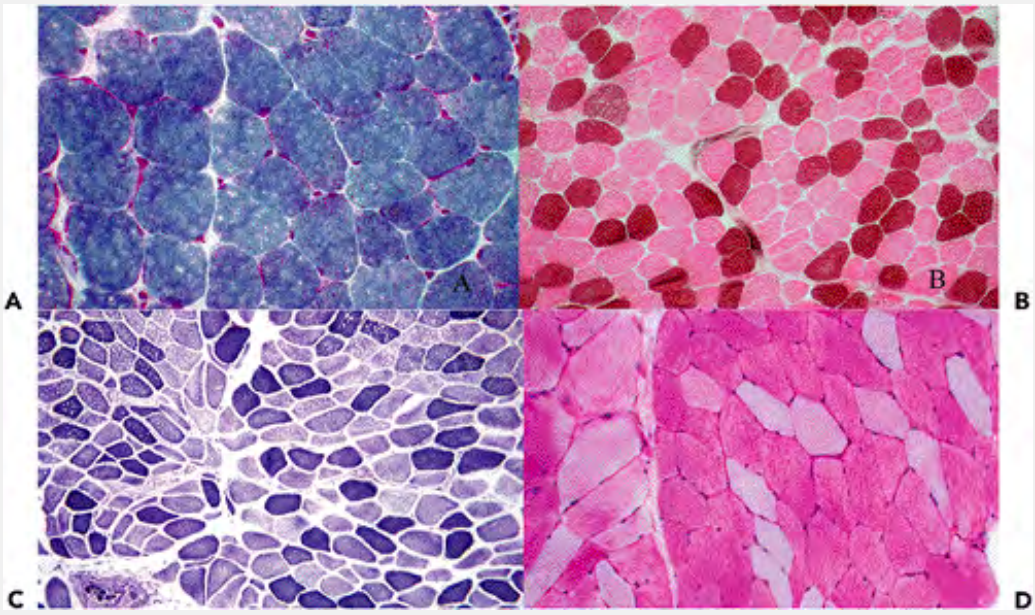

Figure 8.5 A. Reverse trichrome stain. Mitochondria appear as

red granular areas, especially prominent in the subsarcolemmal regions of the fiber. B. Normal muscle. In the standard ATPase reaction, type 1 fibers are light and type 2 fibers are dark (ATPase, pH9.4, eosin counterstain). C. Normal muscle. In oxidative enzyme reactions, type 1 fibers are very dark, and type 2 fibers are intermediate or light in staining intensity (NADH-TR). D. With PAS stain, variable staining of fibers reflects glycogen content and crudely approximates fiber type distribution (PAS).

Proximal muscles, where power rather than finely coordinated movement is required, have a fiber population with a larger mean diameter (85â€“90 Âµm), while those of smaller, distal, and ocular muscles are composed of thinner fibers (20 Âµm). Fiber size in males exceeds that in females, probably in part because of androgenic hormonal influences and more strenuous physical demands. In both genders, exercise promotes fiber hypertrophy. Muscle fibers are smaller in children and in the elderly than in young active adults, although comprehensive normative data at these ages are not easy to find (50,51,52).

Red muscle, having a larger mitochondrial and lipid content and higher capillary density, depends on aerobic respiration and is designed for postural function or sustained activity. The color of red muscles is actually due to relatively greater myoglobin content than white muscles, which contain fewer mitochondria but abundant glycogen, rendering it better suited to anaerobic respiration and to sudden and intermittent contraction. In vertebrates, particularly in birds, red (e.g., soleus) can easily be distinguished from white (e.g., pectoralis) muscles upon external inspection, since an entire muscle in such species may be composed of either red or white fibers. Human muscles, on the other hand, contain both fiber types, which typically assume a mixed mosaic arrangement reminiscent of checkerboard.

Depending on anatomic location and function, the proportion of type 1 and type 2 fibers varies, but a typical muscle contains approximately twice as many type 2 fibers (60â€“65%) as type 1 fibers (35â€“40%).

The demonstration of the histochemical properties of the muscle fibers comprising a biopsy, which is known as

fiber typing, is accomplished by applying histochemical techniques (Table 8.1). Fiber typing is not possible in routine H&E-stained slides and is only appreciated in using histoenzymatic reactions performed on frozen sections. In our laboratory, two complementary histochemical procedures are employed for the detection of fiber types. The most reliable method for this purpose is the myofibrillar ATPase reaction. By changing the pH during the procedure, a spectrum of staining reactions can be produced. In the standard or alkaline ATPase reaction, which is conducted at a pH of 9.4, two fiber types are seen. Type 2 fibers are dark in staining intensity, whereas type 1 fibers are pale (Figure 8.5B). Fibers of intermediate staining intensity are not observed in the alkaline incubation.

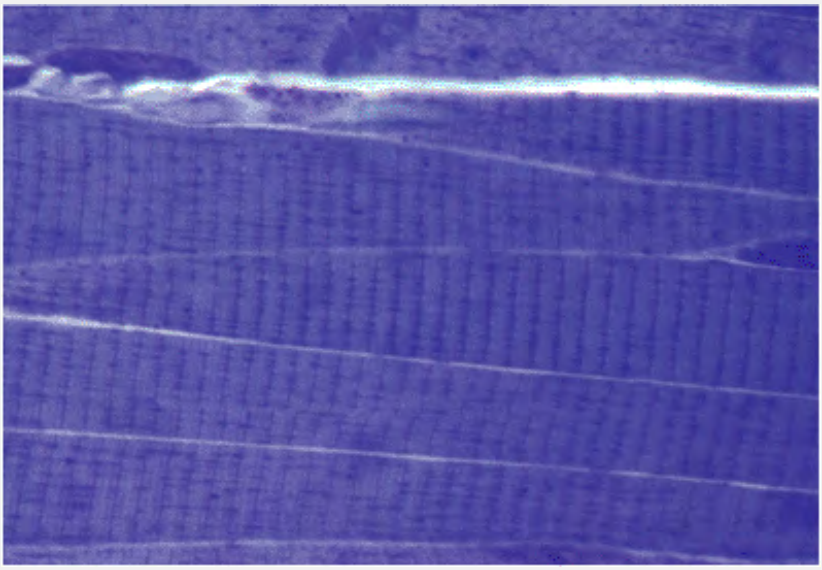

Figure 8.6 Resin section. Sarcomere pattern is shown in longitudinal section (toluidine blue).

Table 8.1 Fiber Typing

Stain/Reaction	Type 1 Fibers	Type 2 Fibers
ATPase, pH 9.4	Light	Dark
NADH-TR	Dark	Light
PAS/phosphorylase	Light	Dark
Oil red O	Dark	Light

If the pH of the incubating solution is brought into the acidic range (pH 4.6) in what is sometimes known as the reverse ATPase reaction, two populations of type 2 fibers emerge. Type 2A fibers are virtually unstained and type 2B fibers are intermediately stained, while type 1 fibers are extremely dark. All the oxidative enzyme reactions, like the NADH-TR used in our laboratory, merely reflect the mitochondrial content of the muscle fibers. Intensely stained fibers are designated as oxidative (type 1) and lighter fibers as type 2 (Figure 8.5C). Most oxidative enzyme reactions further subdivide type 2 fibers into two categories. Type 2B fibers are poorly stained in contrast to type 2A fibers, which exhibit a staining intensity that is intermediate between type 1 and 2B. Although all muscle fibers contain glycogen and the companion enzyme phosphorylase, they are more abundant in type

2 (glycolytic) fibers. The PAS stain, a crude method of detecting glycogen, and the histochemical reaction for phosphorylase can be used as a means of fiber typing (Figure 8.5D). However, staining with these techniques is not totally reliable for fiber typing. We only use the phosphorylase reaction to investigate possible cases of enzyme deficiency (McArdle's disease). Type 1 fibers are rich in lipid, which can be visualized in fat stains such as the oil red O (Figure 8.7); but, like the PAS stain, fat stains are not as reliable for fiber typing as are enzyme reactions.

Striated muscles are partitioned into fascicles, each of which is invested by a connective tissue sheath known as the perimysium. Within this sheath, the intramuscular nerves, primary arteries, secondary and terminal arterioles, and veins travel throughout the muscle. At the innervation zone in the belly of the muscle, intramuscular nerve bundles or twigs are especially numerous (Figure 8.8). Up to 10 myelinated nerve fibers may be present in an individual twig, which is surrounded by a thin mantle of perineurial connective tissue. The myelinated nerve fibers are perhaps best demonstrated in trichrome-stained sections, preferably the RTC, in which the bright redâ€“colored myelin sheaths resemble doughnuts surrounding the unstained axons. Tangential sections of twigs may be mistaken for areas of focal fibrosis or abnormal vascular structures. The perimysium is a framework that lends stability to the fascicles, in part by its attachment to the epimysium. The epimysium forms septa that sequester groups of fascicles, as well as the fascia that encircles the entire muscle and merges with the dense collagenous connective tissue of the tendons.

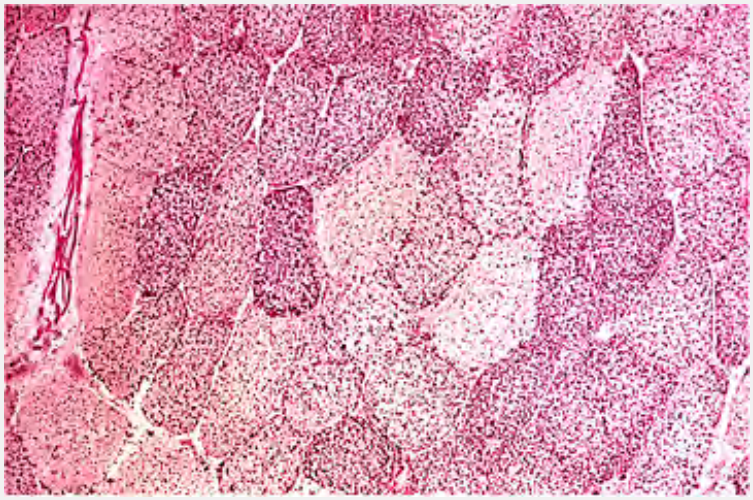

Figure 8.7 Lipid content of fibers is demonstrated with oil red O stain. Oxidative fibers have a more dense lipid concentration (oil red O).

Within each fascicle, the perimysium gives way to a normally unobtrusive network, the endomysium. Each muscle fiber may appear to be partly or completely invested by endomysium, a mesenchymal matrix composed of collagen,

elastic, and reticulin fibers that support the preterminal arterioles and capillary blood supply to the fascicles. Where the muscle-tendon junction has interdigitations of the cell membrane, the interface is enlarged, transferring tension into shear stress. Two transmembrane proteins, the dystrophin-glycoprotein complex and Î±7Î²1 integrin, are especially abundant at the myotendinous junction (53). It is believed that the dystrophin-glycoprotein complex maintains the integrity of the sarcolemma while Î±7Î²1 integrin, a receptor for laminin-2, plays a role in the organization of the basement membrane at the myotendinous junction. At the interface between muscle and either fascia or tendon, the muscle fibers become variable, often small in size, and internal nuclei are

more abundant. As they attach to the tendon or fascia, the fibers are separated by dense collagenous trabeculae (Figure 8.9). Since the normal histology of these regions may easily be misinterpreted as evidence of pathologic change, the muscle biopsy should be obtained from the belly of the muscle, avoiding the tendinous insertions. A deep rather than a superficial biopsy is preferred to avoid the fascia.

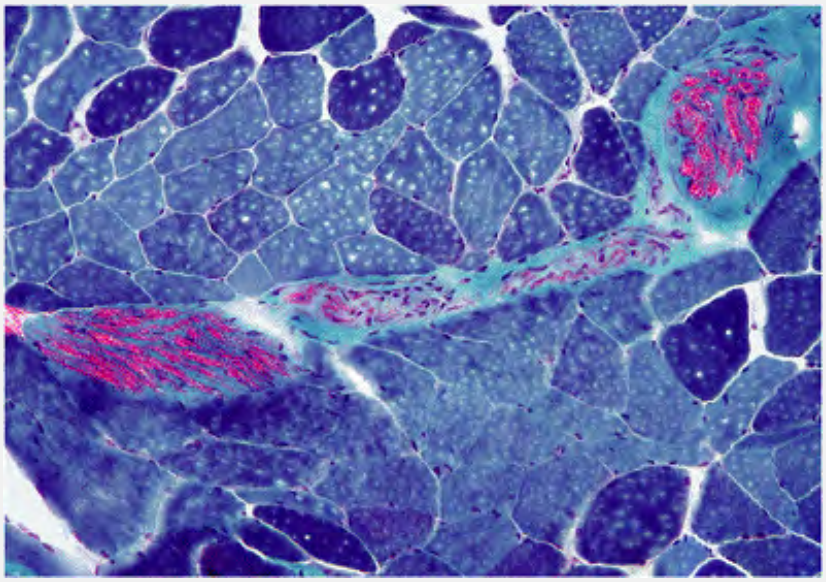

Figure 8.8 Intramuscular nerves. Nerve twigs contain axons surrounded by red-staining myelin sheaths (trichrome).

Several specialized structures are found within the connective tissue supporting framework. Muscle spindles, first described by Hassal and later by Kolliker were once considered to be a pathologic finding (54). Spindles are now known to be mechanoreceptors that sense the length and tension of skeletal muscle, governing integrated muscle activity. Although they are encountered in virtually all muscles, they are more frequently detected in smaller muscles devoted to finely coordinated

activities, such as those of the hand. They are more numerous in distal than in girdle muscles. Quantitative studies have shown that 70 to 100 muscle spindles may be located in an individual muscle. Muscle spindles tend to lie in the deeper portions of the muscle, particularly in the muscle belly. They are often found where type 1 fibers are more plentiful.

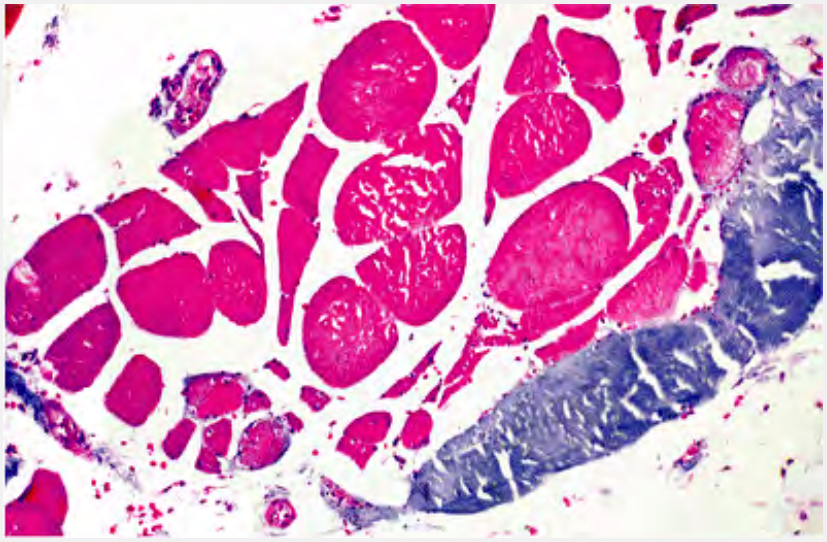

Figure 8.9 Tendinous insertion. At the interface, the muscle fibers normally vary in size and are partly surrounded by connective tissue (trichrome).

As the name implies, muscle spindles are fusiform in shape with a swollen center and tapering ends. They measure 3 to 4 mm in length and 200 Âµm in diameter. A thin fibrous capsule represents the outer boundaries of the muscle spindle. The capsule is an extension of the perimysium, where spindles are usually located. In certain muscles such as those of the eye, face, and mouth, the capsule merges with the perimysium and is somewhat indistinct. The capsule is composed of 10 to 15 layers of flattened pavement cells that are specialized fibroblasts. The pavement cells are

tightly adherent and separated only by thin layers of delicate collagen fibrils. The pavement cells are epithelial-like in that each is surrounded by a basement membrane. As one proceeds from the equatorial region of the spindle toward the poles, the number of layers of pavement cells progressively diminishes.

Within the capsule are 3 to 15 intrafusal fibers in the typical muscle spindle (Figure 8.10). Generally the number of intrafusal fibers is less in small muscles than in larger axial muscles. Two distinct populations of intrafusal fibers are found, both of which are smaller in diameter than the extrafusal fibers. The larger bag fibers, usually one to three per spindle, measure about 20 Âµm in diameter. The chain fibers number two to seven per spindle, with a diameter of 10 Âµm or less. The bag fibers are longer, sometimes extending beyond the polar ends of the capsule. They measure 4 to 8 mm in length. The chain fibers are shorter, measuring 2 to 4 mm. The bag fibers are recognized in the equatorial region of the spindle by the presence of large aggregations of nuclei. Away from the equatorial region, the nuclei remain internal or central in the bag fibers but are far less numerous. The smaller chain fibers are distinguished by a row of central nuclei, which extends along the length of the fiber. In histochemical stains, there are two types of bag fibers. Bag 1 fibers reveal considerable oxidative enzyme activity and are pale in ATPase reactions. On the other hand, bag 2 fibers, which also have high oxidative enzyme

activity, reveal intermediate staining in ATPase reactions. Chain fibers, although they possess high oxidative enzyme activity, stain darkly in ATPase reactions and are considered by many to be type 2 fibers (55).

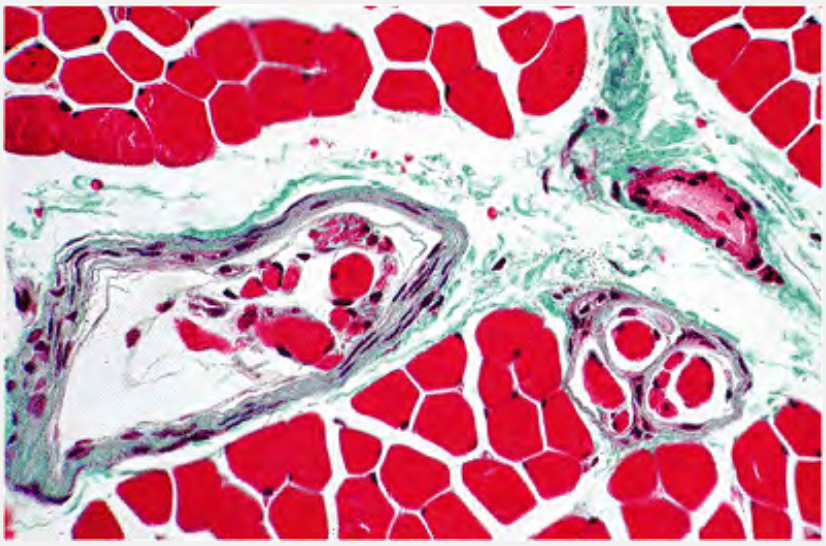

Figure 8.10 Muscle spindle. A fibrous capsule encloses a nerve twig and several intrafusal fibers, which are normally smaller than the extrafusal fibers (trichrome).

The innervation of muscle spindles, which is both motor and sensory, is complex and will only be summarized here (56). The intrafusal efferent fibers are derived from branches of Î² and Î³ efferent axons. The Î² axons appear to terminate primarily on nuclear bag fibers. The Î³ fibers supply both nuclear bag and chain intrafusal fibers. It is not uncommon for intrafusal fibers to have polyneural innervation. Two types of sensory innervation are seen in the muscle spindle. The larger diameter group Ia afferent fibers emanate from the equator. They originate as the annulospiral endings, a series of neural coils and spirals that attach to the nuclear bag and chain fibers. Smaller diameter group II afferent fibers come from the paraequatorial regions of the spindle and are associated mainly with the so-called flower spray endings of Ruffini. The majority of these endings project from the nuclear chain fibers. The secondary, or flower spray, endings consist of a branching network that enwraps the intrafusal fiber between its

polar and equatorial regions.

The Golgi tendon organ is an encapsulated sensory nerve terminal that is located at the junction of muscle with tendon or aponeurosis. The location of these structures allows them to sense changes in muscle tension. They have an inhibitory function in the event of strong muscle contraction. These fusiform structures measure about 1.5 mm in length and 120 Âµm in diameter. They consist of one or more fascicles of collagen fibrils that are attached to tendon or aponeurosis and enveloped by a multilamellar capsule (Figure 8.11). Each structure is connected to 20 to 30 muscle fibers. The Golgi tendon organ is innervated by a myelinated Ib afferent axon, measuring 7 to 15 Âµm in diameter. The afferent nerve typically divides and arborizes around the individual collagen bundles.

Pacinian corpuscles are distributed widely in the subcutaneous tissues of the body, although they may also be encountered within the muscular fascial planes and adjacent to tendons or aponeuroses. They are seldom seen within muscle tissue itself. In the center of the pacinian corpuscle is a central rodlike nerve terminal innervated by fast-conducting group I or II afferent axons. The central axon is surrounded by a capsule composed of concentric layers of cells (Figure 8.12). The elongated cells forming the capsule are surrounded by basal lamina and separated by fine collagen fibrils. Pacinian corpuscles are receptor organs that are sensitive to vibration.

Ultrastructure

The ultrastructural examination of skeletal muscle is conventionally performed on sections oriented longitudinally, wherein deviations from the orderly striated architecture are more easily detected than in cross sections. The sarcoplasm of each muscle fiber is divided into multiple parallel subunits, the myofibrils, which are minute, cylindroid contractile structures

measuring approximately 1 Âµm in diameter. Myofibrils are segmented into a series of identical sarcomeres that are equal in length, whether the muscle is contracted or at rest, and are aligned in register with the sarcomeres of surrounding myofibrils. The unique periodicity of the fine structure of the muscle fiber is a function of the regimentation of this contractile system. The rectangular

banding pattern within each sarcomere is produced by the arrangement of the filaments (Figure 8.13). The Z band, which forms the lateral boundaries of the sarcomere, is an electron-dense bar-shaped structure oriented perpendicular to the long axis of the myofibril. The distance between consecutive Z bands represents the sarcomere length, an average of 2.5 to 3.0 Âµm. The I bands are the most electron-lucent portions of the sarcomere and stand in dramatic contrast to the dark Z bands that bisect them. The I bands are shorter in length than the moderately dense A bands located at the center of the sarcomeres. Within each sarcomere are stacks of parallel filaments that, under the electron microscope, appear to be of two types. The thicker filaments measure 15 nm in diameter and are principally composed of myosin. The thinner filaments, containing chiefly actin, are 8 nm in diameter. The thin filaments are attached to the Z band and extend across the I band, where only thin filaments are found. They penetrate the A band in which alternating thick and thin filaments are visualized. Thick filaments on the other hand, are restricted to the A band region of the sarcomere and determine its length.

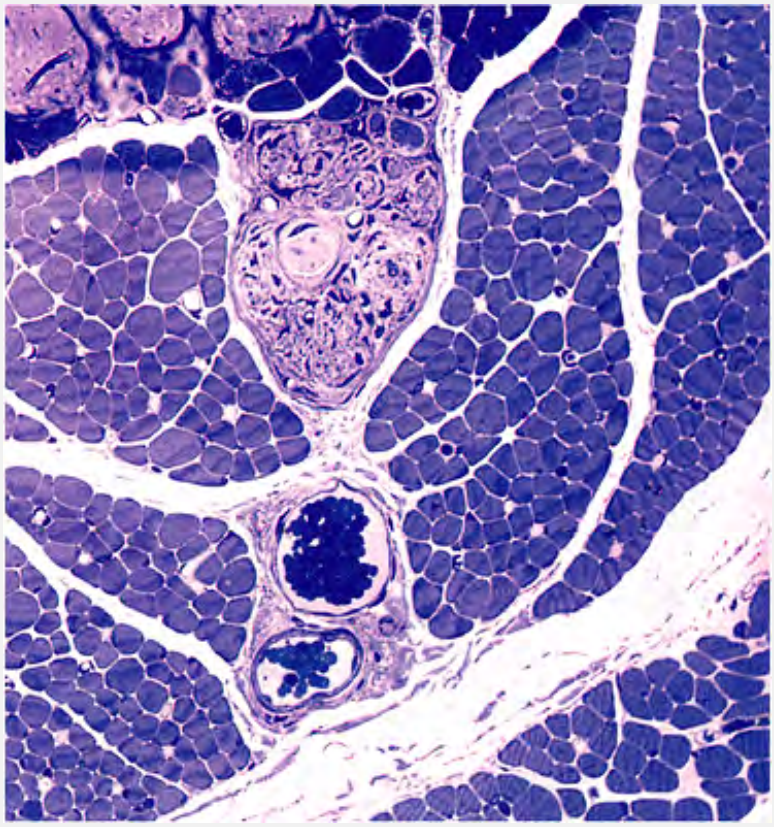

Figure 8.11 Golgi tendon organ. Fascicles of collagen surrounded by several nerve bundles (resin section, toluidine blue).

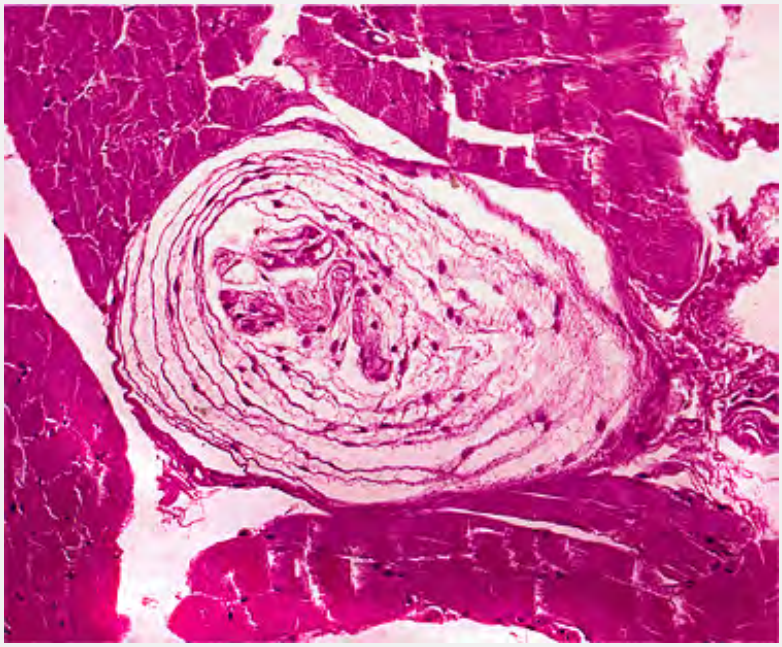

Figure 8.12 Pacinian corpuscle. A central nerve terminal is surrounded by a capsule composed of concentric layers of cells (H&E).

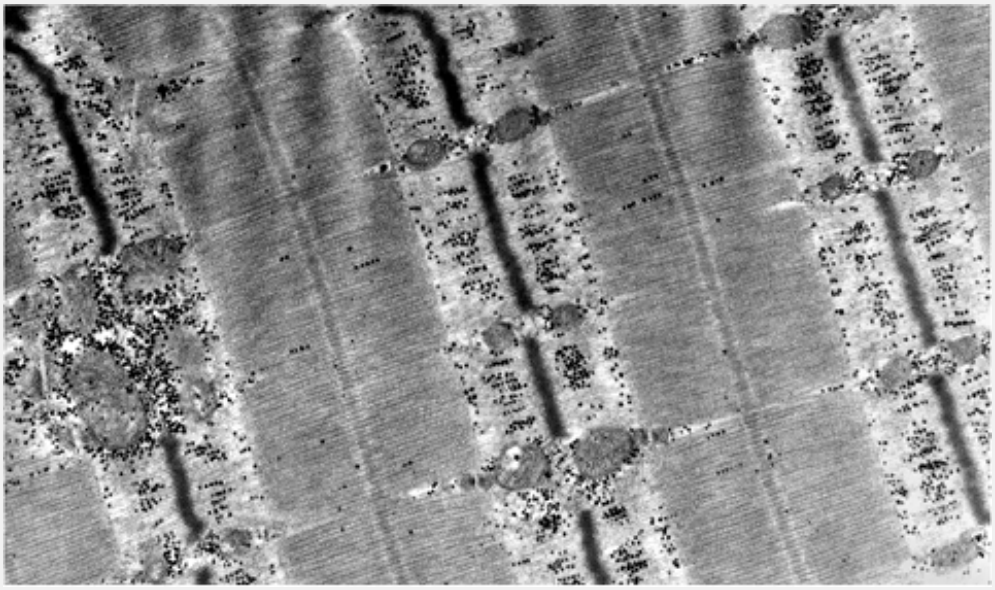

Figure 8.13 Ultrastructurally, the several myofibrils can be seen in register. Each is composed of a series of sarcomeres that contain A, I, and Z band regions (EM).

The sarcoplasmic organelles are more concentrated around the sarcolemmal nuclei and between the myofibrils. The mitochondria are somewhat variable in shape and size, although the majority are oval or elliptical in configuration and 1.0 Âµm in greatest dimension. They are most easily recognized adjacent to the Z bands where their long axes are parallel to those of the myofibrils. Both mitochondria and lipid vacuoles are more conspicuous in oxidative fibers.

Glycogen, composed of granules with a diameter of 15â€“30 nm, is more abundant in glycolytic fibers, particularly in the I band region of the sarcomere. The sarcoplasmic reticulum (SR) and the transverse (T) tubules together comprise the sarcotubular complex. The SR, which is analogous to the endoplasmic reticulum of other cells, is an elaborate system of tubules that, by branching in all directions, surrounds the myofibrils. In contrast to the SR, which has no communication with the extracellular space, the T tubules arise as invaginations from the cell membrane. They are observed at regular intervals along the length of the fiber, particularly at the junction of the A and I bands. The T tubules encircle the myofibrils and are disposed in a predominantly transverse direction. Branches of the sarcotubular complex join together as triads at the A-I band junctions. Here, pairs of terminal cisterns derived from the SR are positioned on either side of a central T tubule. In this location, the SR tubules appear as hollow, membrane-bound profiles, while the T tubules are somewhat more electron dense.

Satellite cells are a population of myoblastic stem cells that are a source of nuclei during muscle growth, particularly hypertrophy.

Satellite cells also have the capacity to synthesize new muscle after myocyte injury. These primitive, indeterminate cells can, under appropriate circumstances, be transformed into blastic elements that serve as an important source of fiber regeneration. Satellite cells represent approximately 10% of the myonuclei seen in cross sections of muscle. There is a decline in the number of satellite cells as a result of the aging process so that they constitute only 2 to 3% of myofiber nuclei in older individuals. Satellite cells are small, mononuclear, fusiform cells that are situated beneath the basement membrane of neighboring muscle fibers (57). They cannot be reliably distinguished from the muscle fiber nuclei under the light microscope. Satellite cells are not randomly distributed along the length of the muscle fiber and are more numerous in certain locations such as the sole plates of the neuromuscular junction and the polar regions of the muscle spindles. Ultrastructurally, the nuclei of satellite cells differ somewhat from the nuclei of muscle fibers. They are more elongated, their nuclear chromatin is peripherally dense, and nucleoli are lacking. The satellite cell nuclei are usually asymmetrical within the cytoplasm, which contains only a few filaments without evidence of sarcomere formation. The sarcoplasm also contains free ribosomes, microtubules, and centrioles, which may be associated with cilia.

Where the cell membranes of the satellite cell and muscle fiber are opposed, numerous pinocytotic vesicles are seen.

Special Techniques

Perhaps more than any other tissue, skeletal muscle in humans has been studied using a wide variety of specialized techniques, in part because human muscle biopsies are frequently collected in such a way as to make both fresh, unfixed tissue and material for special studies available. In addition to routine histochemical methods that are focused primarily on the identification of fiber

types, a number of other histochemical procedures have been employed for the study of both normal and abnormal skeletal muscle. An array of histochemical techniques have been developed to provide greater understanding of muscle metabolism (37,39,40,46). Among these are histochemical techniques to identify various enzymes involved in glycoge metabolism and glycolysis. Familiar examples are histochemical stains for phosphorylase and phosphofructokinase. Other histochemical procedures have been developed to study mitochondrial function. The most widely used is the histochemical stain for cytochrome oxidase. In the workup of human disease, histochemical analysis of muscle tissue can be supplemented by biochemical analysis, specifically when histochemical techniques are unavailable. It is also best, whenever possible, to confirm histochemical findings with biochemical studies. Biochemical analysis has been particularly useful in the study of mitochondrial disease, examining such parameters as the respiratory chain. Molecular techniques are being used with increasing frequency in elucidating normal muscle development as well as muscle disease. A number of abnormal conditions can now be diagnosed using molecular strategies. These include Duchenne dystrophy and other dystrophinopathies (58) and certain mitochondrial disorders in which there is a defect in the mitochondrial genome (59). As mentioned above, it seems likely that the genes that are being discovered in developmental biology one day will contribute to our understanding and diagnosis of muscle disease.

Several techniques have been adapted for the study of intramuscular blood vessels. For example, capillaries are particularly well seen in histochemical procedures for alkaline phosphatase. Capillaries are also nicely demonstrated in immunohistochemical stains for factor VIII.

Immunohistochemistry is an emerging field in pathology that has begun to find a niche in the study of muscle. As already described, muscle fiber typing can be done in frozen sections using

histochemical stains such as ATPase. Antibodies to fast and slow myosins are now available for the identification of type 1 and type 2 muscle fibers in fixed tissue (Figure 8.14) (60). It is also possible to subdivide type 2 fibers into types 2A and 2B using myosin antibodies. Fibers undergoing regeneration can be detected by immunohistochemical methods. Regenerating fibers contain fetal myosins and react using antibodies to vimentin and desmin. Recently visualization of the membrane-associated proteins, dystrophin, and the family of sarcoglycans (Î±-Î´), has become practical (Figure 8.15). Antibodies to dystrophin, as well as to some of the dystrophin-associated glycoproteins, permit the diagnosis of Duchenne dystrophy, selected other dystrophinopathies, and the some of the limb girdle muscular dystrophies (61). In fact, it is now possible to identify an array of myopathies using immunohistochemistry to study disease-related proteins (Table 8.2).

Figure 8.14 Checkerboard pattern is seen with dark type 2 fibers and pale type 1 fibers (immunostain for fast myosin).

The nerve supply to muscle, including the intramuscular nerve twigs and MEPs, cannot be adequately studied in routine samples. The anatomic location of nerve endings and endplates is variable, depending on the muscle selected. They may be restricted to a narrow band across the muscle, or they may be more widely distributed throughout the

muscle tissue. Some investigators prefer to biopsy shorter muscles, maximizing the chance of finding the intramuscular nerves. The external intercostal muscle has been used for this reason. Many limb muscles have a single band of terminal motor innervation that corresponds to the so-called motor point. The motor point can be identified with the use of an electrical stimulator. After the administration of local anesthesia and incision of the skin, the muscle is stimulated using a metallic electrode before any tissue is removed. The nerve endings can be located at sites where a single fascicle rather than the whole muscle contracts after stimulation with a very weak current. Once the innervation zone is established electrically, the biopsy is removed. Using a variety of techniques, different portions of the muscle innervation can be subsequently evaluated.

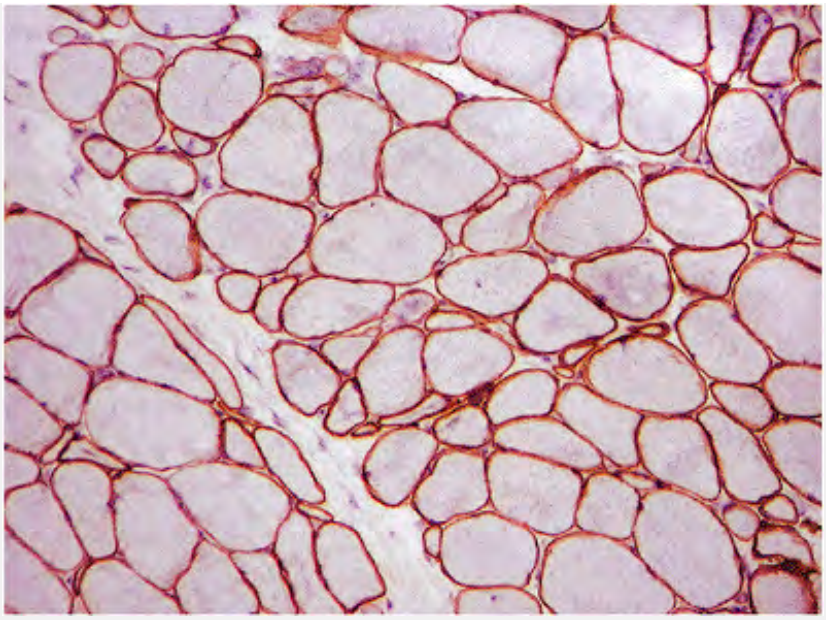

Figure 8.15 Sarcolemmal regions are darkly stained (immunostain for dystrophin).

Table 8.2 Immunohistochemical Identification of Proteins in Skeletal Muscle Disease

Protein	Muscle Disease
Dystrophin	Duchenne muscular dystropy; Becker type muscular dystrophy
Lamin A/C	LGMD 1B
Dysferlin	LGMD 2B

Sarcoglycans	LGMD 2C-2F
Fukutin	Congenital muscular dystrophy
Merosin	Congenital muscular dystrophy
Tropomyosin	Nemaline myopathy
Myotubulin	Centronuclear myopathy
Desmin	Desmin storage myopathy

LGMD, limb girdle muscular dystrophy

Vital staining with methylene blue has been used to demonstrate the intramuscular nerve twigs as well as the endplates (62). This technique requires that the muscle be injected with a methylene blue solution before the muscle sample is actually taken. An undesirable complication of this technique is muscle pain, which many patients experience during the injection of the dye. In order to preserve the staining of the nerve endings, the biopsy must be oxygenated for one hour. This technique is obviously complicated and not recommended for most laboratories. A simpler but less elegant technique for the demonstration of nerve twigs is the staining of muscle with silver methods such as Bodian's stain. The postjunctional portion of the endplate can be stained histochemically for acetylcholinesterase activity (63). The reaction product is not restricted to the postjunctional membrane, and consequently this is a relatively crude method of studying endplates.

More precise methods of studying endplates involve the use of Î±-bungarotoxin and freeze-fracture electron microscopy. Alpha-bungarotoxin is derived from cobra venom and binds specifically with the actelycholine receptor. Immunoperoxidase techniques using Î±-bungarotoxin allow direct ultrastructural visualization of the postjunctional region of the MEP (64). With the use of freeze-fracture preparations, both the active zones of the presynaptic membrane and the acetylcholine receptors of the postsynaptic membrane can be studied in greater detail (65). In certain rare disorders of the neuromuscular junction, freeze-fracture microscopy may be a useful ancillary diagnostic tool.

The nearly crystalline arrangement of filaments within muscle fibers renders them a suitable subject for x-ray diffraction studies. Diffractograms have provided considerable insight into the architecture and structure of the myofilaments (66). A major advantage of x-ray diffraction is its application to living muscle cells. Recently x-ray diffraction has been enhanced by the use of increasingly powerful x-ray sources and electronic signal detectors that have replaced photographic film. Reflection signals from a living muscle fiber can be adjusted to reveal equatorial reflections from the regular lateral spacing of the filaments or meridional reflections originating from the arrangement of subunits in the direction of the fiber axis, depending on the angle of the diffractogram and the camera light.

Finally, morphometric analysis of muscle tissue is indicated in the event that normal or abnormal findings, such as variations in fiber diameters, are minimal and subtle. In the past, morphometry has been performed manually, using an eyepiece micrometer, but this procedure is time-consuming and tedious. More recently, it has been possible to conduct sophisticated morphometric analysis electronically, using a computer-assisted image analyzer (67). Automated image analysis can be adapted for quantitative measurements on photographs of microscopic sections, but systems also exist for totally automated analysis of images taken

directly from microscopic slides or other types of tissue preparations.

Function

Muscle has at least two major functions. In addition to the obvious role in locomotion, skeletal muscle is also an important participant in general protein metabolism. The reader will recall that muscles are a significant repository of protein for many systemic metabolic requirements. Protein metabolism depends upon a number of factors in a healthy person. These include the rate of protein synthesis and breakdown, which in turn are determined by diet, hormonal influences, growth, and muscular activity. In general, protein synthesis and degradation are governed by the dietary intake of amino acids.

However, the aspect of muscle function that is most familiar relates to contraction, subsequent movement, and locomotion. It is this aspect of skeletal muscle function on which we will concentrate. When a muscle undergoes

contraction, it usually exerts force on a movable structure. Isotonic contraction refers to movement that changes the lengths of muscle fibers. If movement does not take place and fiber lengths do not shorten, the contraction is considered to be isometric. The sustained activity of the calf muscles, which do not change length while a person is standing erect, exemplifies isometric contraction. As a rule, a single muscle does not act alone functionally. The coordinated actions of several muscles are usually necessary in the performance of movement. The prime movers are those muscles directly responsible for the desired motion. Antagonists, muscles with opposite action, control the smoothness of the motion. Sometimes agonists and antagonists contract together to stabilize the joint.

An understanding of muscle contraction is predicated on the

concept of the motor unit. In simple terms, the motor unit consists of the anterior horn cell that resides in the spinal cord, its motor axon, the intramuscular branches of the main axon (nerve twigs), and the muscle fibers innervated by the twigs. Each motor unit consists of an average of 50 to 100 muscle fibers. The interface between each muscle fiber and its terminal axon is the motor endplate or neuromuscular junction.

There are at least seven critical steps in the process of muscle contraction, each of which will be briefly described (68).

- The first step is initiated by the excitation and discharge of the motor neuron or anterior horn cell within the spinal cord. The neuronal discharge is associated with a nerve impulse, or action potential, that is propagated along the axon to its terminal. Nerve conduction is an active process so that the impulse travels along the nerve at a constant amplitude and velocity. The impulse is due to a change in ion concentration across the cell membrane that ultimately depends upon alterations in membrane ion channels. Commensurate with depolarization, the voltage-gated sodium channels open, permitting a massive influx of sodium ions.
- It is useful to remember that the neuromuscular junction consists of presynaptic (PRS) and postsynaptic (POS) regions that are separated by a narrow, intercellular synaptic cleft. The process of neuromuscular transmission is heralded by a depolarization of the PRS axon terminal of the motor nerve, which promotes an elevation of intracellular calcium. Calcium ions gain access to the axoplasm through calcium channels in the PRS membrane. In turn, the synaptic vesicles, which contain acetylcholine (ACh), fuse with the axon membrane. This fusion is calcium dependent and leads to a release of ACh into the extracellular space.
- Acetylcholine molecules then cross the synaptic cleft and bind

to the nicotinic acetylcholine receptors (AChR) on the POS membrane of the muscle fiber. The binding of ACh to the AChR increases the sodium and potassium conductance of the muscle membrane. As a result, there is an influx of sodium ions that is accompanied by a depolarizing potential, representing the endplate potential.

- The motor endplate potential is transmitted along the entire muscle fiber surface to initiate the contractile response. Since the T tubules are an extension of the sarcolemma, depolarization spreads along the T tubules, which ramify within the sarcoplasm. Depolarization of the transverse tubular membrane activates the SR by means of the dihydropyridine receptors. These are voltage sensors that respond to the T tubule action potential. They are located next to the calcium channels in the T tubule membranes that trigger the release of calcium from the adjacent SR. Calcium is released from the SR through specific calcium channels known as ryanodine receptors (69).
- Once calcium is released from the SR, it rapidly diffuses through the sarcoplasm. Calcium ions initiate contraction by binding to troponin C. In muscle at rest, troponin I is tightly bound to actin so that tropomyosin covers the sites where myosin can bind to actin. This troponin-tropomyosin complex inhibits the interaction between actin and myosin filaments. When calcium ion binds to troponin C, tropomyosin is displaced laterally, uncovering the binding sites for the myosin heads.
- The molecular basis of muscle contraction involves the shortening of the contractile elements resulting from a sliding of the thin filaments across the thick filaments. The sliding of actin and myosin filaments occurs when the myosin heads bind to actin to form a crossbridge. X-ray crystallography has revealed that each myosin head has an actin-binding site and an ATP-binding site. The site that binds ATP is cleftlike; but,

when ATP is bound and hydrolyzed by ATPase, the conformation of the myosin head changes, and the cleft appears to close. During this conformational change, the rotation of the angle of the crossbridge produces a movement called the power stroke, which advances the myosin filaments along the actin molecules. Every power stroke shortens the muscle approximately 1%. During contraction, numerous power strokes occur each second through crossbridge cycling and involve about 500 myosin heads on each thick filament.

- Following contraction, the muscle relaxes as calcium ions are pumped back into the SR and calcium is released from troponin. This inhibits the interaction between actin and myosin.

Muscle is sometimes conceptualized as machinery that converts chemical energy into mechanical work. Muscle contraction requires large amounts of energy, which is derived from the intermediary metabolism of lipids and carbohydrates. The metabolism of these energy sources, which lead to the production of ATP, is beyond the scope of this chapter.

Gender, Training, and Aging

Some of the earliest studies addressing differences between males and females with regard to muscle fiber size and composition were conducted by Brooke and his colleagues (70). In a seminal study of the biceps muscle in six patients, they established certain principles which remain generally true concerning gender differences in skeletal muscle. Individual muscle fibers are larger in males than in females for several reasons. Explanations include the fact that males are generally bigger than females, being taller and heavier, with a larger muscle mass for body size. Males are also more active and frequently engage in more strenuous physical

exertion. Androgens are also thought to play a role in the size of muscle fibers in males, since it is known that testosterone supplements produce muscle fiber hypertrophy. In males, type 2 fibers are usually larger than type 1 fibers, in contrast to females where type 1 fibers tend to be of equal or greater diameter. An excellent summary of this subject was published by Bennington (67) who showed that some of the differences between males and females are dependent upon the muscles sampled. For example, studies of the biceps muscle essentially verify the findings of Brooke et al. However, examination of the vastus lateralis indicates no significant difference in diameter between type 1 and type 2 fibers in males. Another interesting conclusion from these studies addresses the question of fiber type predominance in the two sexes. With regard to the biceps muscle, males have a much higher percentage of type 2 fibers, whereas females have almost equal numbers of each. On the other hand, in the vastus lateralis, both males and females have similar proportions of type 1 and type 2 fibers.

The effect of exercise and training on skeletal muscle has been examined in a host of investigations over the past 25 years. The results of many of these studies are conflicting, but certain general principles have emerged. It is clear that exercise and training of any type causes an increase in muscle fiber diameters. Activities that are basically anaerobic in nature promote hypertrophy of type 2 fibers, a common finding in sprinters. In long distance runners, for whom aerobic metabolism is more important, type 1 fibers tend to be larger. Most authorities agree that power training such as weight lifting results in remarkable hypertrophy of type 2 fibers and less, if any, enlargement of type 1 fibers.

A more controversial topic is whether there is a change in fiber type composition after long periods of training. It is well known that sprinters tend to have larger numbers of type 2 fibers than sedentary controls and long distance runners tend to have more

type 1 fibers than untrained counterparts. Many investigators tend to believe that these two groups of runners have genetically determined fiber type composition and little, if any, conversion of fiber types takes place during training. However, some studies have shown that while conversion from type 1 to type 2 fibers probably does not occur, certain activities such as endurance running may be responsible for the conversion of type 2B to type 2A fibers over prolonged periods of time (71). Animal studies have shed minimal light on these questions, in part because animal muscle responds differently to exercise and training than does human muscle. In fact, animal experiments have more often clouded the issues of exercise and fiber composition instead of resolving the controversy.

During the process of aging, there is a functional and structural decline in skeletal muscle beginning in the sixth decade and accelerating after the age of 70 years (72). By the age of 75 years, there is a 30 to 50% decline in muscle strength, the cause of which is complex. Because of the alterations in the composition of their connective tissues, associated with decreased elasticity and flexibility, and because many older patients have joint disease of varying severity, the elderly become less active with a corresponding reduction in muscle volume and contractile strength. Some experts view this condition as a form of disuse. Their conclusions are supported by the fact that aging individuals, like young patients who do not use their muscles (for example, as a result of immobilization in a cast), have selective atrophy of type 2 fibers (Figure 8.16). The effect of poor nutrition in the elderly has not been extensively studied, although it is well known that cachexia is also accompanied by atrophy of type 2 fibers.

A second problem in the elderly population is an insidious damage to the motor units, specifically to the anterior horn cells in the spinal cord. It has repeatedly been shown that with advancing age there is a progressive loss of anterior horn cells. Due to degenerative spine disease, there is also injury to nerve roots,

with subsequent radiculopathy. The integrity of the muscle fiber is closely related to the maintenance of its nerve supply. Any sustained interruption of trophic influences from the motor neuron or nerve will culminate in atrophy of the denervated muscle fiber. In acutely denervated muscle, randomly distributed small fibers are seen. When sectioned transversely, atrophic fibers

are characteristically angular or ensate. They appear flattened and bipolar with tapering ends. Most or all of the atrophic fibers are dark in alkaline ATPase reactions and are of glycolytic type. At this stage, selective atrophy of type 2 fibers is commonly the only pathologic abnormality, so that the proper diagnosis of denervation requires corroborative clinical information. With progressive denervation, the proportion of atrophic type 1 and type 2 fibers tends to equalize. As long as atrophic fibers remain scattered and are not yet grouped together, from a diagnostic perspective, the pattern of atrophy is nonspecific.

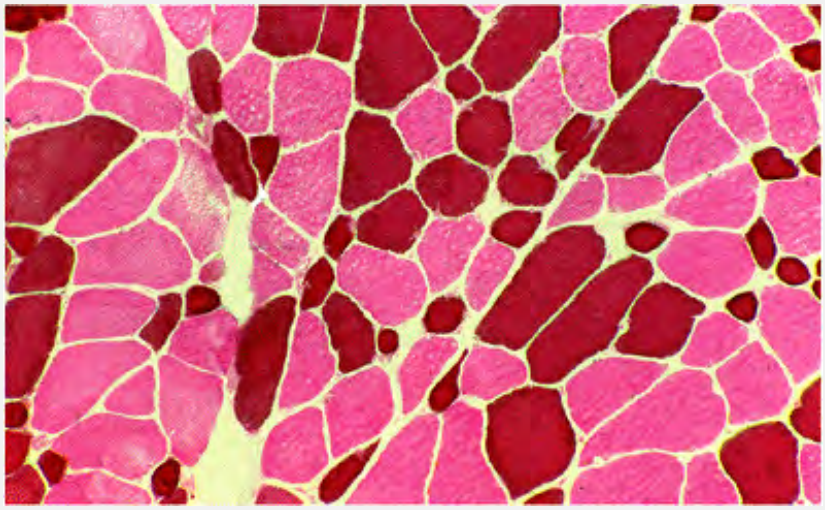

Figure 8.16 Type 2 fiber atrophy (ATPase, pH 9.4, eosin counterstain).

The esterase stain is very useful under these circumstances because denervated fibers are extremely dark in esterase preparations, whereas atrophic fibers in other conditions are not. Atrophic fibers are also excessively dark in oxidative enzyme reactions, but such staining applies to fiber atrophy of almost any cause. Small dark fibers are probably explained by the fact that mitochondria are relatively spared in the atrophic process and occupy a proportionately greater volume of sarcoplasm. The affinity of atrophic fibers for oxidative enzyme stains means that the ATPase reaction is preferable for accurate fiber typing of small fibers, no matter what the pathogenesis of fiber atrophy is.

Prima facie evidence of advanced denervation is a progression from random fiber atrophy to grouped atrophy in which multiple collections of small, angular or ensate fibers are present in the biopsy sample (Figure 8.17). As a consequence of chronic denervation and of reinnervation (73), the normal checkerboard staining profile observed in histoenzymatic reactions is effaced. In an effort to reestablish the nerve supply to denervated muscle fibers, intact intramuscular nerves undergo collateral sprouting, and new synapses are formed with atrophic fibers. As motor units enlarge, reinnervated fibers occupying a large area are converted to one histochemical type. The phenomenon of type grouping (Figure 8.18) is explained by the fact that all muscle fibers within a single motor unit are of the same typeâ€”either type 1 or type 2â€”and the motor neuron, through the trophic influences of its axon and collaterals, governs the histochemical properties of its fibers. The plasticity of muscle fibers allows conversion from one histochemical type to the other when there is reinnervation by a motor neuron of the opposite type. Along with type grouping, target fibers are pathognomic of denervation (74).

Figure 8.17 Grouped atrophy (H&E).

Figure 8.18 Chronic denervation with reinnervation. Type grouping has altered the normal checkerboard staining profile (NADH-TR).

Despite their unique specificity, regrettably bone fide target fibers are present in less than 25% of cases of neurogenic atrophy. Although targets and cores are similar morphologically, they differ in three ways. While both tend to occur singly within a fiber, the target is larger in diameter. The target is limited in length, only extending across a few sarcomeres, in contrast to the core, which may run the entire length of the fiber. Most important is the three-zone architecture of the target fiber (Figure 8.19). The central zone, indistinguishable at the ultrastructural level from the unstructured core, is surrounded by an intermediate zone that forms an intensely stained rim in oxidative enzyme reactions. By definition, the intermediate zone, difficult to identify in most other stains, is absent from a core. It is a zone of transition between the central zone of severe sarcoplasmic disruption and the third zone, which represents the normal portion of the muscle fiber. Targetoid fibers, which lack the intermediate zone of increased oxidative enzyme activity, are morphologically identical to core fibers. The term *core* is conventionally used in cases of congenital central core disease, and the term *targetoid* is applied to cores that are found in any other condition. In our experience, targetoid fibers are more commonly encountered in neurogenic atrophy than any other condition and are more frequently seen than target fibers.

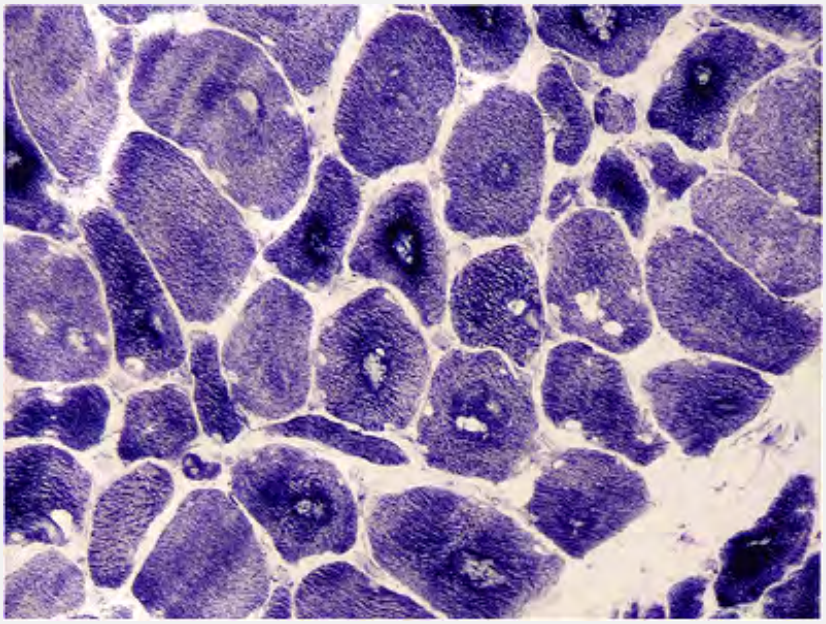

Figure 8.19 Neurogenic atrophy. Target fibers have an inner, unstained zone surrounded by a rim of increased enzyme activity (NADH-TR).

Artifacts

The most common artifacts are related to unsuspected or inadvertent injury to the muscle specimen, irreverent handling at the time of removal, or to improper tissue sectioning and staining. When they are linear in configuration, needle tracts, such as those produced during electromyography (EMG) studies, may easily be recognized. More often, needle tracts are cut tangentially so that the pathologist may be misled by a histologic picture of myopathy exemplified by fiber necrosis, regeneration, inflammation, and interstitial fibrosis (Figure 8.20). This kind of artifact is generally traceable to poor communication between the physician requesting the biopsy and the individual performing the procedure, who is

unaware of the previous intramuscular injections.

Large numbers of neutrophils are occasionally observed within the intramuscular blood vessels. Typically, these cells are marginated and may have begun to penetrate the vascular walls and enter the perimysium or endomysium. In the absence of other pathologic changes within the specimen, the presence of neutrophils usually means that the muscle has been crushed during the biopsy procedure or it has been infiltrated with anesthetic agent.

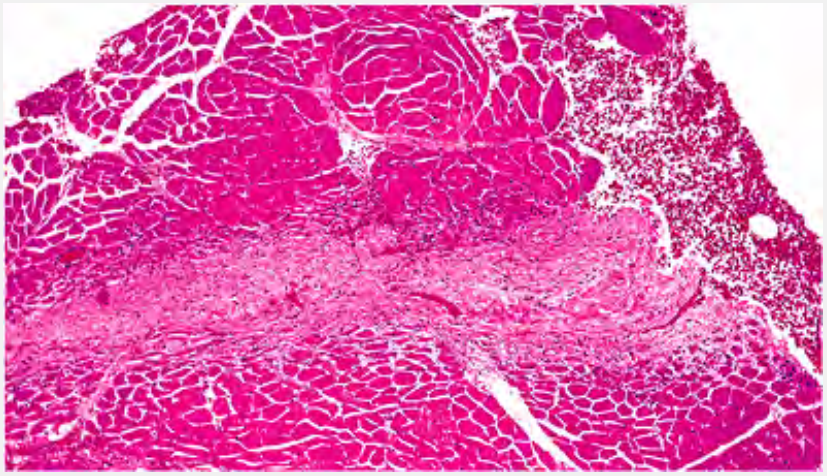

Figure 8.20 Needle tract. Area of injury contains necrotic fibers and a small focus of lymphocytic inflammation (H&E).

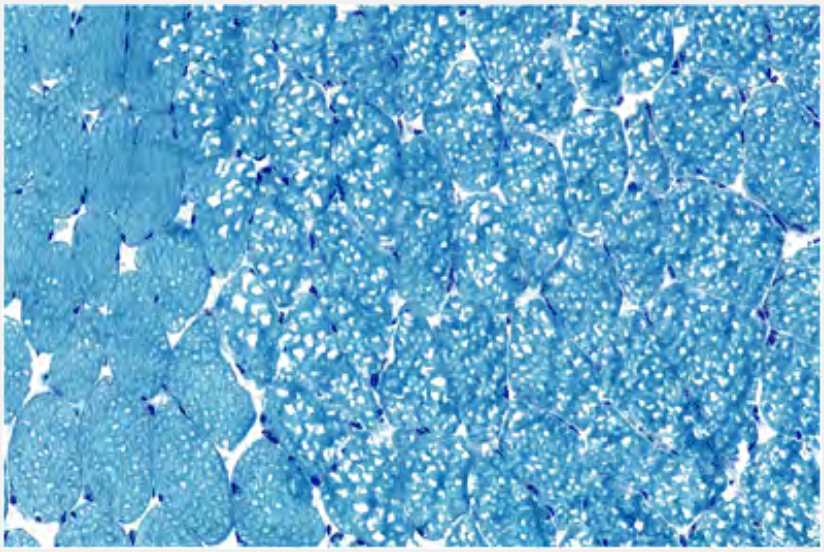

Figure 8.21 Vacuolar artifact. Improper freezing has caused numerous clear holes to form within the fibers (NADH-TR).

Even with the best technical expertise available, muscle tissue is sufficiently fragile that most laboratories find vacuolization of muscle fibers produced during freezing is unavoidable in 10 to 20% of specimens. Vacuolization can be minimized by using proper techniques that permit rapid freezing and by proper specimen storage to prevent thawing. Mild vacuolar artifacts may be tolerable, but large vacuoles that disrupt the sarcoplasm are especially troublesome (Figure 8.21). Larger vacuoles may interfere with accurate biopsy interpretation by distorting the pathologic changes in the sample or by simulating the picture of vacuolar myopathy, such as glycogen or lipid storage disease.

Muscle that is unprotected by isometric clamping is vulnerable to contraction artifact. During uncontrolled contraction, a series of segmental contractions occur along the length of the muscle fiber as the contractile elements are pulled beyond the confines of their respective sarcomeres. This phenomenon is best observed in

longitudinal sections where dark hypercontracted regions are punctuated by pale, ghostlike zones of myofibrillar disruption (Figure 8.22). In transverse orientation, these disrupted segments are seen as irregular fissures in the sarcoplasm. Contraction artifact is particularly undesirable when electron microscopic studies are needed, even if the artifact is subtle and cannot be appreciated at the light microscopic level. The detection of ultrastructural abnormalities, which is dependent on the normal alignment of the myofibrils and myofilaments, is compromised by the distortion of sarcomeric structures. Tissue within the teeth of the clamp is sometimes submitted for processing. This tissue, if not entirely crushed and easily recognized as such, may be compressed, producing an artifact that looks like fiber atrophy. A clue to artifact is the difference in fiber diameters in the rest of the biopsy specimen and the clamped fibers, all of which are uniformly small and angular.

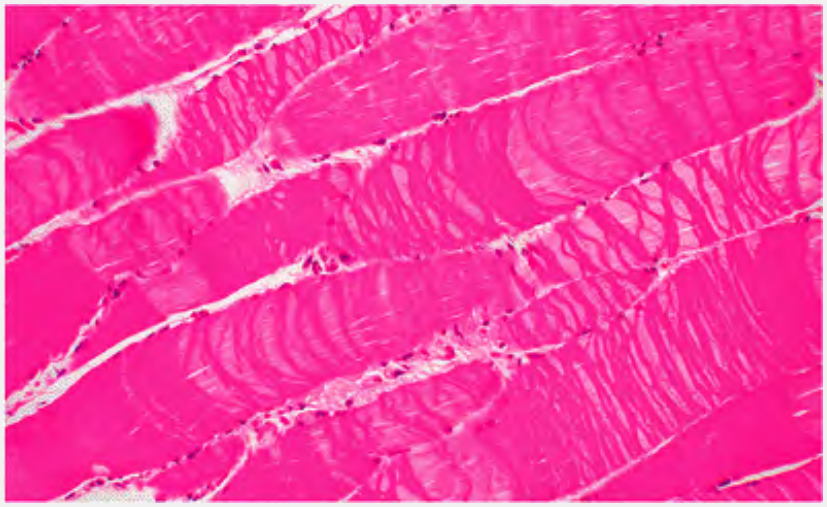

Figure 8.22 Contraction artifact. Dark contraction bands and lucent zones of fiber disruption are seen in longitudinally oriented fibers (H&E).

Dark staining of the sarcoplasm in random fibers is often due to variations in section thickness. Fibers adjacent to the connective tissue of the perimysium are especially susceptible to this artifact. Inconsistencies of section thickness may be recognized when linear, bandlike regions of intense staining are visible within muscle fibers. Excessively pale histochemical reactions can result from the degradation of enzyme systems in the sarcoplasm. Artifacts are distinguished from legitimate abnormal staining if all histochemical reactions in the biopsy are pale. In our experience, this artifact is most often attributable to delayed freezing of the specimen because of a delay in transport. Laboratories that accept consultation specimens from institutions other than their own should be aware of this problem in order to reduce the time required for transportation.

Another transportation-related artifact is seen in specimens shipped in ice when the ice melts, leaving the exposed fresh tissue floating in water. This situation results in a disfiguring and distracting artifact in frozen sections stained with RTC. The normal green staining of the tissue is distorted by irregular red-stained areas that interfere with interpretation of a biopsy (Figure 8.23).

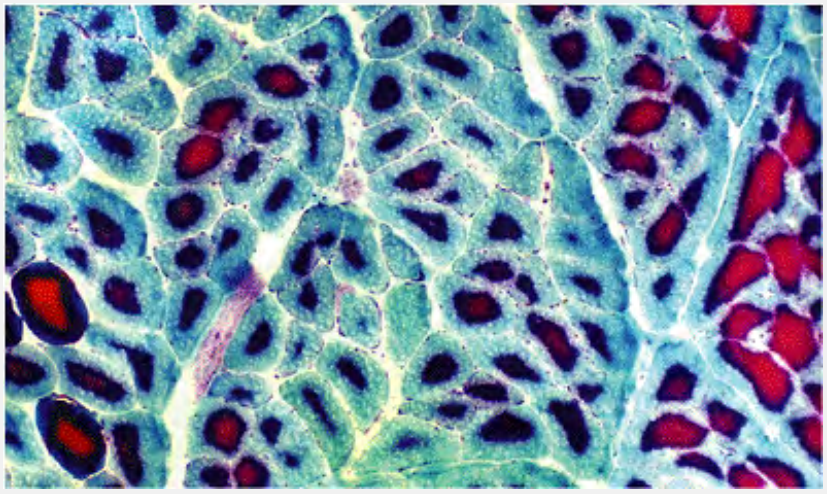

Figure 8.23 Exposure of fresh muscle to water during transport may cause an abnormal staining pattern in RTC, obscuring the detail and granular appearance of mitochondria (RTC).

Differential Diagnosis

Several findings in skeletal muscle biopsies are normal or are minor variations that may be mistaken for pathologic change. These include internal nuclei, ring fibers, hyalin fibers, excessive endomysial connective tissue, perivascular inflammation, variations in fiber diameters, and ragged red fibers.

One of the most common pathological abnormalities in muscle biopsies is nuclear internalization (Figure 8.24). Quantitative analyses have demonstrated that the nuclei are peripherally located in 97 to 99% of normal muscle fibers, which means that up to 3% of fibers with internal nuclei is a normal finding. In many different conditions, an increase in internal nuclei is found, typically affecting 5 to 10% of fibers and particularly those that are mildly atrophic. Nuclear internalization has no specific diagnostic significance and appears to be a reaction to virtually any type of injury. The diagnosis of myotonic dystrophy should be strongly considered if the majority of fibers contain internal nuclei.

One must exercise caution in interpreting the significance of ring fibers in specimens disrupted by contraction artifact because, in this situation, ring fibers are not a genuine pathologic change. In properly processed, uncontracted muscle biopsies, ring fibers are a pathologic criterion of myotonic disorders. The ring is formed by a bundle of peripheral myofibrils that are circumferentially oriented such that they encircle the internal portion of the sarcoplasm, which is normal in structure and orientation. In cross sections of muscle, the ring is especially well visualized in PAS stains where

the striations of the transversely oriented peripheral myofibrils are seen in contrast to the inner sarcoplasmic contents (Figure 8.25). Rings are also seen to advantage in PTAH stains, resin sections, or under phase contrast microscopy. Under the electron microscope,

the pathologically oriented myofibrils are generally normal in structure except for hypercontraction of the sarcomeres (75).

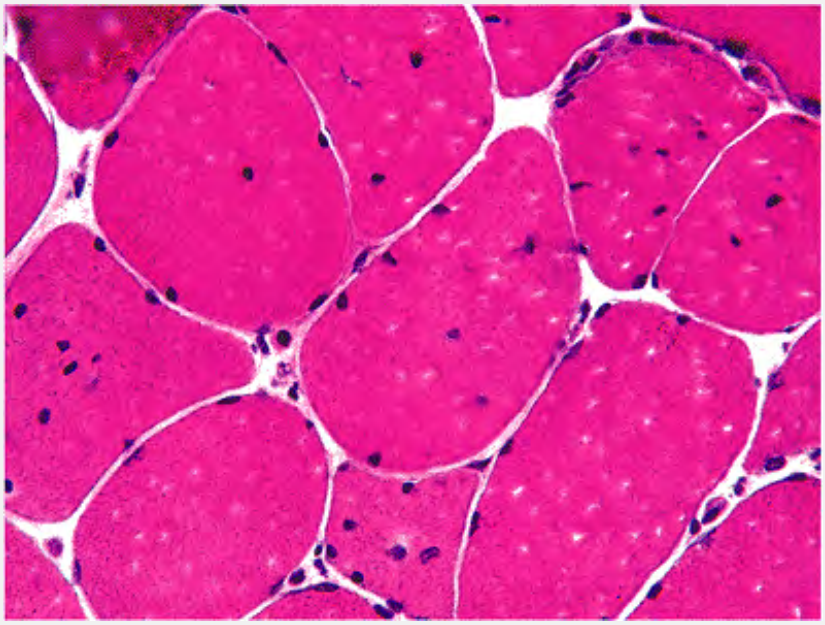

Figure 8.24 Nuclear internalization. Several fibers contain internal pyknotic nuclei, a common nonspecific pathologic change (H&E).

Figure 8.25 Ring fibers. Bundles of myofibrils are circumferentially oriented, forming rings that encircle transversely sectioned fibers. (PAS).

Along with ring fibers, hyalin fibers are evident in specimens damaged by contraction artifact. These fibers are abnormally increased in diameter and rounded in configuration. Their sarcoplasm in both paraffin and frozen sections is smudged or glassy and more deeply stained than in normal fibers (Figure 8.26). The hyalin appearance is the legacy of hypercontraction, as shown in electron microscopic studies. In clamped specimens that are free of excessive contraction, true hyalin fibers are a common feature of Duchenne muscular dystrophy. The pathogenesis of true hyalin fiber formation, which is believed to precede subsequent fiber necrosis (76), is apparently related to excessive irritability secondary to cell membrane instability. It is possible that sarcolemmal damage allows excessive contraction and also promotes cell necrosis. In serial sections of hyalin fibers, areas of necrosis may be found, indicating the importance of hyalinization

as a sign of fiber destruction.

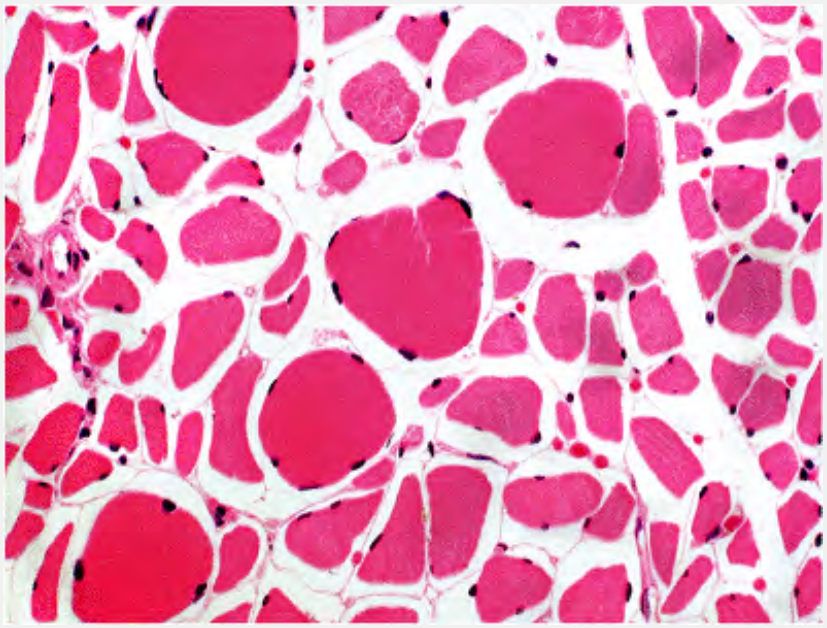

Figure 8.26 Hyalin fibers. Several fibers are enlarged, rounded, with darkly stained sarcoplasm. (H&E).

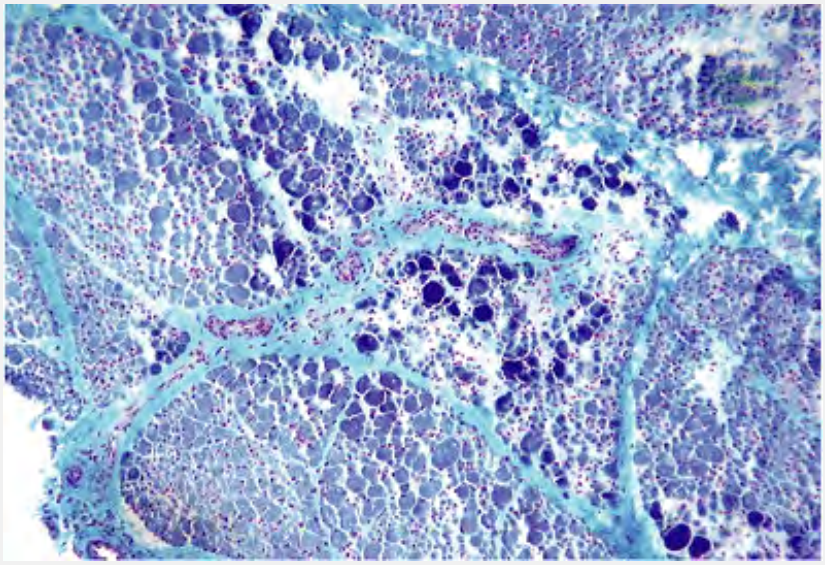

Figure 8.27 Infant muscle. A relative increase in perimysial connective tissue is normal (trichrome).

Excessive quantities of endomysial connective tissue usually represent reactive fibrosis accompanying neuromuscular disease. However, as pointed out above, at the interface between muscle and tendons or fascia, abundant connective tissue is normally present and should not be regarded as reactive fibrosis. Although endomysial connective tissue is not prominent in the biopsies of infants, as indicated previously, the perimysial connective tissue far exceeds the amount present in older children and adults (Figure 8.27).

Interstitial and perivascular inflammatory cells almost always reflect clinical disease, most frequently immunologically mediated or idiopathic inflammatory myopathies such as polymyositis or dermatomyositis. However, in the biopsies of infants it is well to remember that small foci of hematopoiesis are normally present and do not represent true inflammatory infiltrates. Muscles subjected to trauma such as EMG needles may harbor foci of inflammation for months following the diagnostic study and are not clinically significant.

One of the most demanding challenges to the diagnostic pathologist is the muscle biopsy characterized by a variation in fiber diameters or by what appears to be atrophy or hypertrophy. The utility of enzyme histochemistry in these situations cannot be overstated. It is important to recall from previous discussions that (a) a normal variation in fiber size occurs at the junctions of muscle fibers and either tendons or fascia and (b) what at first seems to be atrophy may be normal, depending upon the muscle examined and upon the patient's age and sex. Smaller muscles, and especially those devoted to finely coordinated activities, have much smaller diameters than large, bulky muscles. Muscle fibers

are expected to be much smaller in infants and children than in mature adults; and, as previously noted, there

is an increasing reduction in fiber diameters with advancing age. The significance of fiber hypertrophy should be evaluated in light of the patient's activity and level of regular exercise. In evaluating fiber size, it may be necessary to measure fiber diameters.

Morphometric analysis of the muscle biopsy is imperative when the changes in fiber diameters are minimal and subtle. In order to obtain statically significant morphometric data, the lesser diameter of each muscle fiber should be determined, based upon a minimum number of 200 fibers in the sample (77). The atrophic or hypertrophic process may be selective, affecting only one fiber type, or it may be nonselective (78). True selective atrophy of type 1 fibers is most commonly encountered in myotonic dystrophy. Type 2 fiber atrophy is a common finding in acute denervation, disuse, and myasthenia gravis. True hypertrophy of type 1 fibers is relatively specific for infantile spinal muscular atrophy. True type 2 fiber hypertrophy is generally restricted to congenital fiber-type disproportion. The pattern of atrophy is important in distinguishing between normal and abnormal. Randomly distributed small or large fibers may be normal, depending on other factors discussed above. Grouped atrophy, where five or more small angular fibers cluster together is essentially diagnostic of chronic neurogenic disease. Panfascicular atrophy, in which the majority of fibers in each fascicle are atrophic, is virtually specific for infantile spinal muscle atrophy. Perifascicular atrophy is typical of dermatomyositis.

Ragged red fibers can be observed in elderly people (79). These fibers are recognized in RTC stains performed on frozen sections, where they exhibit an irregular surface and collections of red staining subsarcolemmal material (Figure 8.28). The ragged red areas represent foci of increased, often abnormal mitochondria. Ragged red fibers are generally the hallmark of the mitochondrial

myopathies, which are characterized by mitochondrial dysfunction and often mutations of mitochondrial genes (41). It is now known that mitochondrial damage occurs in the aging cell, including skeletal muscle. Ragged red fibers are considered to be a reflection of this damage, which may be associated with clinical disease but frequently is not.

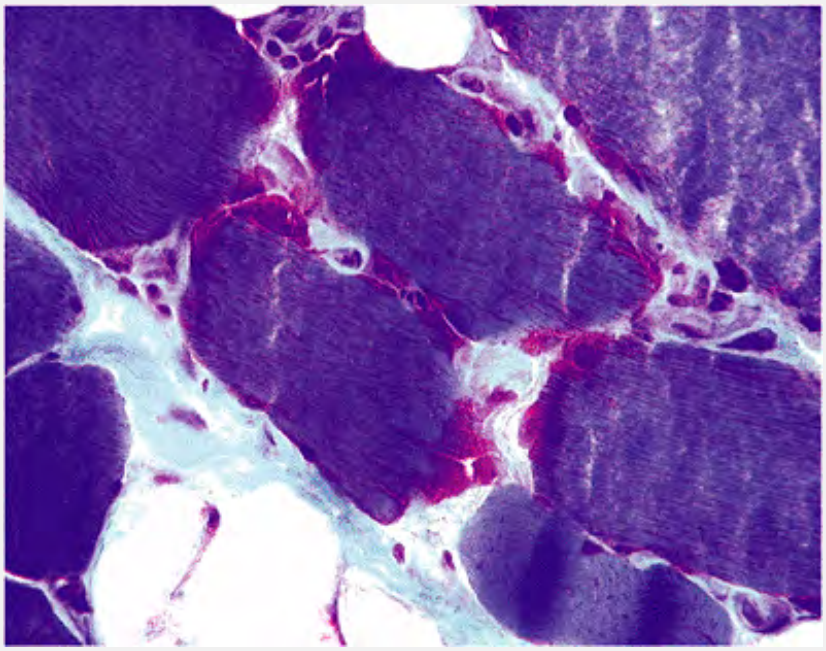

Figure 8.28 Ragged red fibers. Ragged red fibers are recognized in RTC stain as having an irregular sarcolemmal surface with collections of red-staining material (RTC).

Specimen Handling

Muscle biopsies should be performed by physicians with expertise in biopsy technique and a sincere interest in obtaining the best possible specimen. The physician who has direct responsibility for the patient's care needs to be sure that the biopsy comes from an appropriate muscle so that it is representative of the disease

process. In some conditions, the disease process is widespread, such as in many metabolic diseases, and virtually any muscle is suitable for biopsy. However, in other disorders where, for example, symptoms are referable to the legs and spare the arms, a biopsy of the deltoid or biceps brachii muscle is unlikely to reflect the disease process accurately and may be normal or nondiagnostic. Moreover, whenever possible, the tissue sample should be obtained from a region in which the disease process remains active rather than quiescent. In a muscle where the disease process has subsided, the biopsy is apt to be unremarkable. In severely involved muscle, particularly if there is marked weakness or wasting, the pathologic findings are likely to be those of end-stage disease which may defy conclusive pathologic interpretation. Muscles subjected to previous traumatic injury, such as needle tracts incurred during EMG or intramuscular injections of medications, and muscles altered by an unrelated disease process should not be biopsied. The pathologic picture in such muscles may simulate that associated with a variety of neuromuscular diseases and will confuse the pathologist.

The special handling of the muscle biopsy precludes submission of the specimen on weekends and holidays or late in the workday afternoon when laboratory personnel are not available to receive and process the tissue. If possible, a technician familiar with the biopsy technique should assist the physician performing the biopsy and collect the specimen properly. Two separate specimens from the same site are routinely required. The first specimen is maintained at isometric length by its insertion in a muscle clamp. This device is designed to minimize contraction artifact, which inevitably results when an incision is made in the muscle, and it is immersed in fixative. Since the muscle is introduced into the instrument lengthwise, the sample is conveniently oriented for further processing. The biopsy must extend entirely across the clamp, thereby ensuring an acceptable specimen size of at least 1 cm in length. The biopsy should be of sufficient size to maximize

the opportunity of observing the entire pathologic process. To

attain this goal, some clinicians favor obtaining two biopsies routinely, one from the arm and one from the leg, for example. Thus, the major drawback to needle biopsy, which has certain advantages over open biopsy, is the limited size of the sample.

While there is some disagreement regarding the primary fixative for muscle biopsies, we have elected to use 10% formalin, buffered to a pH of 7.4 in a 0.1 M phosphate buffer. Strips of muscle 1 mm in width are dissected from the edges of the sample and postfixed in phosphate-buffered 2% glutaraldehyde for electron microscopic study. After fixation for a minimum of 24 hours in 10% phosphate-buffered formalin, the remainder of the sampled specimen is used for routine paraffin sections. A second unfixed specimen measuring 1 Ã— 0.5 Ã— 0.5 cm is obtained for the preparation of frozen sections. Although the utilization of a muscle clamp is not mandatory, clamping the specimen will help in its orientation.

Several techniques are described for flash freezing (80), but we prefer freezing the sample in liquid nitrogen after coating the surface of the specimen with talc. Whatever technique is employed, the condition on which the freezing technique is based is that it proceeds with extreme rapidity, within 10 to 15 seconds. Freezing the tissue in a cryostat in a fashion similar to most specimens submitted for frozen section diagnosis from the operating room is contraindicated. The frozen sample should be oriented so that cross sections of muscle are cut. Serial frozen sections in our laboratory are stained with H&E, rapid Gomori's trichrome (RTC), and three standard histochemical reactions: ATPase (pH 9.4 and 4.6) and NADH-TR. Other stains such as periodic acid-Schiff (PAS) for glycogen, phosphorylase, and fat stains are performed when indicated. Frozen tissue may also be used for biochemical analysis, for immunohistochemical preparations, and for immunofluorescence microscopy. Inasmuch

as frozen tissue may be needed for future additional studies, muscle biopsies can be sealed in airtight plastic capsules or bags to prevent dessication and freezing artifact while stored in an ultralow freezer at â€“70Â°C.

Gross and Light Microscopic Features

The normal structure of vessels, particularly the aorta, elastic and muscular arteries, and the larger veins, change progressively throughout life (Table 9.1) (1 ,2). These aging changes lead to increased arterial stiffness, detected clinically by alterations in pulse wave velocity (3). It is now clear that aging arteries are especially affected by common disorders such as atherosclerosis, hypertension, and diabetes (Table 9.2). Surgical pathologists must be fully aware not only of the nature and extent of these alterations, but also of their variation from site to site.

Aorta

The length and breadth of the aorta increase progressively throughout life. Although there are some variations in the rate of these changes, both between men and women and from decade to decade, the process continues well into a person's seventies and eighties. This enlargement produces the characteristic unfolding of the aorta so often seen in chest radiographs; and, if the aortic

valve annulus is also involved, aortic incompetence can result. Some atherosclerosis is almost inevitable in the abdominal aorta in the middle aged and elderly, but aging changes are independent of this.

The principal components of all arteries are elastic and collagen fibers, smooth muscle cells, and a mucopolysaccharide-rich ground substance (4). In the media of the aorta and the carotid, the innominate and proximal axillary arteries elastic fibers predominate. Parallel lamellar units of elastin enclose smooth muscle cells, ground substance, and collagen (Figure 9.1). There are about 40 lamellar units at birth and at least 50 in adult life, each measuring about 11 Âµm in thickness. Interconnecting bands of collagen and elastin fibers provide strength, whereas the lamellar arrangement distributes stress evenly across the wall, smoothing the cyclical pressure waves of cardiac contraction (5). Elastic fragmentation with associated foci of fibrosis are the most prominent aging changes and account for the weakening that leads to aortic dilatation (Figure 9.2). The changes in the structure of the extracellular matrix are

thought to be the result of upregulation of genes that mediate matrix metalloproteinase production (6). Apoptosis can be demonstrated in a number of cell types within atheromatous plaques (7) but is unlkely to be a key factor in the aging of the arterial wall (8). Calcification is a common complication; and, although it is most frequent in atheromatous segments, it may occur in areas where the intima is virtually normal. The underlying causes of aortic and coronary arterial calcification remain poorly understood (9 ,10). Small amounts of amyloid can be detected in aortic atheromatous lesions of middle-aged and elderly subjects and may be derived from serum amyloid A or other apolipoproteins (11 ,12).

Aorta

Progressive and linear increase in diameter with age. Eccentric or diffuse fibrous intimal thickening. Fragmentation of elastic lamellae with widening of interlamellar spaces. Focal amyloid deposits. Thickening of walls of vasa vasorum.

Muscular arteries

Progressive dilatation and tortuosity. Caliber of vessels usually less in females, especially coronary arteries. Intimal fibrosis, sometimes suggesting reduplication of the internal elastic lamella. Focal fragmentation and calcification of internal elastic lamella. Increased fibrosis and hyalinization of media. No significant inflammation in atheroma-free segments.

Arterioles

Intimal thickening, usually as concentric layers of fibroelastic tissue. Hyalinization of media.

Capillaries

Basement membrane thickening, approximately twofold increase in thickness from puberty to old age.

Venules and veins

Few detailed studies of small veins. Larger veins show intimal fibrosis and hypertrophy of both circular and longitudinal bundles.

Major Macroscopic and Histologic Features

Table 9.1 Aging Changes in Blood Vessels

Cystic medial degeneration (CMD), originally called *medionecrosis aortae* by Erdheim, is a difficult concept, and many pathologists are unsure about the exact meaning of the term. Histologically, the condition is characterized by degeneration and fragmentation of the elastic layers of the media and formation of mucoid pools (Figure 9.1Bâ€“C). Some areas have few, if any, stainable nuclei, and this is the result of smooth muscle cell death. More recently, areas of smooth muscle cell apoptosis and disorganized proliferation, fibrosis, and angiogenesis have been described,

suggesting that CMD is a process of degenerative injury and repair. In 1977, Schlatmann and Becker (13) showed that the histological alterations of CMD showed a striking correlation with age and may therfore represent the normal aging process of elastic arteries. The same features are seen in hypertensive patients, who have an altered hemodynamic profile, and in genetic disorders of connective tissue, such as Marfan's or some types of the Ehlers-Danlos syndrome. They have also been reported in patients with a history of cocaine abuse (14). In connective tissue disorders, CMD is more pronounced and leads to complications such as intramural hematoma formation or aortic dissection at an earlier age.

Although the exact cause of CMD is unknown, it appears to be related to an imbalance between the mechanical forces imposed on the aortic wall during systole and the

capacity of the aortic wall to resist these forces. The resulting shear forces may cause alterations in the secretion pattern of smooth muscle cells or their death by apoptosis. More recently, p53 accumulation, *bax* upregulation, and both vascular smooth muscle cell apoptosis and regeneration have been demonstrated in areas of cystic medial necrosis (15). In Marfan's syndrome, the histologic changes suggest exaggerated aging, but there are no features that allow a specific diagnosis to be made (Figure 9.2B). The underlying genetic abnormality involves a glycoprotein, fibrillin, that is closely associated with elastin fibers. The exact functions of fibrillin and other associated glycoproteins are uncertain, but they may act as a â€œscaffoldâ€• on which elastin fibers are laid down. There is a wide spectrum of clinical abnormalities in Marfan's syndrome, and certain clinical features, such as arachnodactyly or aortic dissection, are especially common in some families (16).

Condition	Major Histologic Features
Normal adults	Minimal intimal thickening, may be eccentric or diffuse. Intact internal elastic lamella, occasional small breaks only. No significant inflammation.
Atherosclerosis	Eccentric fibrous intimal thickening, intimal and medial foam cell and lipid deposition. Neovascularization with intimal and medial hemorrhage. Dystrophic calcification. Adventitial aggregates of plasma cells, lymphocytes, and histiocytes. Intimal and medial aggregates of T lymphocytes, especially at shoulders of lesion. The most important complication is rupture of fibrous cap of the lesion with associated thrombus formation.
Systematic hypertension	Concentric fibrous intimal thickening and medial hypertrophy, especially in arterioles. Changes pronounced in accelerated or malignant phase, with fibrinoid necrosis. Aneurysmal dilation of intracerebral arterioles and capillaries. Increased atherosclerosis.
Diabetes mellitus	Hyalin change in arterioles. Capillary microaneurysms with basement membrane thickening. Loss of pericytes; retinal neovascularization. Increased atherosclerosis in arteries.
Active arteritis	Acute or chronic inflammatory cell inflammation of adventitia and media. Mural edema, reactive intimal thickening, and endothelial necrosis. Fibrinoid necrosis of wall, occasionally aneurysmal dilatation.
Healed arteritis	Bizarre patterns of disordered fibrous intimal thickening. Medial scarring with patchy aggregates of chronic inflammatory cells. Abnormally prominent medial blood vessels.

Table 9.2 Histologic Changes in Arteries and Arterioles

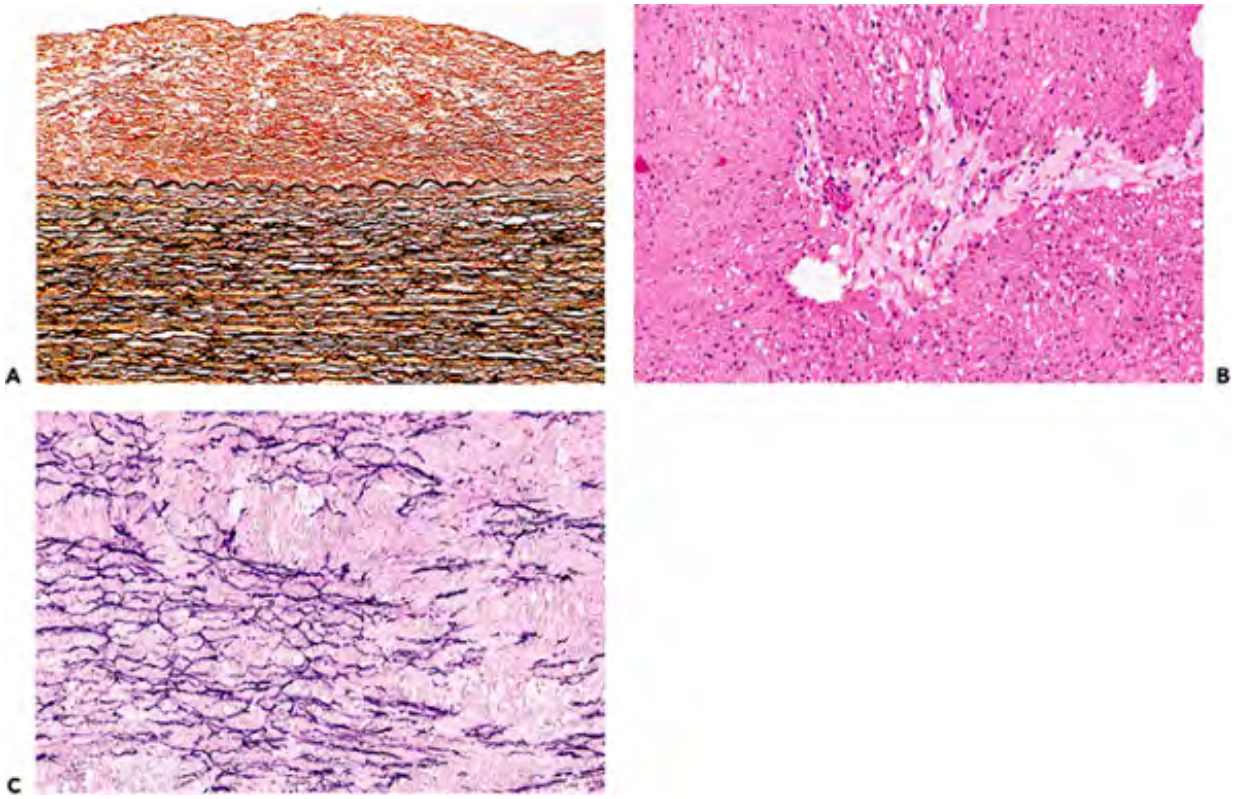

Figure 9.1 A. Inner half of the aortic wall of a 62-year-old man. There is a moderate degree of fibrous intimal thickening, which has no immediate clinical relevance but may predispose to atherosclerosis. There was only slight fragmentation of the elastic lamellae; the overall appearance is well within normal limits for a patient of this age (elastic van Gieson). B. The typical appearance of cystic medial degeneration in an H&Eâ€“stained section. Note the prominent pool of mucoid material. C. This shows a corresponding section to B but is stained for elastic tissue. There is extensive loss of the normal elastic framework.

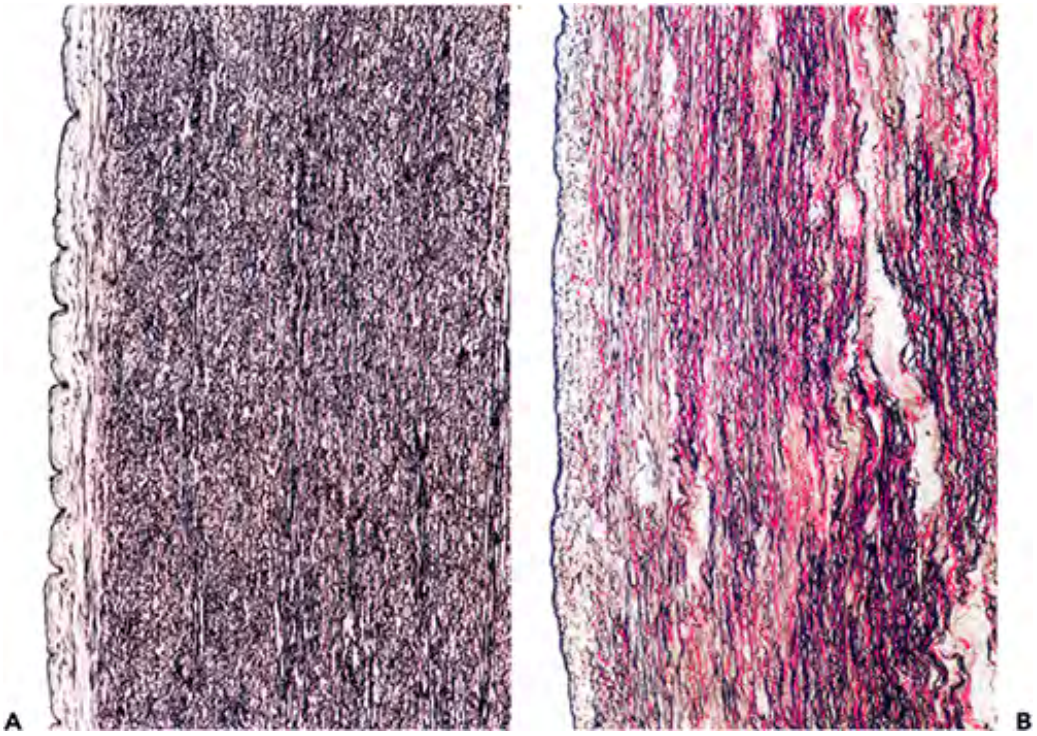

Figure 9.2 A. The normal appearance of the aortic media of a 48-year-old man. There are many parallel lamellae of elastic tissue. There is no significant intimal thickening. B. The aortic wall of a 31-year-old man with Marfan's syndrome. The medial elastic tissue is extensively fragmented, and there is fibrosis and loose mucopolysaccharide-rich areas. Such extensive changes would be unusual even in an elderly patient. (Elastic van Gieson.)

Elastic fragmentation and associated medial necrosis are the most common histologic findings in both ascending and thoracic aortic aneurysms. Despite thinning of the wall due to vascular dilatation, the cellular and matrix components in thoracic aneurysms are in fact increased as a result of vascular smooth muscle hyperplasia. In contrast in abdominal aortic aneurysms there is a reduction in smooth muscle density in abdominal aortic aneurysms (17 ,18). Traditionally, abdominal aortic aneurysms have been considered atheromatous in origin, but this is an oversimplification. Genetic studies have provided compelling evidence for an inherited basis of this disease. Aneurysms have been detected in up to 20% of first

degree relatives, especially when the affected subject is female (19). Whether the atherosclerosis is the primary cause or a secondary complication, the inflammation and medial scarring that accompany all but the earliest stages of atheroma further damage a wall already weakened by normal aging or by specific genetically determined alterations in the matrix of the aortic wall. Patchy chronic inflammatory aggregates, including lymphocytes and plasma cells, are often present in the adventitia of atheromatous segments of the aorta and coronary arteries (Figure 9.3). In biopsies of the ascending aorta during repair of dissecting aneurysms or aortic reconstructions for root dilatation, these chronic adventitial infiltrates must not be mistaken as evidence of aortitis. Small collections of lymphocytes, macrophages, and giant cells are occasionally seen in these biopsies. Although they should be reported, our experience is that they have no clinical significance. In some abdominal aneurysms, the inflammatory infiltrates are especially dense, and surgical repair may be difficult. The inflammation may be a reaction to ceroid pigment, and there can be associated retroperitoneal fibrosis (20).

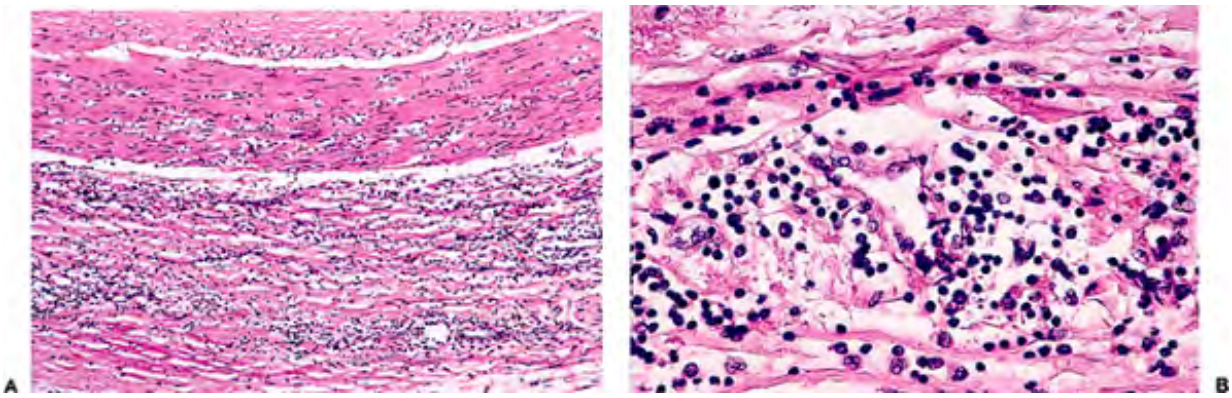

Figure 9.3 A. and B. Adventitial chronic inflammatory infiltrates in the wall of an atheromatous coronary artery. A few inflammatory cells have infiltrated into the media. The magnified view on the right confirms that most of the inflammatory cells are lymphocytes or plasma cells.

Cardiac surgeons have several techniques for repairing aortic coarctations and may submit samples of aorta, the narrowed aortic segment, the subclavian artery, or the ductus arteriosus (arterial duct) for histologic identification. The aorta around the coarctation may show reactive intimal thickening, even in neonates, but the underlying elastic structure is usually well preserved. The coarctation itself can have a variety of appearances. In long-standing cases, there may be dense intimal and medial fibrosis. In neonates, the intima may have a distinctly irregular pattern of fibroelastic intimal thickening, resembling some forms of arterial dysplasia (Figure 9.4). The structure of the arterial duct changes progressively during intrauterine growth and in the postnatal period (21) and can be influenced by prostaglandin treatment. Unlike the aorta and the proximal subclavian artery, which are elastic vessels, the arterial duct has a muscular media and a defined internal elastic lamella.

Arteries

It is only in children and young adults that muscular arteries conform to the classical descriptions of textbooks. The

intima of arteries is defined as the region from and including the endothelium to the luminal margin of the media (22). At birth, the intima is a virtual space with the endothelium closely opposed to the internal elastic lamella. This layer thickens slowly with age, either (a) eccentrically at branching points or bifurcations or (b) diffusely. Both types occur preferentially at sites of altered blood flow or mechanical stress, suggesting that they are adaptive changes (a response to injury). Vascular smooth muscle cells derived from the underlying media and extracellular matrix proteins accumulate in the thickened intima and may serve as a â€œsoilâ€• for the development of atherosclerotic plaques. For example, in the aorta and coronary arteries, the so-called atherosclerosis prone areas are those that show early diffuse or

eccentric thickening.

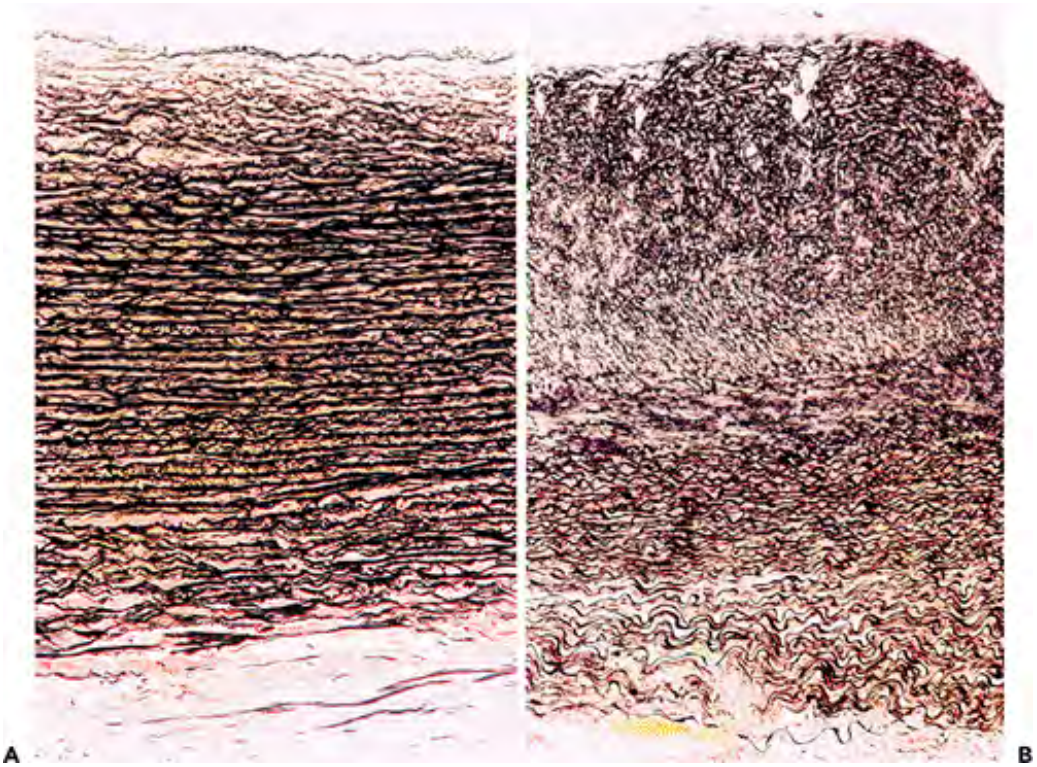

Figure 9.4 Coarctation of the aorta. A. The aortic wall distal to a coarctation in a 3-month-old child. There is slight intimal edema only. B. The coarctation itself; note the irregular arrangement of the intimal fibroelastic tissue. (Elastic van Gieson.)

Progressive intimal fibrosis affects nearly all arteries (Figure 9.5), but in surgical pathology material it is especially noticeable in the spleen, myometrium, and thyroid (Figure 9.6). As in the aorta, fragmentation of the elastic tissue, usually the internal elastic lamella, is common and is of no specific significance (Figure 9.7). In some aging arteries, the internal lamella appears to repeatedly reduplicate, producing a pattern of concentric intimal thickening (Figure 9.5). Small foci of calcification can be identified in otherwise normal vessels, usually just to the medial aspect of the internal elastic lamella. These aging changes, often loosely termed arteriosclerosis, have been studied most extensively in the

coronary arteries, where women generally show substantially less elastic fragmentation and intimal fibrosis than do men of the same age (45). About 75% of the mass of the media is smooth muscle cells. These run in a spiral or circumferential pattern around the wall. As in the intima the small amounts of associated collagen and elastin increase throughout life. Arteries dilate and become more tortuous with increasing age, and this has a fortuitous antiocclusive effect. The caliber of the coronary arteries in middle-aged and elderly women is less than that of men. This may make coronary artery surgery more difficult and contribute to the poorer results recorded in women (23). If arterial dilatation is pronounced and irregular, as in so-called coronary artery ectasia, spontaneous thrombosis may result.

Nutrients reach the media of elastic or muscular arteries by direct diffusion through the intima or via small branches, the vasa vasorum, which reenter the media from the adventitial aspect. Vasa are best seen in biopsy samples taken from the ascending aorta during root repairs and sometimes have remarkably thick muscular walls (Figure 9.8). In

atheromatous arteries, there is often marked neovascular proliferation. Hemorrhage from these vessels contributes to the growth of lesions and their lipid content (24).

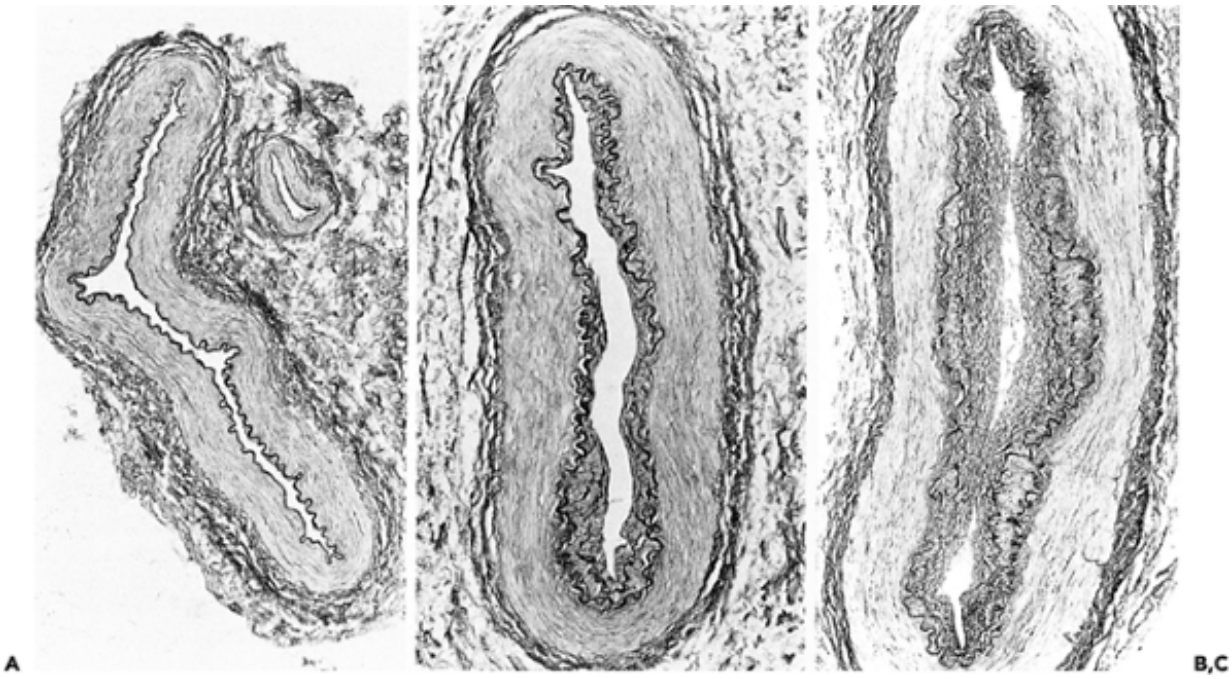

Figure 9.5 Aging changes in muscular arteries. A. (left) Normal appearing artery from a 17-year-old girl. B. and C. Note the progressive intimal fibrosis in arteries from elderly males. In C there is some reduplication of the internal elastic membrane. (Elastic van Gieson.)

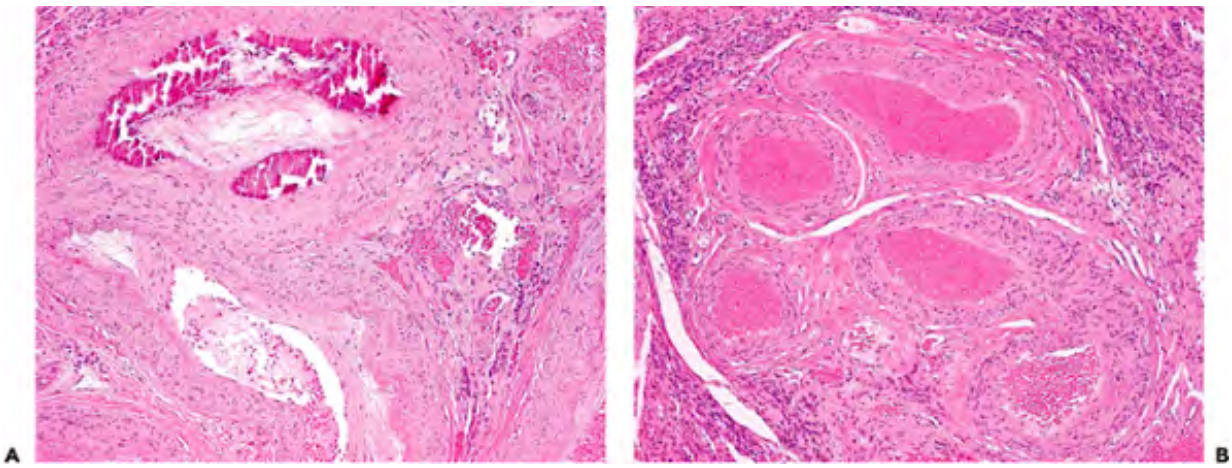

Figure 9.6 A. and B. Aging changes in arteries. These thick-walled vessels were close to the serosa of the myometrium in a 52-year-old woman. Note the prominent calcification in A and the increased tortuosity in B. These changes have no importance. They

can be seen in other sites, especially in thyroidectomy specimens.

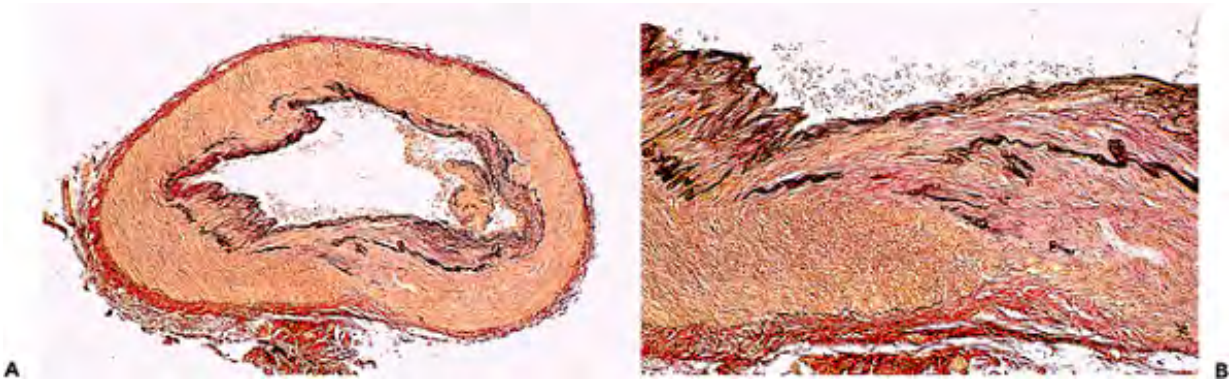

Figure 9.7 A. and B. Temporal artery from a 72-year-old woman who died suddenly from coronary heart disease. There was no past history of headache or temporal arteritis. Note the fragmentation of the elastic lamella with a little associated fibrosis (red coloration in B). Changes such as these are commonplace in the elderly and must not be interpreted as evidence of previous arteritis (elastic van Gieson).

The different stages, or phases, of atherosclerotic plaque development have been categorized in the American Heart Association (AHA) classification into three types of early lesions (plaque types Iâ€“III) and three types of mature late lesions (plaque types IVâ€“VI). Early lesions consist of adaptive intimal thickening (type I), fatty streaks (type II) with accumulation of lipid-rich foam cells and T lymphocytes), and pathological intimal thickening (type III, early atheroma). Late stages include fibroatheroma (type IV), fibrotic or calcified plaques (type V), and complicated plaques (type VI) (25 ,26). Recently, there has been much interest in the concept of the so-called vulnerable plaque: plaques at high risk for development of superimposed thrombosis or plaque hemorrhage. Several postmortem studies of coronary arteries from patients with myocardial infarction or sudden cardiac death have shown that vulnerable lesions have specific features

such as a large lipid core, a thin fibrous cap, and marked inflammatory activity in the plaque tissue (27).

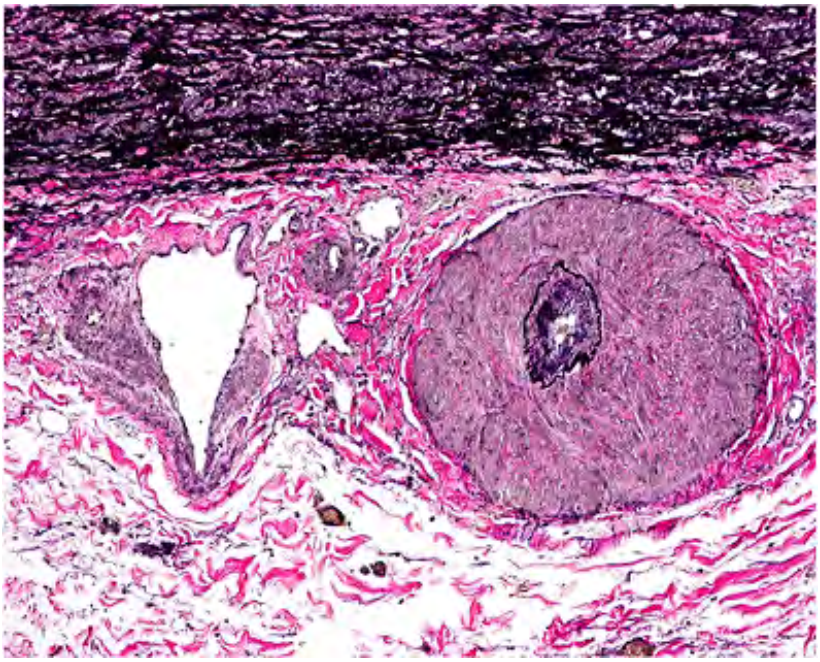

Figure 9.8 The aortic adventitia. The thick-walled vessel is a vasa vasorum. The thin-walled vessel (*left*) is a small vein.

Virmani et al. (28) have modified the AHA classification in order to highlight the variation in plaque morphology in relation to the onset and evolution of atherothrombotic complications. In their classification, the late stages of plaque development are divided into fibrous cap atheroma, thin cap fibroatheroma, healed plaque rupture or erosion, and calcified plaques. This classification emphasizes that complicated (thrombosed) plaques can be the result of rupture of a fibrous cap or erosion of the endothelial lining (Table 9.3).

Inflammatory Infiltrates in Arteries

Apart from a few scattered macrophages or mast cells, the adventitia of arteries is devoid of inflammatory cells. However, for many years it has been known that, in the chronic advanced

stages of atherosclerosis, nodular or patchy inflammatory infiltrates can form at the sites of atheromatous lesions, a process that increases with the severity of atherosclerosis (29). These aggregates can resemble the lymphoid follicle-like lesions that form in diseases of disordered immunity, such as rheumatoid disease. Immunohistochemistry has shown that these highly organized structures containing germinal centers surrounded by both T and B cells. Small vessels are lined by plump endothelium, which stains with antibodies that identify high endothelial venules (see Immunohistochemistry section,

below). Arteries in chronically inflamed tissues and within tumors often show pronounced fibrous intimal thickening, sometimes termed endarteritis obliterans (Table 9.2). In the early stages of this process, the fibrous tissue has a loose histologic appearance, and the ground substance may be basophilic. Although inflammatory or tumor cells often closely surround the adventitia, they do not usually penetrate far into the muscular wall.

Pathologic intimal thickening
Smooth muscle cell proliferation, intimal fibrosis, extracellular lipid but no lipid core or necrosis
Fibrous cap atheroma
Well-formed lipid core with thick fibrous cap, free of inflammatory cells (>80 Âµm coronary artery >200 Âµm carotid artery)
Thin fibrous cap atheroma
Thin cap of inflamed fibrous tissue with underlying lipid core
Ruptured plaque
Luminal thrombus communicating with lipid core via a ruptured fibrous cap
Eroded plaque
Luminal thrombus with endothelial ulceration; lipid core may be absent or small and does not communicate with lumen
Calcified lesions
Heavily calcified plaques with or without thrombus or lipid core

This is a simplified version of the classification of Virmani R, Kolodgie FD, Burke AP, et al. Lessons from sudden cardiac death: a comprehensive morphological classification for atherosclerotic lesions. *Arterioscler Thromb Vasc Biol* 2000;20:1262-1275; Virmani R, Farb A, Burke A, et al. Coronary heart disease and its syndromes. In: Virmani R, Farb A, Burke A, et al. *Cardiovascular pathology.* Philadelphia: WB Saunders, 2001:26â€“53, with permission. Lesion	Histologic Features

Table 9.3 Modified American Heart Association Classification of Atheromatous Lesions

These changes must be carefully distinguished from those of systemic vasculitis. In general terms, vasculitis tends to affect vessels of a specific size, cause necrosis of vessel walls (Figure 9.9) with associated hemorrhage, and lead to tissue infarction. In healed vasculitis, there is irregular fibrosis of the muscular wall (Figure 9.10).

Arterioles

There are no specific histologic features that accurately distinguish small arteries from larger arterioles; but, for convenience, arterioles are said to have a diameter of less than 100 Âµm. However, in biopsy material, there is so much variation in the contours of these small vessels that accurate distinction is often impossible and probably unnecessary. Larger arterioles have an obvious media and an adventitial layer of connective tissue. In the smallest (terminal) arterioles, an internal elastic lamella may not be identified. The smooth muscle cells are arranged circumferentially, each cell winding around the wall several times.

This is the structural basis of the precapillary sphincter. Small arterioles have a very thin adventitia but are richly supplied by sympathetic nerve fibers.

Hyalinization is a common lesion of arterioles and small arteries and increases with age and in conditions such as hypertension and diabetes. The glassy uniform appearance is the result of accumulation of a variety of plasma proteins and small amounts of lipids. As in arteries, reduplication of elastic tissue and intimal fibrosis are common changes in the aged. In severe longstanding benign hypertension and in the malignant phase, the arteriolar lumen can be substantially narrowed by concentric layers of fibrous tissue and smooth muscle cells, changes that are outside the normal range of aging (Table 9.1). Fibrinoid necrosis of the arteriolar media is the hallmark of malignant hypertension and some forms of acute vasculitis (Figure 9.9). It must always be regarded as pathologic. In the earliest changes of diabetic microangiopathy, arterioles and capillaries often show prominent basement membrane thickening (30). This thickening can be readily identified in renal and peripheral nerve biopsies. Although there is physiologic evidence of small vessel disease in the heart and the peripheral vasculature, characteristic histologic changes of diabetic microangiopathy are seldom seen in these sites. In diabetes the amounts of type IV collagen and laminin are increased, but the proteoglycan component of the basement membrane is reduced. Albumin and immunoglobulins accumulate in these abnormal basement membranes, binding to glycosylated protein residues and contributing to the overall eosinophilic appearance.

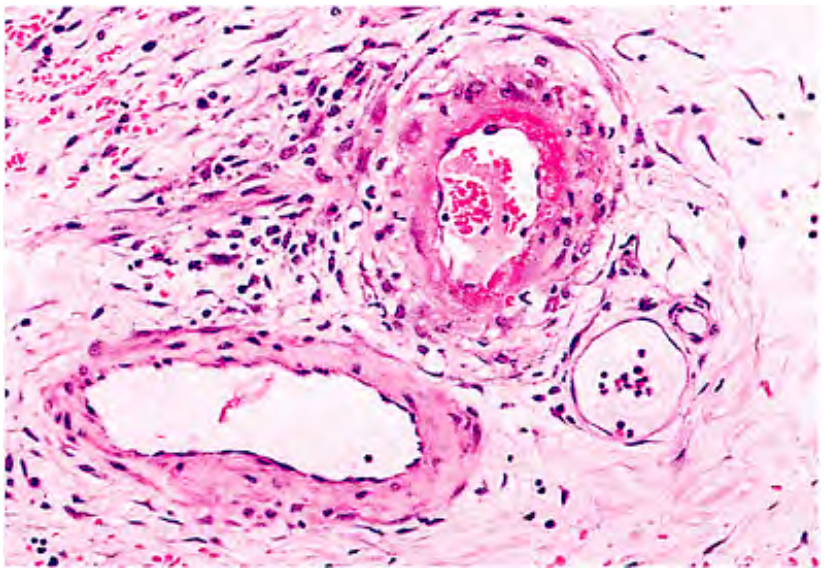

Figure 9.9 Florid fibrinoid necrosis in a small intestinal vessel of a girl with systemic lupus erythematosus. Fibrinoid necrosis is not a feature of normal aging or uncomplicated hypertension. It always should be regarded as pathologic. In this case, the involved vessel is probably an arteriole. Note the small vein (*lower left*) and capillary (*lower right*).

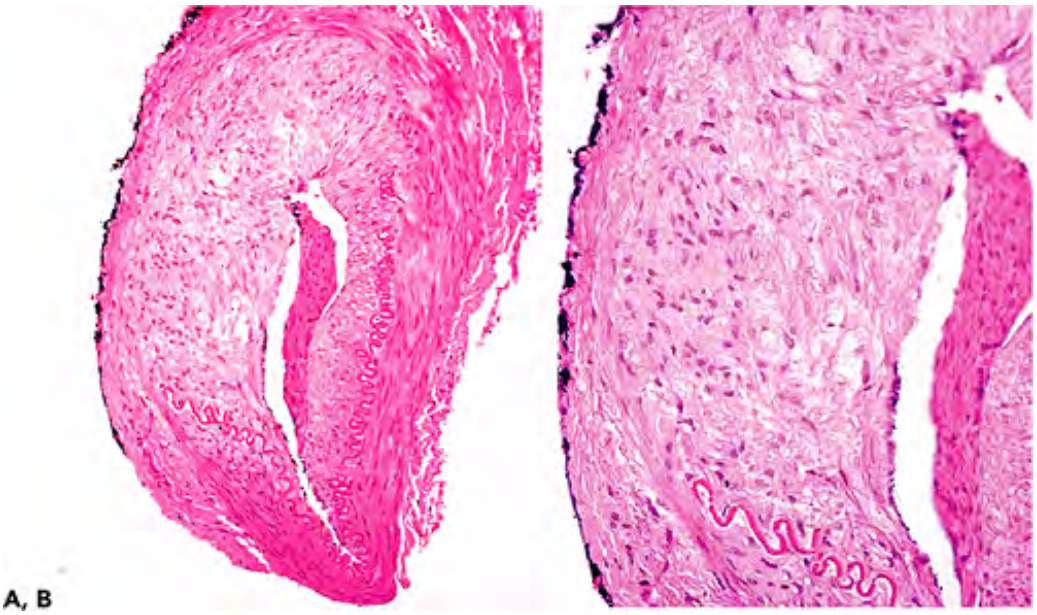

Figure 9.10 Healed temporal arteritis. This patient had been receiving steroid therapy for two weeks when this biopsy was

performed. A. The low power view shows irregular thickening of the wall and a loss of about 50% of the internal elastic lamella. B. This higher power view shows fresh fibrous scarring of the media. Changes such as these are not part of the normal aging process (see Figure 9.6).

Capillaries

In contrast to arterioles, capillaries have neither a muscular media nor an elastic lamella. A single but complete layer of endothelial cells lies on a basement membrane whose thickness varies from site to site. Basement membrane thickness increases with age, almost doubling in muscle capillaries from 10 to 70 years of age. There is no fibrous tissue support peripheral to this, but pericytes are present in and among the basement membrane. It is difficult to identify pericytes in routine sections, but they are easily seen by electron microscopy and also stain with antismooth muscle actin antibodies. They provide structural support; and, because they contain several forms of myosin, they may be able to regulate blood flow. It is likely that they are involved in the synthesis of vascular basement membrane and are capable of phagocytosis (31). It is generally accepted that the turnover of pericytes is increased in the capillaries of diabetics, and this may contribute to the development of small vessel disease (30).

The endothelium of capillaries may have circular fenestrations that act as pores through the full thickness of the endothelial cell. Fenestrations are especially prominent in renal glomerular endothelial cells and are found in the intestinal mucosa, skin, and endocrine glands. In contrast, fenestrations are poorly developed or absent in brain, muscle, lung, and connective tissue (5).

In certain sites, such as the liver, spleen, pituitary, adrenals, and bone marrow, the vessels that connect arterioles and venules are

known as sinusoids rather than capillaries. With diameters of up to 30 to 40 Âµm, they are generally more distended than capillaries. They have prominent fenestrations, but there are also significant gaps between endothelial cells. In the liver, there is no significant associated basement membrane.

Venules and Veins

The transition from venous capillary to muscular venule and small collecting vein is characterized by the gradual acquisition of a muscular media. Even in medium-sized veins (Figure 9.11), the internal elastic lamella is often incomplete and the muscle fibers are only poorly oriented into circular and longitudinal layers. The paracortical or high endothelial venules of lymph nodes have an important role in T-lymphocyte recirculation (32). The endothelial cells of postcapillary venules have a prominent cuboidal or columnal appearance, usually with an ovoid nucleus and a single central nucleolus. They stain specifically with the HECA-452 antibody (see below).

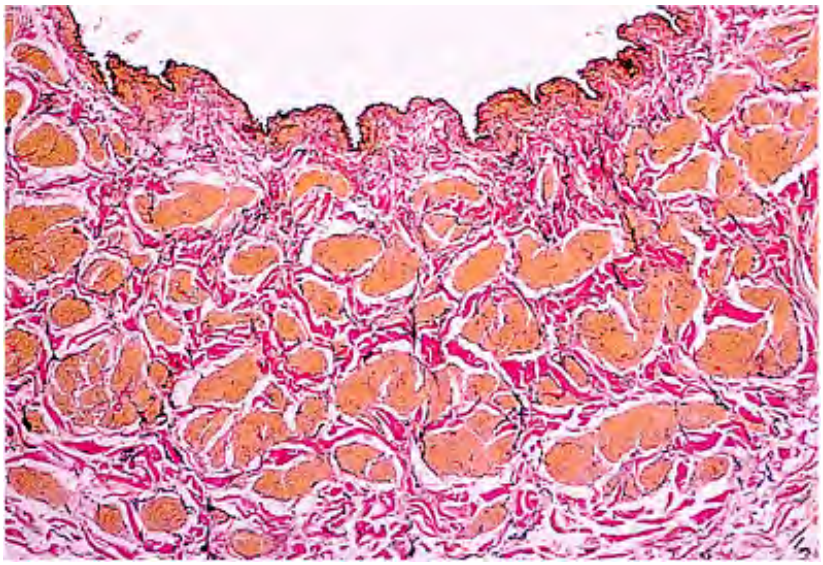

Figure 9.11 A renal vein from a 58-year-old woman, close to the junction with the inferior vena cava. There is no significant intimal thickening, and a thin internal elastic lamella can be identified.

Note the thin layer of subendothelial collagen. The muscular wall is composed of coarse fascicles, which are not clearly arranged into circular and longitudinal layers (elastic van Gieson).

Placental, dural, and retinal veins and the veins of erectile tissue have very little muscle. In general, the veins of the lower limb have thicker walls than those of the arm and abdomen. Most veins have valves to prevent the reflux of blood. The increasing use of the saphenous vein as an arterial conduit has led to a greater understanding of the normal structure of larger veins and the changes that occur in them as a result of aging. Large veins have a thin layer of subendothelial connective tissue with one or more incomplete elastic lamellae. Around this, there is an inner longitudinal and outer circular smooth muscle coat. The connective tissue adventitia is often well developed. Saphenous veins in middle-aged and elderly patients show intimal fibrosis and longitudinal and circular muscle hypertrophy with a substantial increase in medial connective tissue. Sometimes a prominent third outer longitudinal muscle layer (Figure 9.12) forms between the circular coat and the adventitia (33). These changes must be distinguished from the form of atherosclerosis that develops in vein bypass grafts.

Lymphatics

At the light microscopic level, small lymphatics closely resemble capillaries. In general terms, lymphatics have a larger diameter and a less regular cross-sectional profile (34). They begin as dilated channels with closed ends and anastomose freely. Although they are present in most tissues, they are rarely found in the epidermis, nails, cornea, articular cartilage, central nervous system, or bone marrow. Lymphatic channels have numerous valves and are often slightly distended at these sites, producing a

slightly beaded appearance. Lymphatics with a diameter of more than 0.2 mm usually have a thin muscular media, with no clear division into circular or longitudinal coats, and a fibrous adventitia. A longitudinal muscular layer is present in the right lymphatic and thoracic ducts. As detailed and illustrated below, lymphatic vessels stain specifically with two antibodies, D2-40 and LYVE-1.

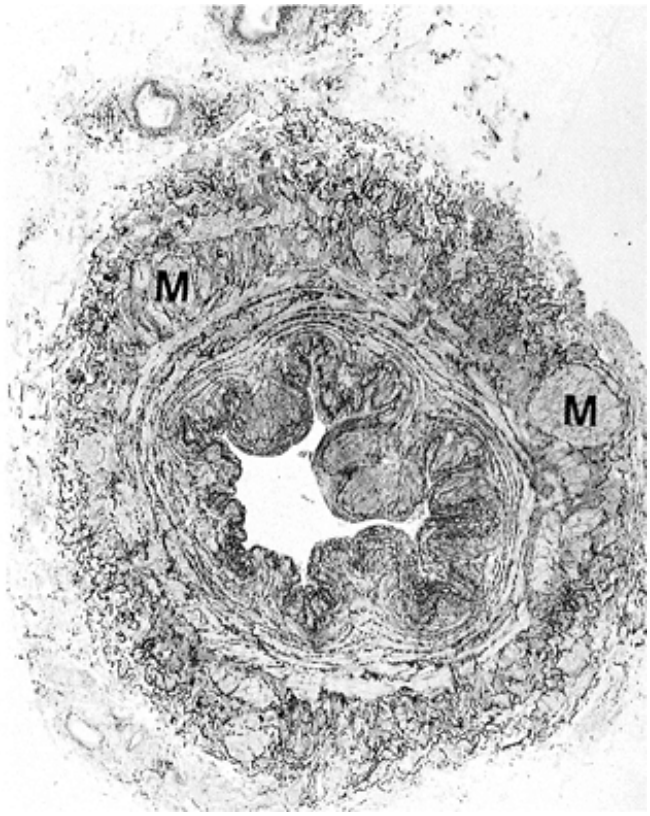

Figure 9.12 A saphenous vein with a prominent third outer longitudinal muscular coat (*M*). Reprinted with permission from: Milroy et al. Histological appearances of the long saphenous vein. *J Pathol* 1989;159:311â€“316.

Pulmonary Arteries and Veins

Although the basic histologic structure of pulmonary vessels resembles that of their systemic counterparts, there are

differences that reflect the much lower pressure of the pulmonary circuit. The lumina of major pulmonary arteries are widely dilated in comparison with wall thickness. The intima is hardly discernible. In an adult, the pulmonary arterial media is composed of only 10 to 15 parallel elastic lamellae, whereas, even in a young child, 40 aortic lamellae can be identified. The thickness of the pulmonary trunk is about 40 to 80% that of the aorta (Figure 9.13).

In the systemic circulation, the transition from elastic to muscular arteries is abrupt and is usually at the point of a major arterial orifice. In contrast, even pulmonary arteries as small as 0.5 to 1.0 mm in diameter are elastic vessels (35 ,36). Muscular pulmonary arteries and arterioles also have thin walls in relationship to their luminal diameter, but this may be difficult to appreciate unless special techniques of perfusion or fixation are used. In comparison with systemic arteries, there is usually a prominent internal and external elastic lamella. Arterioles give rise to a rich network of alveolar capillaries. Pericytes are not easily identified, and in places the endothelium and alveolar epithelium appear to share a common basement membrane. The walls of pulmonary veins are less structured than their systemic counterparts. The media is composed of a rather haphazardly arranged but roughly circular layer of connective tissue and muscle. No distinct and continuous elastic lamellae are present, and valves are said to be absent (Figure 9.14).

It can be difficult to distinguish the early vascular changes of pulmonary hypertension from those of normal aging (Table 9.4). The histologic changes have been described and comprehensively illustrated (35 ,36). The initial changes in both conditions include intimal fibrosis and medial muscular hypertrophy, and each of these features is most prominent in muscular arteries and larger arterioles (37). The absence of significant changes in the larger arteries may be misleading. In long-standing pulmonary hypertension, the complex changes in muscular arteries include florid intimal thickening, marked medial hypertrophy, and

prominent dilatation of small branches of parent vessels (Figures 9.13D , 9.15). In the

most extreme examples, angiomatoid malformations may develop, and occasionally there is fibrinoid necrosis of the vessel wall (38 ,39). Lung biopsy is no longer used for the assessment of pulmonary hypertension in children with congenital heart disease nor in adults with primary pulmonary hypertension. However surgical pathologists must make a careful assessment of the pulmonary arteries and veins in lung biopsy specimens and be able to describe and grade these alterations accurately (40).

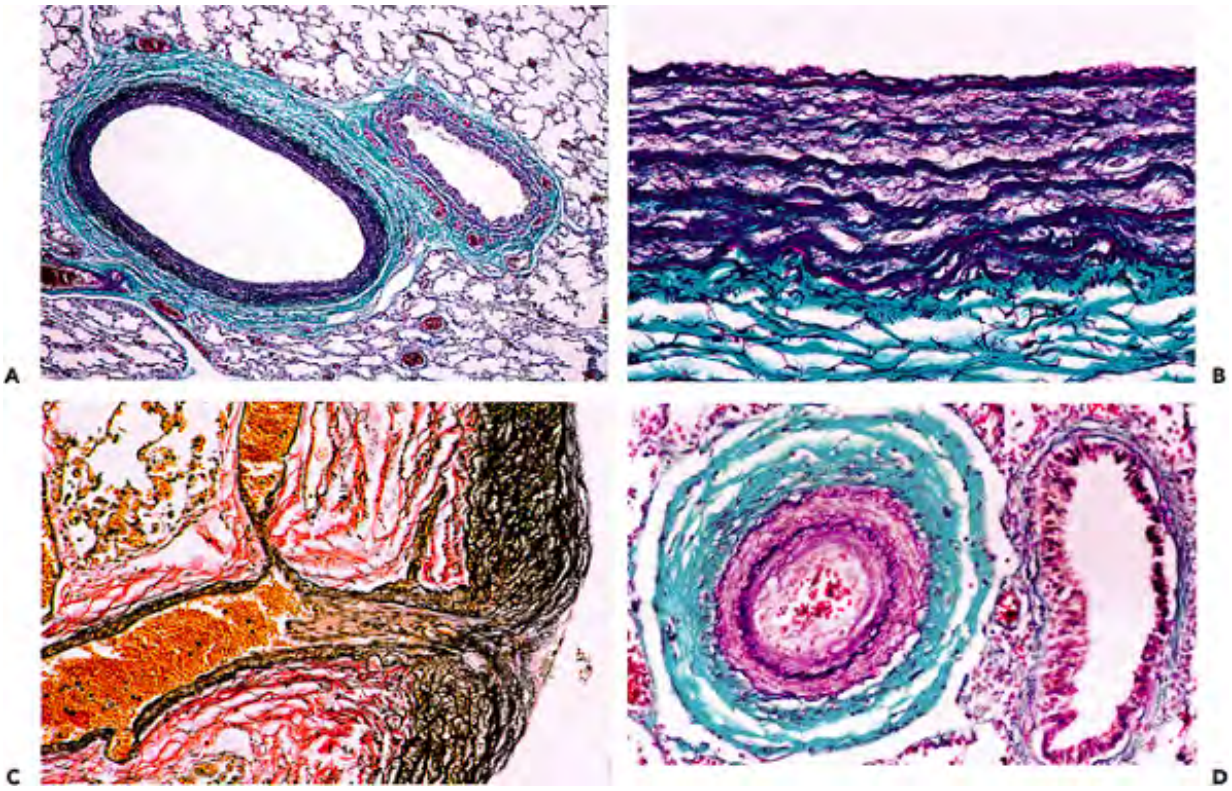

Figure 9.13 A. Elastic pulmonary artery from a 1-year-old child. The lung was inflated via the main pulmonary artery, which therefore appears much larger than the corresponding bronchus. B. A magnified view of the elastic wall (Gomori's trichrome). C. The transition from elastic to muscular pulmonary arteries in a 73-year-old man. Note the larger number of elastic lamellae. There is

slight fibrous intimal thickening only (elastic van Gieson). D. A small pulmonary artery from a patient with longstanding pulmonary hypertension and chronic obstructive airways disease. There is hypertrophy of the muscular wall and pronounced fibrous intimal thickening (Gomori's trichrome).

Aging changes in pulmonary veins are seldom described in detail. In severe, long-standing cardiac failure, intimal fibrosis, medial hypertrophy, and hyalinization are prominent pulmonary venous abnormalities. Marked medial hypertrophy may confer an arterialized appearance to pulmonary veins, and they may appear to have an internal and external elastic lamina. Multiple levels should be taken and stained for elastin and by a trichrome method. The elastic lamellae are seldom complete in these abnormal veins, and there is often more medial fibrosis than in corresponding pulmonary arteries. Even so, accurate distinction of abnormal pulmonary arteries and veins can be difficult.

Anastomoses, Angiodysplasias, and Vascular Malformations

There is potential for anastomoses between many arteries and veins. These are especially developed in the skin, where they contribute to thermoregulation. They vary in size from about 200 to 800 Âµm and in some sites, such as the nail bed, have a complex structure. There are also anastomoses between pulmonary and bronchial veins and between the portal and systemic circulations. Peripheral glomus tumors almost certainly arise from supporting cells that surround the normal but rather complex anastomosing channels between digital arterioles and venules. Glomus cells do not express endothelial markers but, because they stain with smooth muscle actin and vimentin, may be related to vascular smooth muscle (41). The potential connections

between the portal and systemic circulations, either in the submucosa of the esophagus or rectum or in the periumbilical or diaphragmatic region, may be massively dilated in advanced hepatic disease. Biopsies are seldom performed surgically.

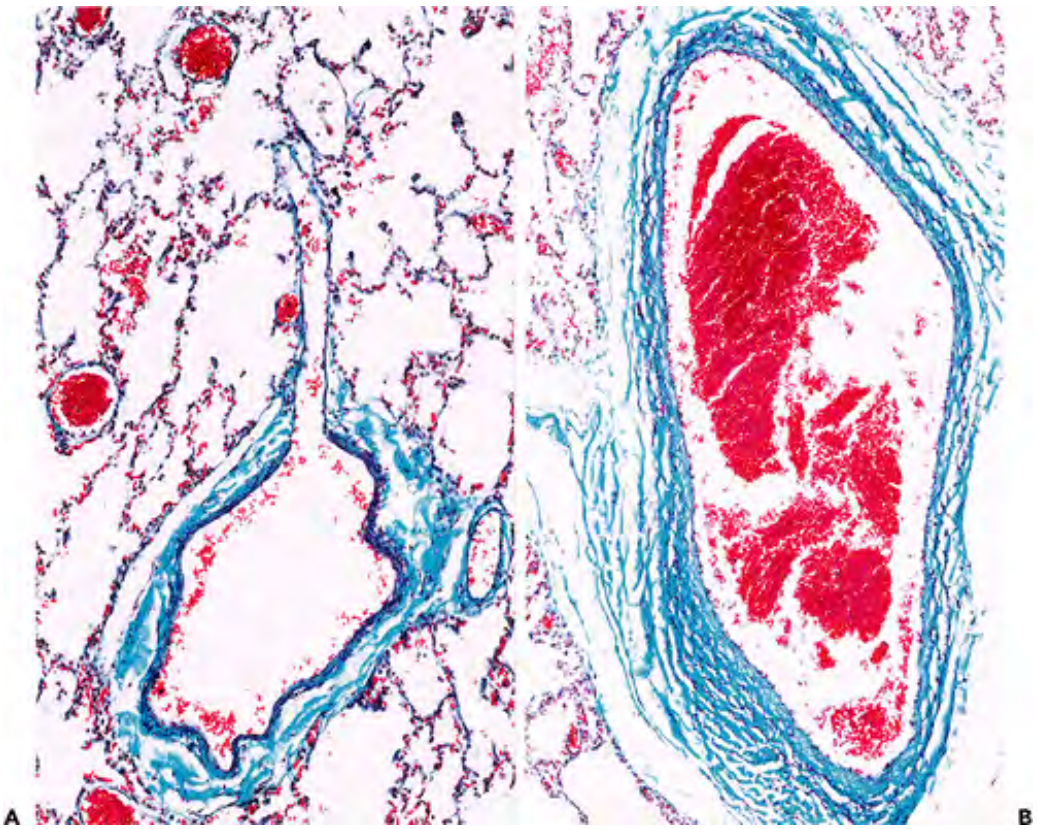

Figure 9.14 Normal pulmonary veins. A. A pulmonary venule draining into a small vein. Very little muscle is present in the wall. B. A large pulmonary vein close to the hilum of the lung. (Gomori's trichrome)

Elastic arteries (>500 Âµm)

Widely patent lumen, media of 10 to 15 parallel lamellae of elastic tissue

Slight intimal fibrosis; increased medial thickness due to collagen deposition; occasional atheromatous plaques

Atherosclerosis and dilation of main pulmonary arteries; medial

Vessel	Normal	Age-Related Changes	Pulmonary Hypertension
		thickening due to hypertrophy of admixed muscular elements	
Muscular arteries or arterioles	Thin muscular wall often with distinct internal and external elastic lamina	Increased muscular media, eccentric intimal fibrosis, especially in vessels less than 300 Âµm in diameter	Complex changes include florid intimal thickening, medial hypertrophy, dilation of small branches, angiomatoid (plexiform) lesions, and fibrinoid necrosis
Veins	Thin media of irregularly arranged fibrous tissue and muscle. No distinct elastic lamella. No valves.	Few detailed studies. The media may appear hyalinized.	Intimal fibrosis, medial muscular hypertrophyâ€”occasionally sufficient to mimic appearance of arteries

Table 9.4 Histologic Features of Pulmonary Vessels

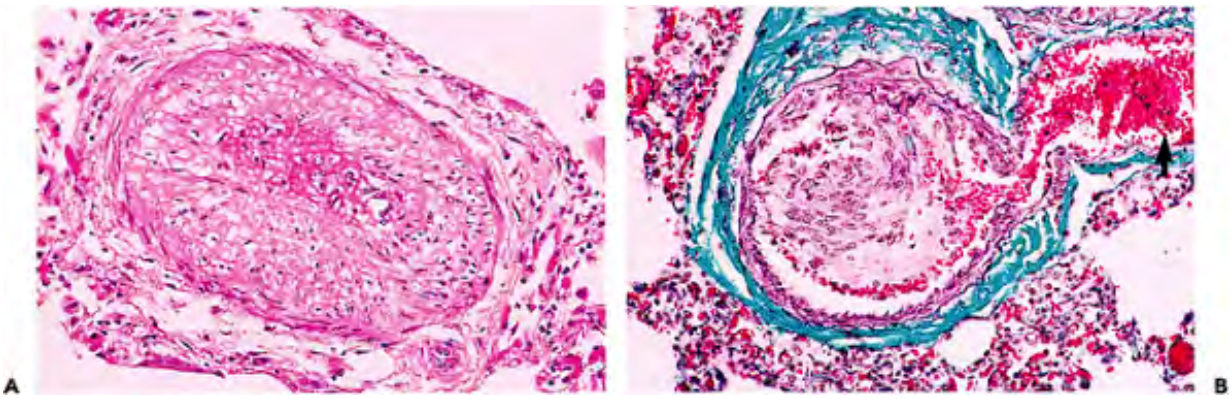

Figure 9.15 Advanced pulmonary hypertensive changes. A. There is marked hypertrophy of the medial muscle in a small pulmonary artery. B. An early plexiform lesion with nearby dilated thin-walled branches (*arrow*). (Gomori's trichrome.)

Surgical pathologists must be familiar with the normal vascular patterns of the cerebral meninges and the colonic submucosa if cerebral arteriovenous malformations and large intestinal angiodysplasia are to be accurately assessed. Each of these areas has a rich vascular supply with numerous, sometimes thick-walled, venous channels. Malformations or angiodysplasias must only be diagnosed if there is undoubted evidence of an abnormal vessel wall. Aging changes and atherosclerosis seldom involve the smaller leptomeningeal arteries. In arteries, eccentric fibrous intimal thickening or disruption of the elastic lamellae support a diagnosis of a malformation. Veins in these malformations have irregular contours, the thickness of their muscular wall may vary markedly, and the wall can be uniformly fibrosed.

Angiodysplasia of the colon is a common cause of lower gastrointestinal hemorrhage. The lesions are usually present on the antimesenteric border of the cecum, often close to the ileocecal valve (42). They are not direct arteriovenous anastomoses but rather dilatations of preexisting, and previously normal, capillary rings and veins (Figure 9.16). The dilatation of these vessels may be the result of increased colonic muscular pressure causing intermittent obstruction of draining vessels. Multiple blocks must be examined and the appearances contrasted with a control section of submucosa from a normal colon. Submucosal arteries of the large intestine may show pronounced age-related tortuosity, and this must not be interpreted as an abnormality. A proportion of cases with good clinical or radiologic evidence of angiodysplasia will not be confirmed histologically. Some cases of massive gastrointestinal hemorrhage result from abnormally large submucosal arteries. This is most common in the stomach but also has been reported in the large and small intestine. Arteries in the submucosa of the proximal portion of the stomach can arise directly from omental vessels and may have a larger caliber than superficial arteries arising from a submucosal plexus, the so-called caliber-persistent artery or Dieulafoy's lesion

(43 ,44).

Vascular malformations are congenital lesions composed of mature but often malformed (dysplastic) blood vessels. They result from dysregulation in the signalling pathways of vasculogenesis in early embryonic life (45) and must be distinguished from true angiomas and reactive hyperplasias. They may be solitary lesions or be part of a dysmorphic syndrome and grow slowly but progressively, usually commensurate with the growth of the patient (46 ,47).

They are classified according to the size of the predominate type of vessel. Clinically, a distinction is made between low- and high-flow lesions. The latter are usually arteriovenous malformations characterized by connections between feeding arteries and draining veins, without an interconnecting capillary bed, the so-called arteriovenous fistula (48). Fistulae are rarely found in tissue sections; but in these lesions arteries have a tortuous course, and a proportion of veins may show intimal thickening with collagen and elastin deposition in their walls. Pure venous malformations are composed of dilated vascular channels with walls of variable size, showing irregular degrees of attenuation and fibrosis. Complications include thrombosis with organization, papillary endothelial hyperplasia (Masson's pseudotumor), and nodular calcification. In lymphatic malformations, the vascular channels vary considerably in size and may have an incomplete muscular wall. As in other vessels their endothelium stains with CD31 and CD34 antibodies and with factor VIII-related antigen.

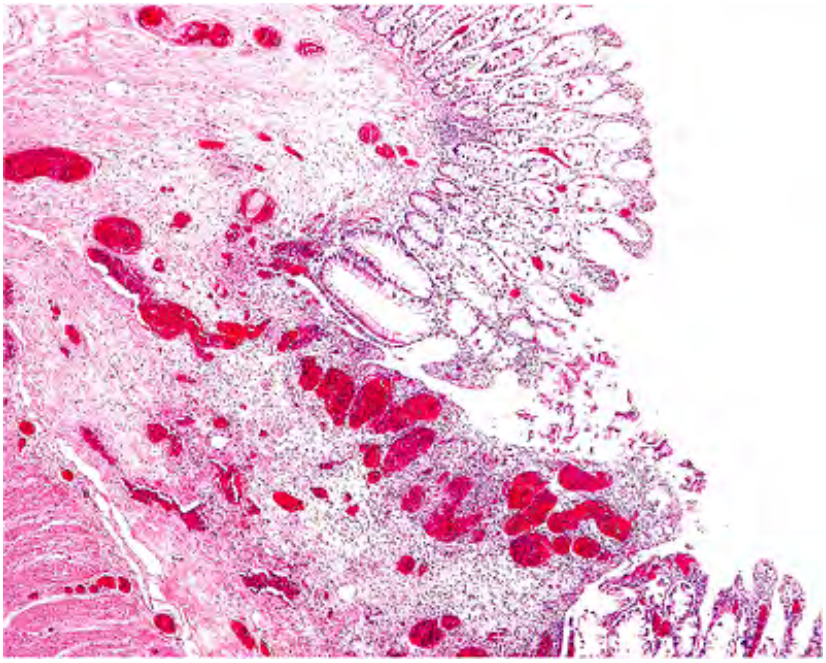

Figure 9.16 Angiodysplasia of the colon. Note the many dilated thin-walled blood vessels in the submucosa. Although these vessels are distended, their basic structure is unaltered.

Vascular Surgery

The changes commonly seen in vessels after surgical procedures and interventions are summarized in Table 9.5 .

Endarterectomy

Patency can be restored to a partially occluded artery by drawing out a proportion of the atherosclerotic intima. The procedure is usually applied to the carotid bifurcation, the iliac, femoral, or, occasionally, coronary arteries. Ideally, the surgeon should establish a plane between the innermost media and the intima, and the atheromatous material should be removed in its entirety. At its bifurcation the carotid artery has an elastic wall, and the material removed will include layers of elastic tissue, atheromatous debris, and thrombus. Acute postoperative thrombus

formation is the most important immediate complication of the procedure. Longer term complications are recurrent thrombosis, aneurysmal dilatation, and restenosis due to fibrous intimal proliferation (49).

Bypass Grafts

The pathologic changes that occur in autologous saphenous vein bypass grafts have been described in detail (50). Care must be taken to distinguish these changes from those associated with normal aging. When subjected to arterial pressure, many vein grafts dilate and most develop some fibrous intimal thickening and medial muscular hypertrophy. In time, many develop pronounced fibrous intimal thickening with areas of lipid deposition, intramural hemorrhage, and thrombosis. These appearances closely mimic atherosclerosis and are an important cause of graft failure. In one postmortem study in which saphenous vein conduits were sampled throughout their length, more than 75% narrowing was demonstrated in 11 to 26% of the segments examined (51). Grafts can sometimes be dilated by angioplasty, but redo coronary bypass procedures are now a significant part of the work of all cardiac surgery departments.

Endarterectomy

Acutely: surface platelet and fibrin deposits on inner face of surgical dissection, occasionally progressing to occlusive thrombosis.

Chronically: variable degrees of fibrous intimal hyperplasia, occasionally progressing to restenosis. â€œFalseâ€• aneurysm formation.

Vein bypass grafting

Acutely: thrombosis, dissection at anastomosis site.

Chronically: dilatation with fibrous intimal thickening and medial muscular hypertrophy (to be contrasted with preimplant state). Occasionally, marked intimal fibrosis with lipid deposition and

hemorrhage, leading to occlusion (â€œvein atherosclerosisâ€•).

Internal mammary and radial artery grafting

Acutely: thrombosis at anastomoses sites.

Chronically: occasional grafts become fibrosed. Graft atherosclerosis uncommon.

Angioplasty and stenting

Acutely: acute inflammation, dissection, and thrombosis.

Chronically: restenosis due to reactive fibrous intimal thickening, now reduced by drug eluting stents.

Prosthetic vessels

Acutely: thrombotic occlusion.

Chronically: extensive macrophage and giant cell infiltration of fabric wall. Formation of fibrin-rich pseudointima, occasionally progressing to partial or complete occlusion. Graft failure and thrombosis.

Procedure	Spectrum of Histologic Change

Table 9.5 Pathologic Changes After Vascular Surgery

In cardiac surgery, coronary artery stenoses are routinely bypassed with the left or right internal mammary artery. The origin of the artery from the subclavian artery is preserved, and it is then dissected away from the chest wall. There is usually a surrounding cuff of soft tissue, but some surgeons dissect this away, producing a so-called â€œskeletalizedâ€• graft. Long-term patency rates are superior to saphenous vein grafts. The caliber of the normal internal mammary artery is similar to that of distal coronary arteries. Preexisting occlusive disease is present in fewer than 5% of patients, and only occasional grafts develop atheromatous obstructions (52). In its proximal portion, the internal mammary is an elastic

artery, but the media is muscular from about the level of the

fourth rib.

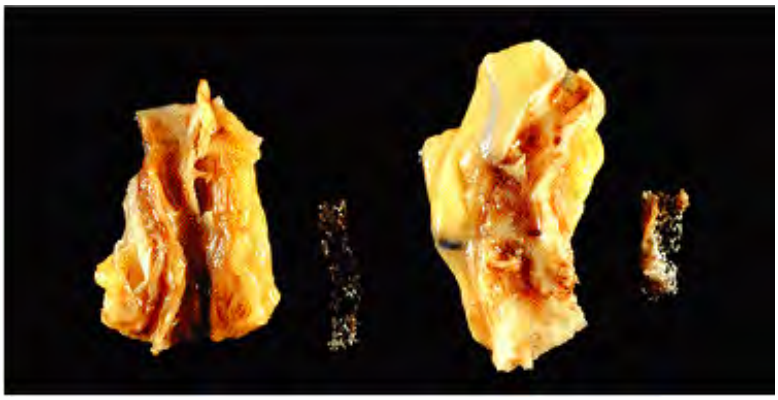

Figure 9.17 Coronary artery stenting. Metallic stents were inserted three weeks before this patient's death. The stent placed in the left anterior descending artery (*left*) is fully patent and an excellent result has been obtained by the angioplasty procedure. In contast, some reactive fibrosis has formed in the stent that was placed in the right coronary artery (*right*).

Segments of the radial artery are also used as free grafts. Like saphenous vein grafts, they are anastomosed proximally to the aortic root and distally to the coronary arteries. The radial artery is muscular and is invariably free of significant atheroma.

Angioplasty

Percutaneous coronary angioplasty (PTCA) with stent emplacement is now the treatment of choice for many proximal coronary stenoses and is increasingly used as a primary intervention to open thrombosed coronary arteries after myocardial infarction (53). The mortality rate in most centers is now less than 1%, and over 90% of procedures are initially successful (52). In order to dilate the vessel, the heavily fibrous and focally calcified atheromatous plaque must be cracked open. Only when this has occurred can the deeper intima and underlying media be distended by the inflated balloon and held open by the expandable metallic

stent. Early histologic studies of patients dying soon after angioplasty demonstrated a characteristic pattern of radial tears or splits, sometimes with dissections extending into the underlying media.

Stents minimize the complications of these changes, but stent thrombosis is an occasional complication (54). Restenosis is the result of fibrous intimal proliferation, thrombus formation, and an overall reduction in the size of the vessel lumen, the so-called constrictive remodelling (55 ,56). Stents coated with immunosuppressant or antineoplastic agents, such as sirolimus or paclitaxel, are now used routinely and have reduced rates of restenosis as compared to bare metal stent (57 ,58). If death occurs soon after the procedure, the stent can be carefully extracted from the opened artery (Figure 9.17), which is then processed in the usual way. After late closure, stents can be cut with an electric diamond saw and then embedded in hard plastic.

Prosthetic Vessels

Various types of fabric graft are used for the treatment of peripheral vascular disease, for closing cardiac septal defects, or in other more complex procedures in children with congenital heart disease. Acute occlusion of prosthetic vessels is usually the result of surgical technique or poor flow rates. In time, prosthetic grafts develop a pseudointima. This has a jellylike consistency, may develop a partial (though not a complete) endothelial lining, and is composed of fibrin and enmeshed leukocytes (59). However, the most striking feature of these prosthetic vessels is the intense mononuclear and giant cell reaction that develops around the woven fibers of the graft. There is usually a moderate degree of adventitial fibrosis that binds the prosthesis to the surrounding tissues and reduces its elasticity. Long-term complications include thrombosis, particularly at flexures or surgical anastomoses, infection, and deterioration of the fibers of the graft.

Electron Microscopy

Ultrastructural studies have made enormous contributions to our understanding of vascular biology. However, even surgical pathologists with a specific interest in vascular pathology have only limited experience and expertise in electron microscopy. Some of the most important ultrastructural features of vessels are summarized in Table 9.6 .

Endothelial cells are joined by tight, adherans or gap junctions. Transendothelial channels characterize fenestrated endothelium, as in hepatic sinusoids, glomeruli, and endocrine organs. Cytoplasmic inclusions of endothelium include lysosomes, plasmalemmal vesicles, and Weibel-Palade bodies (see Figure 9.19).

Capillary endothelium is surrounded by basement membrane in which pericytes are embedded. There is very little basement membrane around lymphatic vessels. There are direct appositions between processes of pericytes and endothelium through gaps in the basement membrane.

Smooth muscle cells are invested in basement membrane and are linked by communicating (gap) junctions. Elastin and collagen fibers may be closely opposed to the surfaces of smooth muscle cells.

No significant media in small arterioles, capillaries, or lymphatics. The adventitia is composed of collagen and some elastin fibers. It has a well-developed structure in large veins but is very thin in some arteries.

Table 9.6 Ultrastructural Features of Vascular Tissues

Endothelial Cells

The entire vascular system is lined internally by a single layer of rather spindle-shaped endothelial cells. Small fingerlike microvilli, 200 to 400 nm long, may be seen on the surface of endothelial cells (Figure 9.18). A thin polysaccharide layer, the glycocalyx, coats the luminal surface of the endothelium. This is up to 100 nm in thickness, but its exact function is uncertain. Although endothelial cells have relatively sparse endoplasmic reticulum, a small number of free ribosomes, and an inconspicuous Golgi apparatus they produce a variety of molecules that are important in blood coagulation and the regulation of vascular tone.

Junctional complexes between endothelial cells are tight, adherens, or gap junctions (60). Tight junctions have a barrier function and help to maintain cell polarity. Molecules of the claudin family create the barrier and regulate electrical resistance between cells (61 ,62). Loss of this barrier function may be important in disorders such as diabetic retinopathy (63 ,64). Adherens junctions regulate permeability to white cells and soluble molecules and have a role in contact inhibition. Gap junctions are assembled from proteins known as connexins and form channels between adjacent cells (65). Alterations in gap junction proteins have been documented in human heart disease, including atrial and ventricular arrhythmias (66).

Inclusions of Endothelial Cells

Lysosomes are readily identified in most endothelial cells and are involved in intracytoplasmic digestion of foreign debris and products of metabolism. In many areas of the vascular system, membrane-bound vesicles measuring up to 80 to 90 nm can be identified (Figure 9.19). They are most prominent on the abluminal surface of the endothelial cell. They were originally known as plasmalemmal vesicles but are now usually termed caveolae. Their functions include the sequestration and concentration of small molecules, and they contribute to the

endothelial barrier function, regulation of nitric oxide synthesis, and cholesterol metabolism (67). Weibel-Palade bodies are characteristic inclusions of endothelium and measure up to 3 Âµm in maximum dimension. These membrane-bound structures contain up to 25 parallel tubular arrays. Immunologic studies have shown that Weibel-Palade bodies are sites of storage of von Willebrand factor. They are a useful marker of endothelial cells but are seldom as conspicuous as in Figure 9.19 .

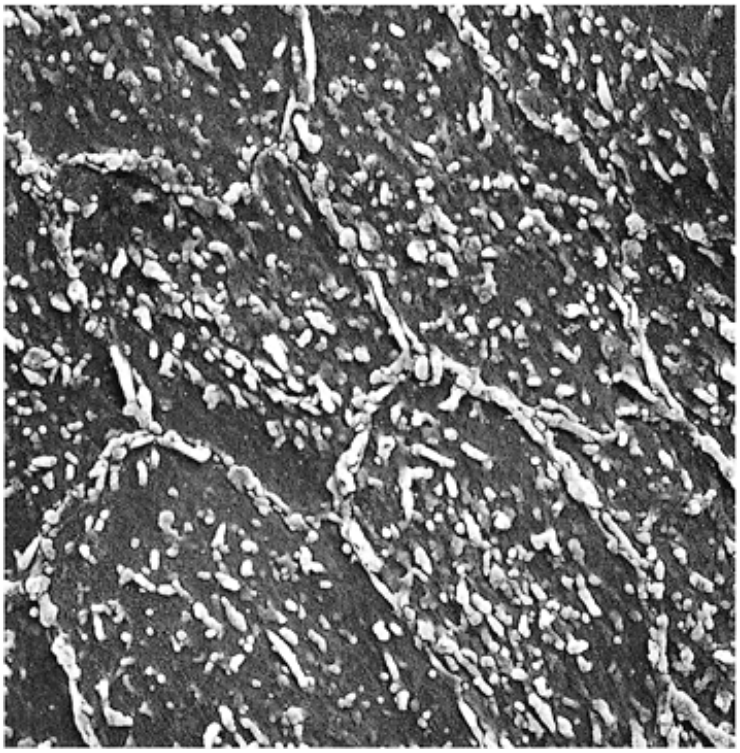

Figure 9.18 Scanning electron microscopic appearances of the endothelium from an experimental animal perfused under pressure with fixative. The junctions between individual endothelial cells are clearly seen; and, in this preparation, microvilli are particularly prominent (original magnification Ã—1,200).

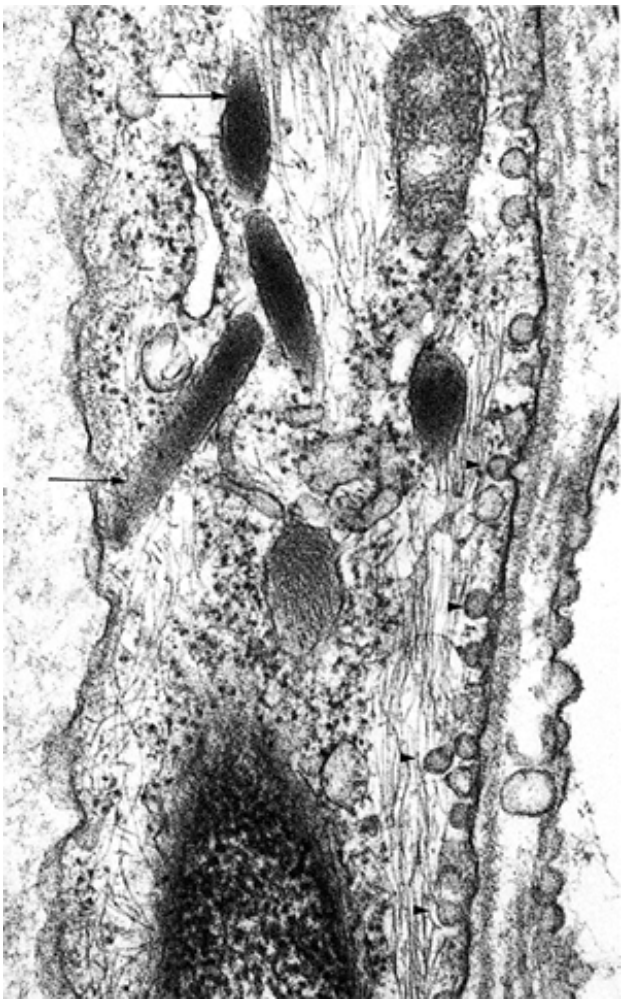

Figure 9.19 Transmission electron micrograph of an endothelial cell from a small subcutaneous capillary. Plasmalemmal vesicles are present on the abluminal surface (*arrowheads*). There are conspicuous Weibel-Palade bodies (*arrows*). Only part of the endothelial cell nucleus is included (*bottom*) (original magnification Ã—15,000).

The permeability of capillaries varies considerably from organ to organ. In some sites, such as the renal glomerulus,

the hepatic sinusoids, the small intestine, and some endocrine glands, there is a rapid interchange between blood and the surrounding tissue. Some of these permeability differences are

related to the exact nature of the junctions between endothelial cells, but endothelial fenestrae also have an important role in this respect. These fenestrations are in fact the openings of irregular, and sometimes incomplete, transendothelial channels that allow the rapid interchange of fluid between the blood vessel lumen and the interstitium.

Media

In the human aorta, homogeneous parallel elastic lamellae alternate with layers containing smooth muscle cells and a variety of extracellular components. Smooth muscle predominates in muscular arteries. The power of contraction of smooth muscle is as great as skeletal muscle and can be maintained for longer periods with greater shortening. The structure of smooth muscle cells is maintained by the intermediate filaments vimentin and desmin, and the contractile forces are generated by actin and myosin filaments. Smooth muscle cells are arranged in parallel longitudinal bundles with the wide part of one cell opposed to the tapering part of another. Each smooth muscle cell is covered by a basal lamina which merges with fine collagen and elastin fibers (5).

Individual smooth muscle cells are often linked by communicating (gap) junctions, but tight junctions are not generally seen. In the microcirculation and in some larger arteries and arterioles, there are gap junctions between the smooth muscle cells and the overlying endothelium (68). These myoendothelial junctions could have an important role in relaying physiologic or pharmacologic stimuli between the blood vessel lumen and the media.

Adventitia and Supporting Cells

The adventitial layer consists almost entirely of collagen and elastic fibers. The thickness of this layer varies with the size of the

vessel, and it may be continuous with the surrounding connective tissue. In some medium-sized veins, it is particularly well developed but in cerebral arteries may be as thin as 80 Âµm. A layer of elastic tissue, the external elastic lamella, is present at the junction of the media and adventitia. In human material, it is seldom as pronounced as the internal elastic lamella but is prominent in many other mammalian arteries. The pericytes that are present in and among the basement membrane of capillaries and small venules superficially resemble fibroblasts. The ultrastructural appearance of their cytoplasmic filaments suggests that they are contractile, and this is further evidence that they are of mesenchymal origin (31).

Lymphatics and Veins

The smallest lymphatic vessels have wider lumina than blood capillaries and a discontinuous basement membrane. A variety of anchoring filaments bind the lymphatic endothelium to the surrounding collagenous tissues, perhaps providing the sort of support normally produced by basement membrane and enmeshed pericytes in capillaries. The ultrastructural appearances of venous capillaries, venules, and small veins mirror those seen at the light microscopic level.

Antigen Expression of Normal and Neoplastic Vascular Tissue

Endothelium

Endothelial cells cover the inner surface of the entire vascular tree, arterial, venous, capillary, and lymphatic. The most widely used antibodies are directed against von Willebrand factor (factor VIII), CD31, and CD34 (Figure 9.20). Because these antigens are present in all types of endothelial cells, they are considered to be

panendothelial markers. The lectin Ulex europaeus 1 agglutinin binds to some Î±-L-fructose containing glycocompounds and therefore to virtually all human endothelia (69). The staining pattern is sometimes more intense than with factor VIII antibodies, especially in immature vessels (70). However, all endothelial markers cross-react to some extent with other cell components. For example, in areas of hemorrhage or thrombosis, CD31 reacts strongly with platelets, macrophages, and lymphocytes, and von Willebrand factor can produce diffuse extracellular staining. Nevertheless these antibodies are indispensable for the identification of vascular tumors such as angiomas, hemangioendotheliomas, and angiosarcomas and can be helpful in the identification of tumor emboli in vascular or lymphatic channels, rather than in artifactual tissue spaces.

Antibodies that recognize proteins involved in the early steps in angiogenesis include antiendoglin (CD105) and anti-VEGF (71). In different sites in the vascular system, the endothelium may show marked heterogeneity in morphology, gene expression patterns, and related differences in functional status. However, there are only limited variations in the immunophenotypic profile of endothelial cells. Antibodies to glucose transporter proteinâ€“1 (GLUT-1 antibodies) react with the endothelium of cerebral capillaries, the placental vasculature, and one specific type of angiomaâ€”the juvenile capillary angioma (Figure 9.21) (72). Another site specific antibody is anti-HECA 452, which reacts specifically with the plump endothelial cells of high endothelial venules in lymphoid tissue and postcapillary venules in chronically inflamed tissues (Figure 9.22). In inflamed tissues and in atheromatous lesions, endothelial cells undergo profound functional alterations (endothelial activation) associated with upregulation of antigens such

as ICAM-1, VCAM-1, and CD31 or with de novo expression of leukocyte adhesion molecules such as E-selectin. Until recently,

there were no specific markers of lymphatic endothelium. Both D2-40 and LYVE-1 stain lymphatic endothelium specifically (Figure 9.22) (73), and D2-40 staining has confirmed the lymphatic origin of Kaposi's sarcoma (74) (Figure 9.23).

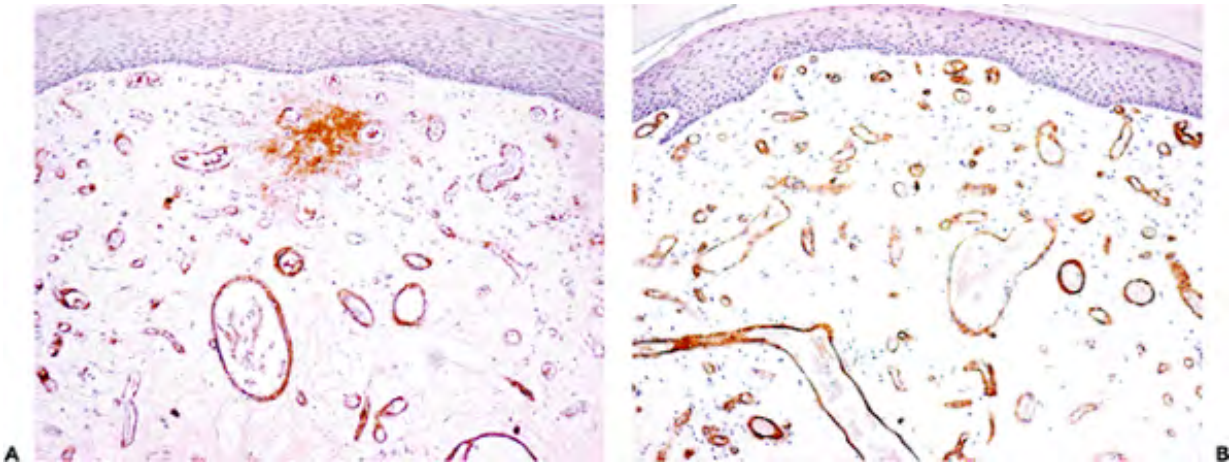

Figure 9.20 Staining of small vessels in a hemangioma with antibodies to factor VIII (A) and CD34 (B). As in these illustrations, the staining with CD34 is usually sharper than with factor VIII. Some nonspecific extravascular staining is often seen with factor VIII but has no significance.

Smooth Muscle

Biochemical and immunohistologic studies have demonstrated that vascular smooth muscle has a distinctive component of contractile and intermediate filament proteins (75). In most smooth muscle, Î³-smooth muscle actin and desmin predominate. In contrast, in vascular tissue there is abundant Î±-smooth muscle actin, and vimentin exceeds desmin. Antibodies directed against smooth muscle actin (SMA-1) are excellent markers of medial muscle; SMA-1 recognizes the full spectrum of proliferating (or synthetic) and mature (or contractile) smooth muscle phenotypes. As SMA-1 reacts with pericytes, it clearly outlines capillaries in reactive microvascular proliferations and in pyogenic granulomas and

juvenile angiomas during their growth phase. Generally all benign vascular proliferations, including glomus tumors, stain strongly with SMA-1 antibodies (Figure 9.24). In contrast, this staining is often incomplete or even

absent in angiosarcoma, hemangiopericytoma, or Kaposi's sarcoma (Figure 9.23).

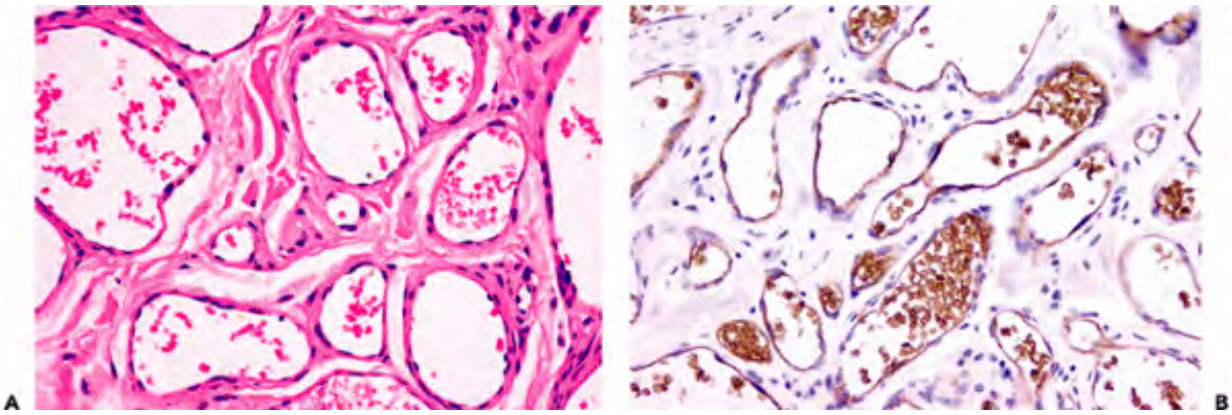

Figure 9.21 Site-specific staining of vascular endothelium. The vascular endothelium in this juvenile capillary hemangioma from a 3-year-old male (A) is specifically stained with the GLUT-1 antibody (B). This antibody also stains the endothelium of cerebral capillaries and the placenta. In contrast, the more commonly used endothelial antibodies such as factor VIII, CD31, and CD34 stain most types of normal and neoplastic endothelia.

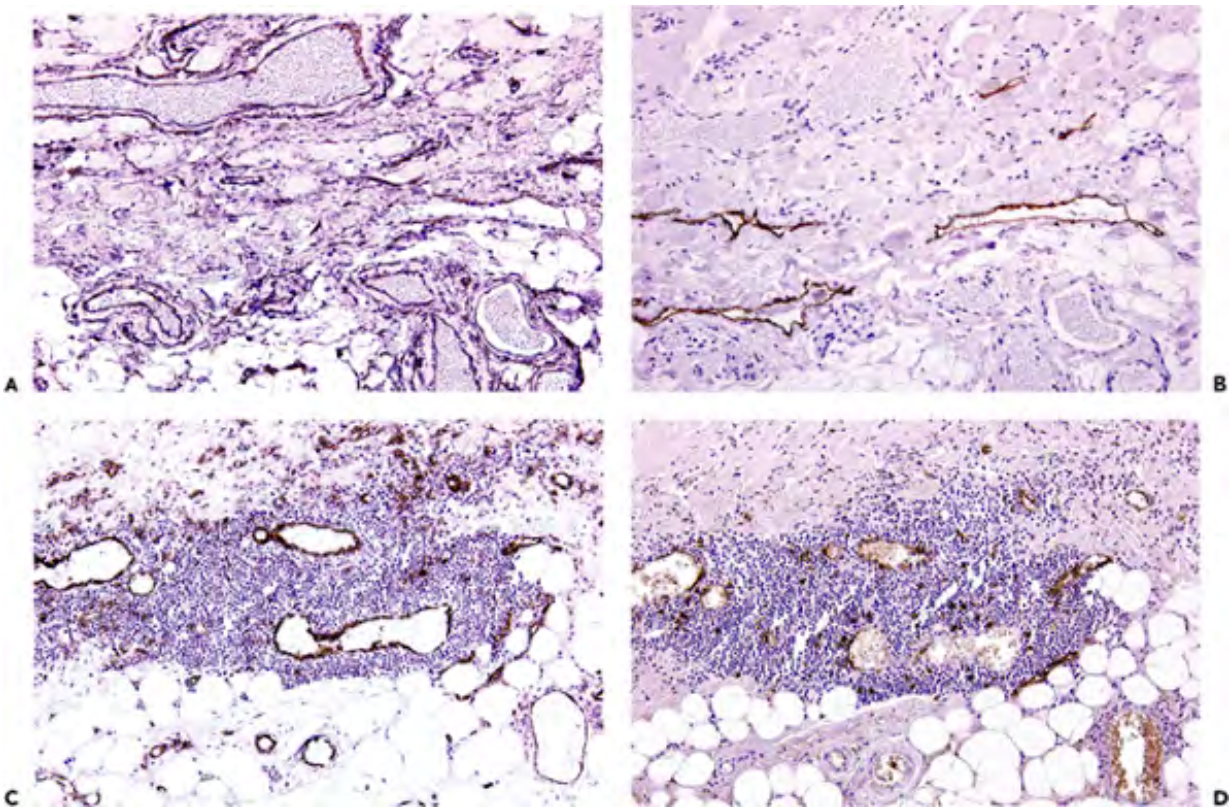

Figure 9.22 Immunohistochemical staining of vessels. A. and B. show a mixture of vessels from the subcutaneous tissues of a 68-year-old female from close to a leg ulcer: CD31 antibody staining identifies many vascular spaces (A), and a similar section is stained with the antibody D2-40, which recognizes lymphatic endothelium only (B). C. and D. are from a nodular inflammatory infiltrate in the aortic adventitia adjacent to a large atheromatous plaque: C has been stained with CD31, which recognizes most vessels, and D was stained with HECA-452, which recognizes high endothelial venules.

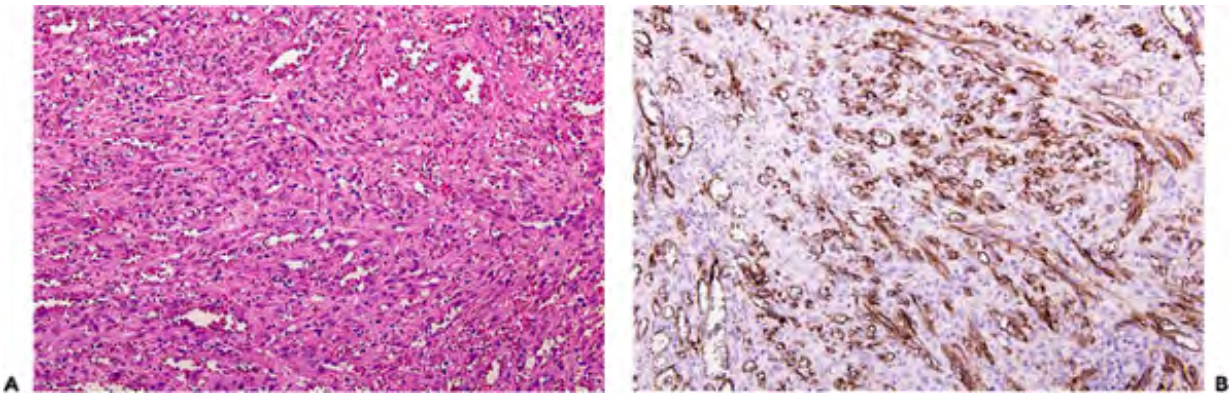

Figure 9.23 Kaposi's sarcoma. A. has been stained with H&E. B. was immunostained with the D2-40 antibody, a specific marker of lymphatic endothelium. Note the strong positive staining; LYVE-1 is another antibody that specifically stains lymphatic endothelium.

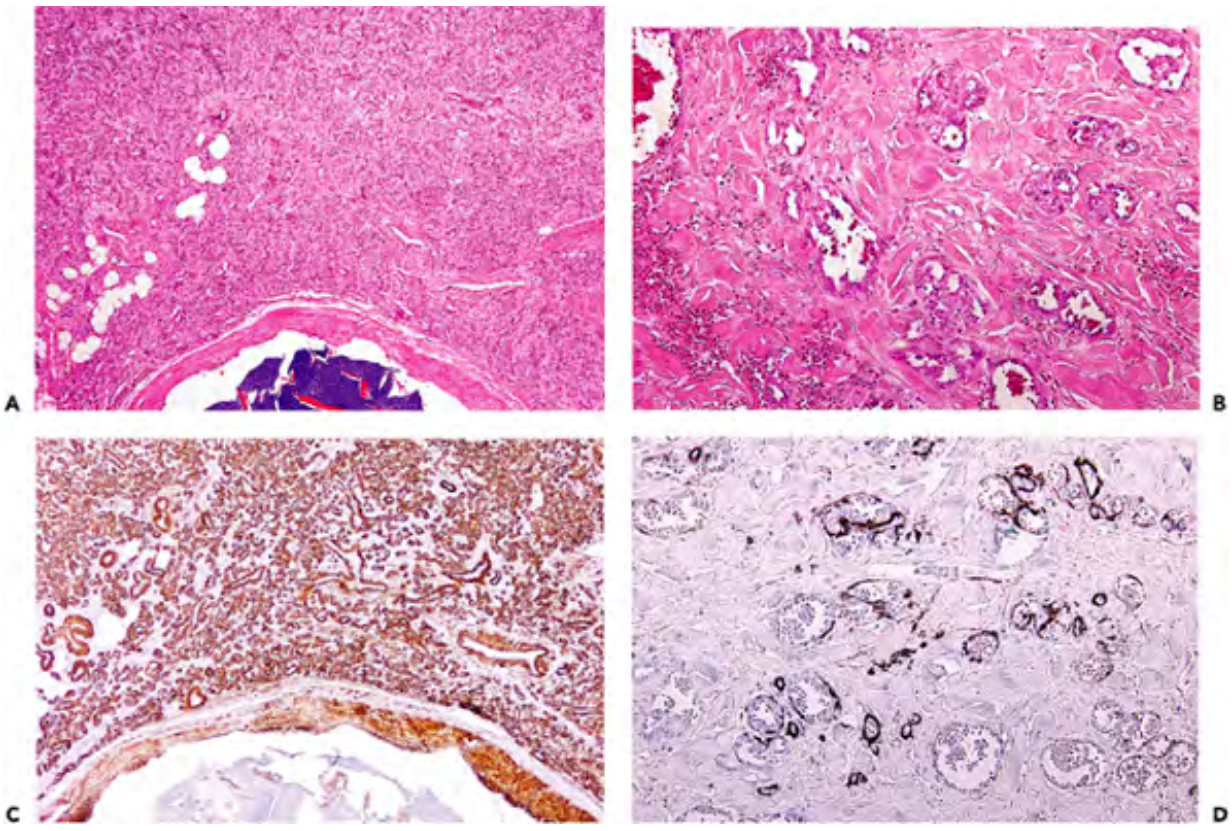

Figure 9.24 Patterns of staining with smooth muscle actin antibody. A. and C. are from a benign vascular proliferation. Note the intense staining of the walls of these small vessels. B. and D.

are from an angiosarcoma. Only small amounts of actin are present in the walls of the malignant blood vessels (D).

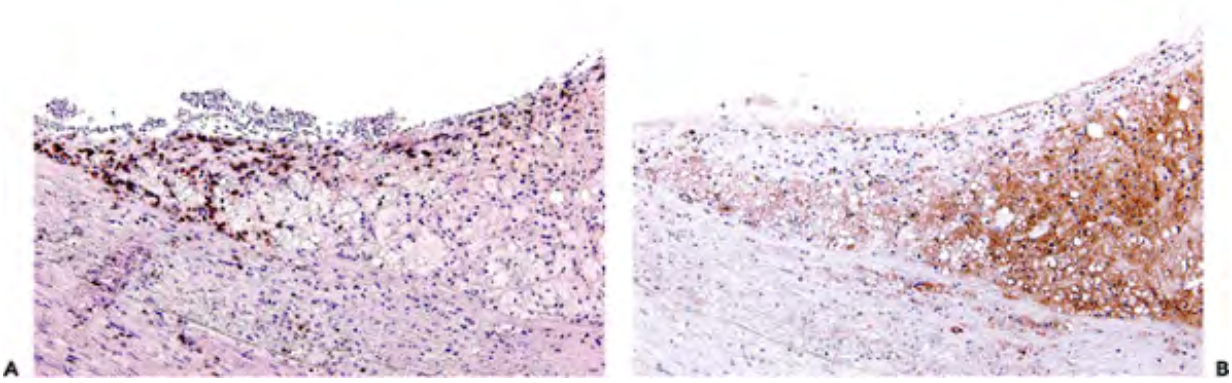

Figure 9.25 Immunohistochemical staining in atherosclerosis. A. CD3 positive lymphocytes are present at the edge of a lesion. B. Macrophages react for CD68.

Other Useful Antibodies for Diagnostic Vascular Pathology

Immunohistochemical studies of the inflammatory infiltrates in atheromatous lesions (Figure 9.25) have contributed greatly to our understanding of the pathogenesis of atherosclerosis (76) but, as yet, have no value in everyday surgical pathology. T-lymphocyte markers, such as CD3 and CD4, may be of use in the diagnosis of vasculitis, especially temporal arteritis with minimal inflammatory activity (77). In transplant arteriosclerosis, there is a high relative proportion of CD8+ T lymphocytes, which also express granzyme B. In addition to von Willebrand factor (factor VIII), antifibrinogen antibodies are excellent for the demonstration of vascular leakiness and tissue damage (24 ,78); CD61 stains platelet aggregates in microvessels [for example in small vessel vasculitis (78)], angiolipomas, and coagulopathies [such as in the antiphospholipid syndrome]. Glycophorin A is a specific marker of

erythrocytes and their precursors in the bone marrow. The epitopes are preserved in tissues for long periods, and the antibody is valuable in the detection of old hemorrhage; for example, in completely organized pulmonary thromboemboli (79) and in atherosclerotic plaques (80).

Antiamyloid antibodies (antiamyloid A, anti-immunoglobulin antibodies) are used to differentiate the nature of amyloid depositions, which have a preferential distribution in vessel walls. Cerebral vascular amyloid deposits usually do not stain with these antibodies. In pathologic conditions, such as cerebral amyloid angiopathy or amyloid found occasionally in cerebral vascular malformations, the depositions show positive staining with anti-Î²-amyloid antibody.

Peripheral Nervous System

Carlos Ortiz-Hidalgo
Roy O. Weller

Introduction

From a practical point of view, the pathology of peripheral nerves falls into two main categories: (a) peripheral neuropathies, which are diagnosed and treated by physicians and for which an elective nerve or muscle biopsy may be performed as a diagnostic procedure rather than as a therapeutic exercise, and (b) tumors and traumatic lesions, which are removed surgically mainly as a therapeutic measure to alleviate symptoms.

For the diagnosis of peripheral neuropathies, a detailed knowledge of the structure, immunohistochemistry and ultrastructure of peripheral nerves, and clinicopathological correlations is essential. The diagnosis of tumors and traumatic lesions, conversely, relies more on identifying the cellular components within the lesion and their interrelationships. This chapter, therefore, concentrates first on how to identify different cellular components in normal peripheral nerves and, second, on how knowledge of the normal structure of peripheral nerves can be used to identify and assess pathological lesions.

Development of the Peripheral Nervous System

The first anatomical evidence of nervous system differentiation is the neural plate, which develops as a thickened

specialized area in the middorsal ectoderm of the late gastrula stage of the developing embryo. This zone later becomes depressed along the axial midline to form a neural groove that folds inward to form the neural tube (1). Before fusion is completed, groups of cells become detached from the lateral folds of the neural plate to form the neural crests. Anteriorly, neural crests are located at the level of the presumptive diencephalon and extend backward along the whole neural tube (2).

The neural crest yields pluripotent cells endowed with migratory properties (1). In the peripheral nervous system, the neural crest is the source of neurons and satellite cells in the autonomic and sensory ganglia; ectodermal placodes may also give rise to ganglion cells in the cranial region. Schwann cells are also derived from the neural crest. Migrating pluripotent neural crest cells and their subsequent development is determined and progressively limited, perhaps by the inductive effect of neuregulins and their receptors erbB2 and erbB3, by environmental factors, and by relations with other cell types (1,3). The transcription factor Sox-10, that is initially expressed in the earliest migrating neural crest cells, appears to be intimately involved in the development of Schwann cells from the neural crest. Interestingly, the major myelin protein, P0, is also a transcriptional target for Sox-10 (3).

Many of the events that occur during the later stages of development of peripheral nerves are recapitulated during the regeneration that follows nerve damage in postnatal life. Developing neuroblasts of the dorsal root ganglia (posterior sensory root ganglia) extend neurites both centrally into the neural tube and toward the periphery.

Developing motor neurons in the anterior lateral parts of the neural tube extend their neurites toward the periphery. Schwann cells derived from the neural crest become associated with the developing peripheral nerves and eventually form myelin around many of the axons. The proximal portions of the anterior horn cell axons and the central axons of the sensory ganglion cells are myelinated within the neural tube by oligodendrocytes (Figure 10.1).

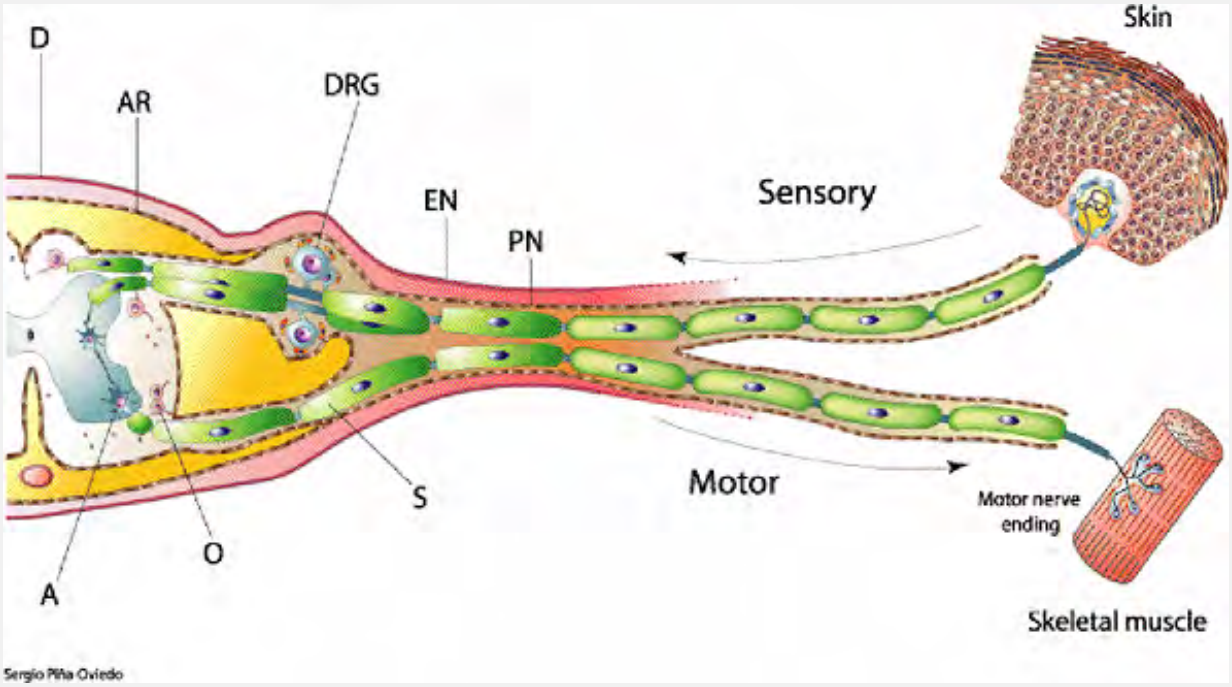

Figure 10.1 Anatomy of spinal nerve roots. Motor axons arising from the anterior horn cell (*A*) are initially myelinated by oligodendrocytes (*O*) and then pass into the anterior root to be myelinated by Schwann cells (*S*). Sensory nerve axons pass into the dorsal root ganglion (*DRG*), and the central extension of the sensory neuron passes via the dorsal root into the spinal cord. Arachnoid (*AR*) appears to be continuous with the perineurium of the peripheral nerve (*PN*). Dura (*D*) extends from the spinal cord to coat the roots within the intervertebral foramen and is continuous with the epineurium (*EN*).

Growth of Axons

One of the major questions that has been raised is how neuronal processes grow over long distances and arrive at specific terminal regions. Genetic determinants, growth factors, and the extracellular matrix appear to play important roles in the appropriate guidance of neuronal processes (4,5). In 1909, Santiago RamÃ³n y Cajal proposed the concept of neurotrophic substances to explain the directionality and specificity of axonal growth in the developing nervous system, but it was not until the 1960s that nerve growth factor (NGF) was discovered by Rita Levi-Montalcini and Stanley Cohen, as a target-derived neurotrophic factor that supports the survival and differentiation of sensory and autonomic ganglia in the peripheral nervous system (6).

Nerve growth factor is a protein composed of three subunitsâ€”alpha (Î±), beta (Î²), and gamma (Î³)â€”but only the Î²-NGF has nerve growthâ€“promoting activity. Beta-NGF in humans is a 14.5 KDa polypeptide, Î³-NGF is an arginyl esterase, whereas the function of the Î± subunit is not known (6,7). Other substances that participate in axon growth are members of the NGF family [such as brain-derived neurotrophic factor (BDNF)]; neurotrophins 3 (NT-3), 4/5 (NT-4/5), and 6 (NT-6); semaphoring-3A, neuropilin-1, and ephrin (8). The tips of growing axons possess multiple surface receptors for soluble and bound molecules that provide information for the axons' growth course (8). Nerve growth factor interacts with the NGF receptor on the surface of the axon and promotes motility of the growing tip of the axon by interaction with the cytoskeleton of the cell. Mitochondria, neurotubules, neurofilaments, actin filaments, and some cisternae of smooth endoplasmic

reticulum are incorporated into the axonal growth cone by axoplasmic flow. In addition to its growth promoting properties, NGF

also promotes the early synthesis of neurotransmitters.

Schwann cells in the developing nerve produce NGF and possess NGF receptors on their surface membranes, but expression of these receptors diminishes markedly as the peripheral nerve matures. As NGF binds to Schwann cell receptors and becomes concentrated on the surface of the primitive Schwann cell, it provides a chemotactic stimulus for growing axons (9). Failure of trophic interactions between the target organ and its innervation may result in nerve dysfunction. Indeed, cases of human neuropathies have been attributed to deficiency of neurotrophic factors; important data that provides a rational basis for the clinical use of neurotrophic agents in peripheral neuropathies (7).

The extracellular matrix also plays an important role in axonal growth and guidance. The tip of the growing axon has receptors for adhesion to extracellular substances such as collagen, fibronectin, laminin, and entactin; binding of extracellular components to these receptors promotes elongation of axons and stimulates cytoskeletal protein synthesisâ€”and therefore cell movement and axon growth. Some of these extracellular components are found within or near basement membranes surrounding Schwann cells (10,11).

Schwann Cells and Myelination

Schwann cells move freely between and around developing peripheral nerve axons, forming primitive sheaths around the neurites and growing in parallel with them. Contact with axons stimulates Schwann cell division in vitro (12). In vivo Schwann cell multiplication virtually ceases in the normal adult animal, but mitotic activity is induced by peripheral nerve damage. It is thought that exposure of the axon to the Schwann cell following loss of myelin sheaths (demyelination) or during axonal regeneration following axonal degeneration (wallerian degeneration) promotes Schwann cell division and that the relationship between Schwann cells and axons in the normal nerve induces some sort of contact inhibition in the

Schwann cells. If axon regeneration does not occur following axon damage, Schwann cells gradually decrease in number, suggesting that Schwann cell growth and survival depend on contact with axons (12). Experimental evidence also suggests that continued axon regeneration depends on the presence of Schwann cells (13).

By the ninth week of gestation, fascicles of the human sural nerve are identifiable and contain large axon bundles surrounded by Schwann cell processes (14). Between weeks 10 and 15, Schwann cells extend several long flattened processes that wrap around large clusters of fine axons. At this stage, two to four Schwann cells are located within a common basement membrane and form Schwann â€œfamiliesâ€• (15).

Myelination of peripheral nerves in humans commences between the twelfth and eighteenth week of gestation (16). Initiation of myelination depends on the diameter of the axon and its association with Schwann cells. By the time that axons have increased in diameter to between 1.0 and 3.2 Âµm, they are in a 1:1 relationship with Schwann cells and have either formed mesaxons or membrane spirals with compact sheaths of 3 to 15 layers (12,15). The reason why some nerves become myelinated and others do not is not clear. Schwann cells around myelinated fibers and around unmyelinated fibers are both able to produce myelin, but the factors that determine whether myelination occurs are unknown. Certain transcription factors, such as Krox-20 and Oct-6, are known to be involved in the myelination program (3,4). In Oct-6 null mice, for instance, myelination is severely delayed, while in Krox-20 null mice myelination fails completely (3). Schwann cells in developing and regenerating peripheral nerves also express high levels of the neurotrophin receptor p75NTR. Neurotrophins are a family of proteins that play a variety of functions in the development and maintenance of the peripheral nervous system (17). Certain glycoproteins, such as myelin-associated glycoproteins, are believed to participate in establishing specific Schwann cellâ€“axon interactions in the developing peripheral nervous system (18).

Experimental studies have shown that axons may induce the formation of myelin if the unmyelinated sympathetic chain is grafted onto a myelinated nerve such as the saphenous nerve. Schwann cells that had not previously formed myelin will do so if they come into contact with large, regenerating axons that were previously myelinated (3). It appears also that Schwann cells may influence the caliber of axons since axonal diameter may be decreased markedly in some hereditary demyelinating neuropathies in which there is a genetic defect in Schwann cells and in myelination (12,13). It has been demonstrated that myelinating Schwann cells control the number and phosphorylation state of neurofilaments in the axon, leading to enlargement of the axon itself. Conversely, absence of myelin results in fewer neurofilaments, reduced phosphorylation levels, and therefore smaller axon diameters (18). Myelin-associated glycoprotein (MAG) acts as a myelin signal that modulates the caliber of myelinated axons (19). Maintenance of an axon therefore appears to depend not only on influences from the neuron cell body but also on interactions of the axon with the accompanying Schwann cells (12).

Some 70% of axons within a mixed sensory nerve, such as the sural nerve, are very small and will become segregated into groups of 8 to 15 axons lying in longitudinal grooves within one Schwann cell; these will form the unmyelinated fibers within the peripheral nerve. Thus, all axons in the peripheral nervous system are invaginated into the surfaces of Schwann cells, but myelin sheaths only form around the larger axons, which represent only a small proportion of peripheral nerve fibers.

Anatomy of Peripheral Nerves

An understanding of the anatomy of peripheral nerves is essential for the interpretation of clinical signs and symptoms and for planning an autopsy to investigate a patient with a peripheral neuropathy

(14,15,19,20).

Major nerves, such as the sciatic and median nerves, contain motor, sensory, and autonomic nerve fibers; they are thus compound nerve trunks. It was Sir Charles Bell, the Scottish physician, who first demonstrated that motor function lay in the anterior roots; FranÃ§ois Magendie, the French physiologist, showed that the sensory function lay in the posterior roots. This (anterior-motor; posterior-sensory) is known as the Bell-Magendie law. Motor nerves are derived from anterior horn cells in the spinal cord or from defined nuclei in the brainstem. The initial segment of the axon lies within the central nervous system and is ensheathed by myelin formed by oligodendrocytes (Figure 10.1). As the axons pass out of the brainstem or spinal cord they become myelinated by Schwann cells. Anterior spinal roots join the posterior roots as they pass through the intervertebral foramina to form peripheral nerve trunks. Cranial nerves leave the skull through a number of different foramina. The junction point between oligodendrocytes and the Schwann sheath of the cranial nerves, known as Obersteiner-Redlich zone (O-Rz), has some clinical significance. For example, the pulsatile compression of the O-Rz by a vessel in some exit foramina may be responsible for the clinical symptoms of trigeminal and glossopharyngeal neuralgia, hemifacial spasm, torticollis spasmodicus, or even symptoms of essential hypertension when a vascular cross-compression of the left vagus nerve occurs (21)

Motor nerves end peripherally at muscle endplates and many of the sensory nerves are associated with peripheral sensory endings. The cell bodies of sensory nerves lie outside the central nervous system in the dorsal root ganglia or in cranial nerve ganglia (15). Each ganglion contains numerous, almost spherical neurons (ganglion cells) with their surrounding satellite cells. Such satellite cells are derived from the neural crest and have an origin similar to that of Schwann cells (22). Satellite cells have been referred to in the past by a large variety of names such as amphicyte, capsular cells, perisomatic gliocyte, or perineuronal satellite Schwann cells.

Dorsal root ganglion cells were first described by the Swiss anatomist Albert von Kolliker in 1844. They are examples of pseudounipolar cells, which means that a single, highly coiled axon, or stem process, arises from each perikaryon; but, at varying distances from the neuron, there is a T- or Y-shaped bifurcation, always at a node of Ranvier, with the formation of central and peripheral axons. Thus, the initial segment of axon gives the impression that the cell is a unipolar neuron when it actually has two axons (Figure 10.1). The central axon passes into the spinal cord, either to synapse in the posterior sensory horn of gray matter or to pass directly into the dorsal columns. Peripheral axons pass into the peripheral nerves (15).

Autonomic nerves are either parasympathetic or sympathetic. Preganglionic parasympathetic fibers pass out of the brainstem in the cranial nerves III, VII, IX, and X and from the sacral cord in the second and third sacral nerves. Postganglionic neurons are situated near or within the structures being innervated. Sympathetic preganglionic fibers arise from neurons in the intermediolateral cell columns of gray matter in the thoracic spinal cord and pass out in thoracic anterior roots (15). These preganglionic fibers are myelinated and reach the sympathetic trunk through the corresponding anterior spinal roots; they synapse with the sympathetic ganglion cells in paravertebral or prevertebral locations. The autonomic nervous system innervates viscera, blood vessels, and smooth muscle of the eye and skin (15).

Histology, Immunocytochemistry, and Ultrastructure of Peripheral Nerves

Components of the Nerve Sheath

Macroscopic inspection of a normal peripheral nerve reveals glistening white bundles of fascicles bound together by connective

tissue. The intraneural arrangement of fascicles is variable and changes continuously throughout the length of every nerve. Damaged peripheral nerves are often gray and shrunken due to the loss of myelin. Microscopically, transverse sections of a peripheral nerve (Figure 10.2) show how endoneurial compartments containing axons and Schwann cells are surrounded by perineurium to form individual fascicles embedded in epineurial fibrous tissue.

Epineurium

The epineurium consists of moderately dense connective tissue binding nerve fascicles together. It merges with the adipose tissue that surrounds peripheral nerves (Figure 10.2A), particularly in the subcutaneous tissue. In addition to fibroblasts, the epineurium contains mast cells. Although mostly composed of collagen, there are elastic fibers in the epineurium so that, when a specimen of unfixed nerve is removed from the body, there is some elastic recoil of the epineurium (20,23). The amount of epineurial tissue varies and is more abundant in nerves adjacent to joints. As nerve branches become smaller to consist of only one fascicle, epineurium is no longer present. In nerves that consist of several fascicles, one or more arteries, veins, and lymphatics run longitudinally in the epineurium parallel to the nerve fascicles (the vasa nervorum) (15,20,25) (Figure 10.2). Inflammation and occlusion of such arteries is an important cause of nerve damage in vasculitic diseases (25). The overgrowth of epineurial adipose tissue produces

the so-called lipofibromatous hamartoma, which classically affects the hands and is associated with enlargement of the affected digit (26).

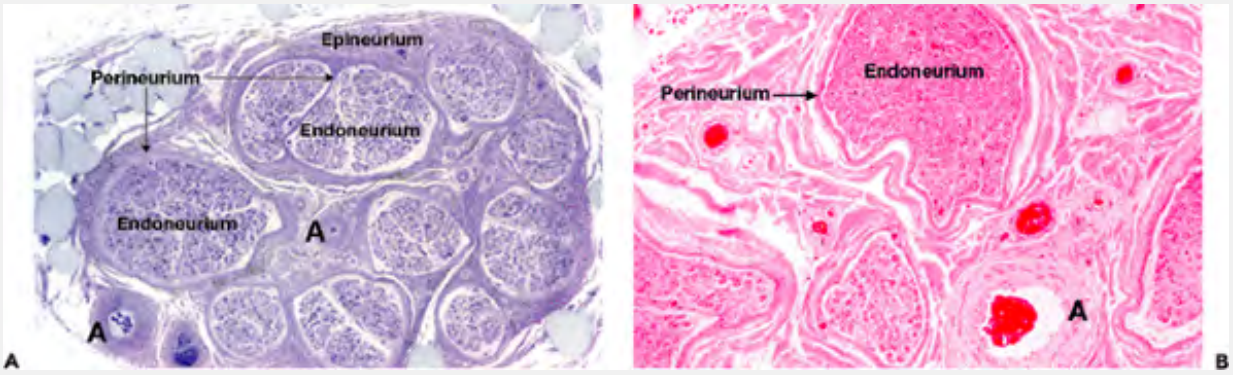

Figure 10.2 Peripheral nerve sheaths and compartments. A. A low-power view of a transverse section of a normal sural nerve. The nerve fascicles with roughly circular outlines are surrounded by perineurium and embedded in the connective tissue of the epineurium. Epineurial blood vessels (*arrow*) are also cut in cross section, and there is adherent adipose tissue (*upper left*) (1-Âµm resin section, toluidine blue, Ã—16). B. The endoneurial compartment containing myelinated and nonmyelinated nerve fibers and their accompanying Schwann cells is surrounded by perineurium. A large epineurial artery (*arrow*) is seen at the lower right (paraffin section, H&E, Ã—45).

Perineurium

Originally described by Friedrich G.J. Henle in the nineteenth century, the perineurium has, in the past, been known by a variety of different terms, such as mesothelium, perilemma, neurothelium, perineurothelium, and, more recently, perineurial epithelium (15,20).

Based on the pioneer work of the 1995 Nobel Prize winners Christiane NÃ¼sslein-Volhard and Wieschaus, an intercellular signaling molecule secreted by Schwann cells known as Desert Hedgehog, was described, that functions as an important molecule in

the formation of the perineurium. Apparently this molecule signals to the surrounding connective tissue cells to organize the perineurium (3).

The perineurium consists of concentric layers of flattened cells separated by layers of collagen (Figures 10.2,10.3,10.4). The number of cell layers varies from nerve to nerve and depends on the size of the nerve fascicle. In the sural nerve, for example, there are 8 to 12 layers of perineurial cells, but the number of layers decreases progressively so that a single layer of perineurial cells surrounds fine distal nerve branches (20). Perineurial cells eventually fuse to form the outer-core of the terminal sensory endings in pacinian corpuscles and muscle spindles (20,24,27). In motor nerves, the perineurial cells form an open funnel as the nerve ends at the motor endplate. Paraganglia of the vagus nerve may lie just underneath the perineurium (28).

By electron microscopy, perineurial cells are seen as thin sheets of cytoplasm containing small amounts of endoplasmic reticulum, filaments, and numerous pinocytotic vesicles that open on to the external and internal surfaces of the cell. Basement membrane is usually seen on both sides of each perineurial lamina (29,30). Numerous cell junctions, including well-formed tight junctions (zonulae occludentes), are present between adjacent perineurial cells and appear to be critical for the formation of

the blood-nerve barrier (15,30). Claudins are integral membrane proteins that play a major role in tight junctions and are present in normal and neoplastic perineurium. Claudins comprise a group of approximately 20 different proteins that are exclusively localized in tight junctions (31). In peripheral nerves, claudin-1 expression is largely limited to perineurial cells but is also present in paranodal regions and in the outer mesaxon along internodes (31,32). When tracer substances such as ferritin and horseradish peroxidase are

injected into the blood, they do not enter peripheral nerves. Their entry is prevented by tight junctions in endoneurial capillaries and by the tight junctions in the inner layers of the perineurium. Thus, there is a blood-nerve barrier analogous to the blood-brain barrier (30). The blood-nerve barrier is present soon after birth and may prevent the entry of drugs and other substances into nerves that may otherwise interfere or block nerve conduction (30,33). No such blood-nerve barrier exists in the dorsal root ganglia or in autonomic ganglia; these sites in the peripheral nervous system are vulnerable to certain toxins, such as mercury (34).

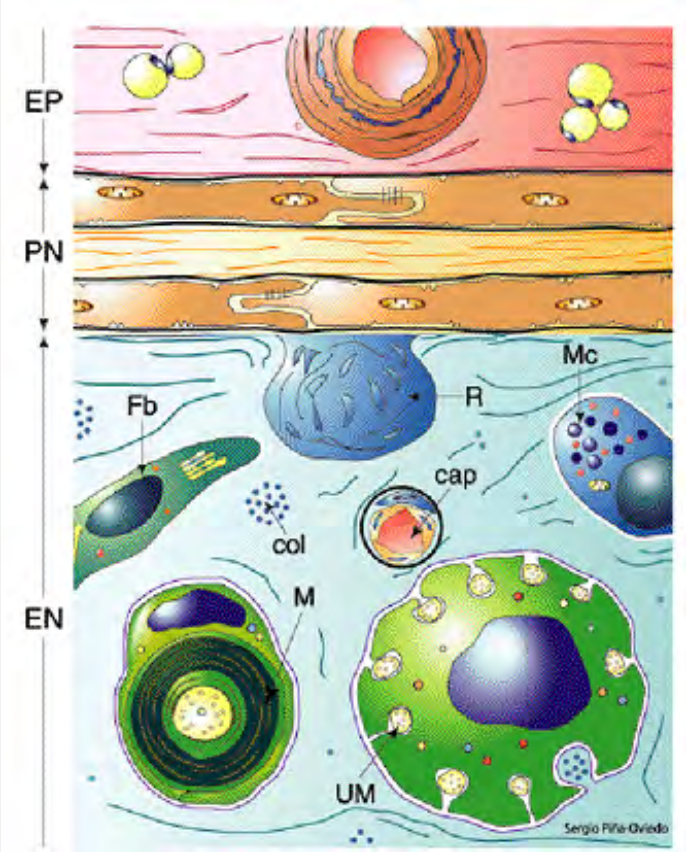

Figure 10.3 Diagram to show the major elements of peripheral nerve compartments. The epineurium (*EP*) contains collagen, blood vessels, and some adherent adipose tissue. The flattened cells of the perineurium (*PN*) are joined by tight junctions and

form flattened layers separated by collagen fibers. Renaut bodies (*R*) project into the endoneurium (*EN*). Schwann cells forming lamellated myelin (*M*) (drawn uncompacted in this diagram) surround the larger axons. Multiple unmyelinated axons (*UM*) are invaginated into the surface of Schwann cells. Other elements include fibroblasts (*Fb*), mast cells (*Mc*), capillaries (*cap*), and collagen (*col*).

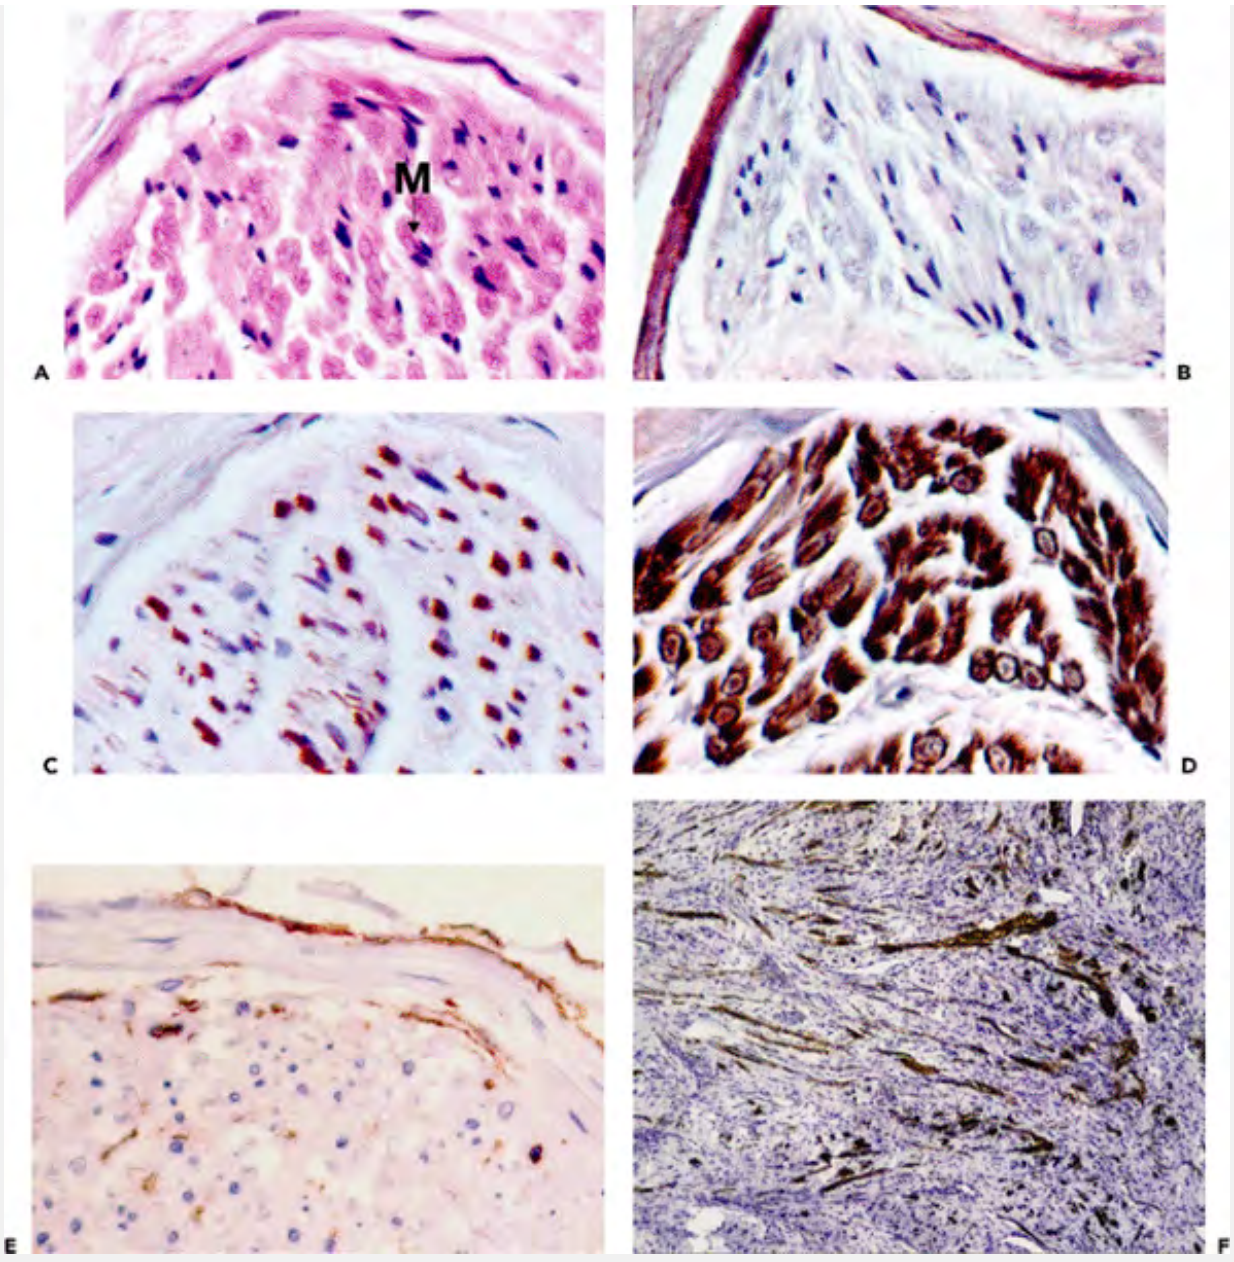

Figure 10.4 Immunocytochemistry of a normal peripheral nerve. A. Part of single nerve fascicle, cut in transverse section. Perineurium (*top*) surrounds the endoneurium containing myelinated nerve fibers (*M*). The nuclei are mainly those of Schwann cells (paraffin section, H&E, Ã—160). B. Similar field to (A) stained for epithelial membrane antigen. The perineurium (*top*) is densely stained [immunoperoxidase technique (ABC) with

antiepithelial membrane antigen (anti-EMA) antibody, Ã—160]. C. Part of a nerve fascicle stained for neurofilament protein. Large myelinated axons are well stained, but unmyelinated axons are much smaller and more difficult to detect [immunoperoxidase technique (ABC) using an antibody against the 80 KDa neurofilament protein, Ã—160]. D. Part of a nerve fascicle stained for S-100 protein showing densely stained Schwann cells [immunoperoxidase (ABC) using anti-S-100 protein antibody, Ã—160]. E. Part of a nerve showing CD34+ endoneurial cells. These cells are clearly distinct from the Schwann cells that comprise the bulk of the cell in the nerve [immunoperoxidase technique (ABC) using anti-CD34 (QBend10) antibody, Ã—160]. F. A traumatized nerve cut in longitudinal section showing regenerating axons (stained brown) (immunohistochemistry for GAP 43, Ã—40). (Photograph provided by Professor James Nicoll.)

If the perineurium is injured, there is breakdown of the blood-nerve barrier and perineurial cells migrate into the endoneurium to surround small fascicles of nerve fibres (35). This is classically seen in amputation neuromas but is also observed in focal compressive lesions of nerve (36). The swelling of the nerve and the concentric arrangement of the perineurial cells in the compressive lesions spawned the term *localized hypertrophic neuropathy,* but it is quite different from hypertrophic neuropathy (36), in which Schwann cells form whorls around individual axons in response to recurrent segmental demyelination (see below).

Whereas the epineurial sheath of the nerve is continuous with the dura mater at the junction of spinal nerves and spinal nerve roots (Figure 10.1), the perineurium blends with the pia-arachnoid. There are some morphological similarities between perineurium and arachnoid cells, although arachnoid cells are not usually coated by basement membrane. Immunocytochemically, perineurial cells and

pia-arachnoid cells are positive for epithelial membrane antigen (EMA) (Figure 10.4) and vimentin but are negative for S-100 protein and CD57 (37,38). Perineurial cells also express insulin-dependent glucose transporter protein I (Glut-1) (32,39).

Epithelial membrane antigen belongs to a heterogenous family of highly glycosylated transmembrane proteins found originally on the surface of mammary epithelial cells (40) but which are also present in the cells of virtually all epithelial tumors (40). However, EMA is not restricted to epithelial structures and has been identified on plasma cells and on cells in certain lymphomas and soft tissue tumors (20,40). Perineurial cells, arachnoid, and pia share certain ultrastructural characteristics and express EMA and vimentin in their cytoplasm. Immunohistochemistry has demonstrated that perineurial cells proliferate in some conditions, such as traumatic neuroma, Morton's neuroma, neurofibroma, solitary circumscribed neuroma, neurothekeoma, pacinian neuroma, and in the mucosal neuromas associated with multiple endocrine neoplasia (vide infra) (33,41).

Some tumor cells break through the perineurial sheath to grow along the perineurial space; perineurial invasion has been correlated with decreased survival times in some cancers (42). The problem for the histopathologist, however, is that sometimes perineurial invasion cannot be unequivocally determined on hematoxylin and eosin (H&E)â€“stained sections. Immunocytochemistry for Glut-1, EMA, and claudin-1 may be used to rapidly and accurately assess the presence of perineurial invasion (38,43). Care must be taken, however, when examining cases of vasitis nodosa, in which benign proliferating ductules may be found within the perineurium and endoneurium (44). Nerve involvement has also been reported in fibrocystic disease of the breast, normal and hyperplastic prostate, and normal pancreas (44).

Endoneurium

The endoneurium is the compartment that contains axons and their

surrounding Schwann cells, collagen fibers, fibroblasts, capillaries, and a few mast cells (Figures 10.3,10.4,10.5).

In cross sections of peripheral nerves, some 90% of the nuclei belong to Schwann cells, 5% to fibroblasts, and 5% to other cells (such as mast cells and capillary endothelial cells). Within the endoneurium, CD34+ bipolar cells with delicate dendritic processes have been identified and are distinct from Schwann cells (45,46). Similar cells have been identified in peripheral nerve sheath tumors in various proportions (45).

Some investigators have observed endoneurial dendritic cells, distinct from Schwann cells and conventional fibroblasts, that may function as phagocytes under certain conditions (47). In this regard, it has been described within the human endoneurium, an intrinsic population of immunocompetent and potentially phagocytic cells (endoneurial macrophages), that share several lineage-related and functional markers with macrophages and may represent the peripheral counterpart of del-Rio-Hortega cells (microglia) of the CNS (48,49).

Nerve fibers may be myelinated or unmyelinated but not all nerves have the same nerve fiber composition. Most biopsies of peripheral nerves in humans are taken from the sural nerve at the ankle, and it is the composition of this nerve that has been most closely studied (50). Fibroblasts are ultrastructurally identical to fibroblasts elsewhere in the body. Mast cells are a normal constituent of the endoneurium and are also seen in sensory ganglia and in the epineurial sheath of peripheral nerves. There is an increase in the number of mast cells in some pathological conditions such as axonal (wallerian) degeneration

and in some neoplastic entities such as von Recklinghausen's disease (neurofibromatosis). A characteristically high number of mast cells is seen in neurofibromas, but they are only present in the Antoni B areas of schwannomas (24,51). Mast cells are thought to influence

growth of neurofibromas because some of their mediators may also act as growth factors (52). Apparently the inciting factor for mast cell migration into nerve sheath tumors is Kit ligand that is hypersecreteted by NFâ€“/â€“ Schwann cell populations (52). Mast cell stabilizers are claimed to reduce proliferation and itching of neurofibromas (52). Following nerve injury, there is breakdown of the blood-nerve barrier as endoneurial vessels become permeable to fluid and protein; this increase in permeability may be related to the release of biogenic amines from mast cells within the endoneurium. Proteases released from mast cells have a high myelinolytic activity and may play a role in the breakdown of myelin in certain demyelinating diseases (52,53).

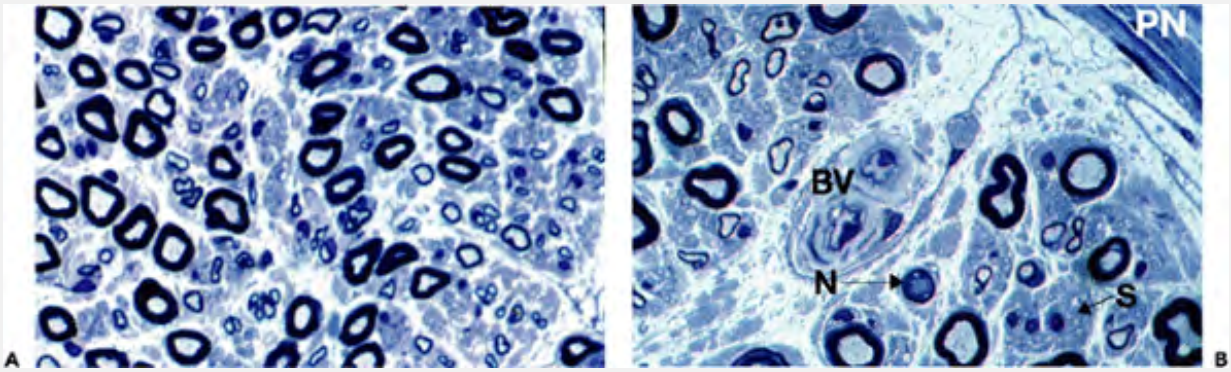

Figure 10.5 High-power histology of human sural nerve in transverse section. A. Large- and smalldiameter myelinated fibers are seen. In the normal nerve, these fibers are separated from each other, but small numbers of clusters (see Figure 10.12B) are seen in this illustration (1-Âµm resin section, toluidine blue, Ã—160). B. Part of a sural nerve fascicle cut in transverse section. Perineurium is at the top right (*PN*). Both large and small myelinated fibers vary in cross-sectional outline. Splits within the sheath are Schmidt-Lanterman incisures. Also visible are an endoneurial blood vessel (*BV*) and a section

through a fiber near the node of Ranvier (*N*). Unmyelinated axons are seen as unstained circles within Schwann cells (*S*). (1-Âµm resin section, Ã—310.)

Collagen within the endoneurial compartment is highly organized and forms two distinct sheaths around myelinated and unmyelinated nerve fibers and their Schwann cells (see Figures 10.8, 10.10). The outer endoneurial sheath (of Key and Retzius) is composed of longitudinally oriented large diameter collagen fibers; the inner endoneurial sheath (of Plenk and Laidlaw) is composed of fine collagen fibers oriented obliquely or circumferentially to the nerve fibers. The term *neurilemma* has been applied to the combined sheath formed by the basement membrane of the Schwann cell and the adjacent inner endoneurial sheath (15,24). Thus the term *neurilemmoma* is inappropriate when used to describe tumors of Schwann cell origin (schwannomas). The longitudinal orientation of collagen fibers in the outer endoneurial sheath, together with the Schwann cell basement membrane tubes, may play an important role in guiding axons as they regenerate following peripheral nerve damage (3,24).

Renaut bodies (Figures 10.3, 10.6) are seen not infrequently in the endoneurium of human peripheral nerves. Described in the nineteenth century by the French physician Joseph Louis Renaut, they are cylindrical (circular in cross section), hyalin bodies attached to the inner aspect of the perineurium. Composed of randomly oriented collagen fibers, spidery fibroblasts, and perineurial cells, Renaut bodies stain positively with Alcian blue because of the presence of acid glycosaminoglycans. The rest of the endoneurium also contains Alcian blueâ€“positive mucoproteins (24,54). Renaut bodies express vimentin and EMA and produce extracellular matrix highly enriched in elastic fiber components (55). In longitudinal section, they may extend for some distance along the nerve and end in a blunt and abrupt fashion (55). These bodies are more prominent

in horses and donkeys than in humans (2). Their precise function is not known, but Renaut himself thought that they may act as protective cushions within the nerve. They increase in number in compressive neuropathies and in a number of other neuropathies, including hypothyroid neuropathy, and may be a reaction to trauma (54,55).

Blood Supply of Peripheral Nerves

Vasa nervorum supplying peripheral nerves are derived from a series of branches from associated regional arteries. Branches from those arteries enter the epineurium (Figures 10.2, 10.3)

to form an intercommunicating or anastomosing plexus. From that plexus, vessels penetrate the perineurium obliquely and enter the endoneurium as capillaries often surrounded by pericytes (Figure 10.5). Tight junctions between the endothelial cells of the endoneurial capillaries constitute the blood-nerve barrier (30).

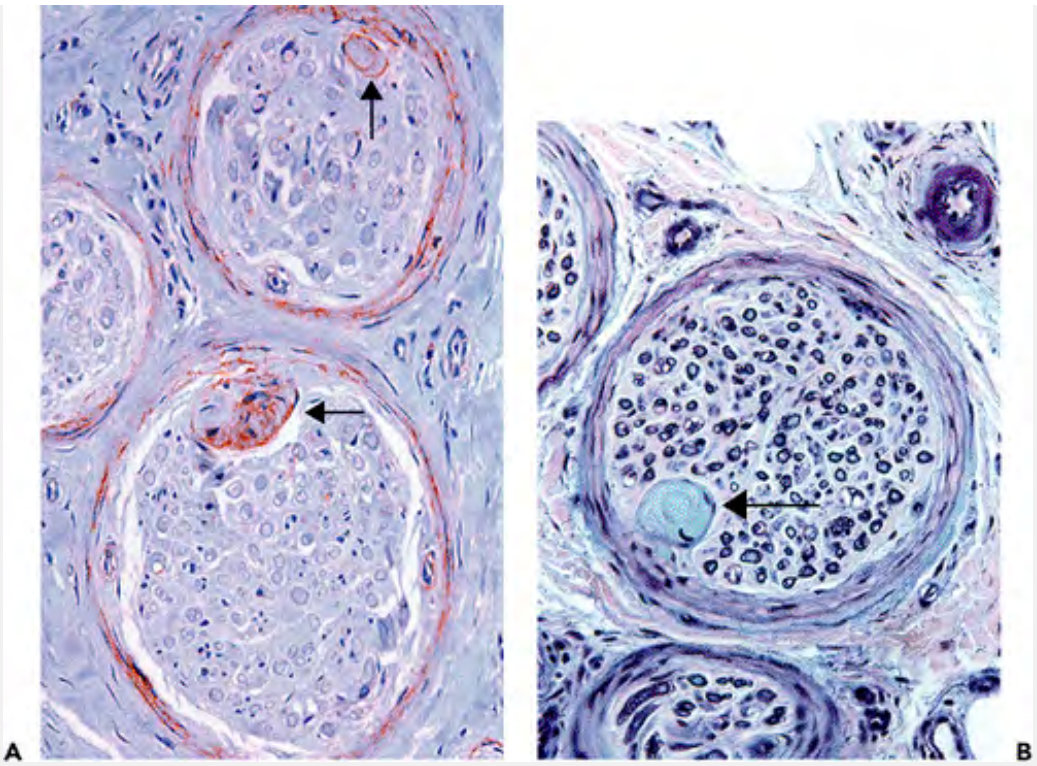

Figure 10.6 Nerve fascicles showing Renaut bodies (*arrows*). A. Immunostaining for epithelial membrane antigen (EMA). B. Russell-Movat pentachrome, showing the Renaut bodies in blue.

Complete infarction of peripheral nerves is very uncommon, probably due to the rich anastomotic connections of epineurial arteries. However, inflammation and thrombotic occlusion of epineurial arteries is seen in vasculitides (56), and occlusion by emboli occurs in patients with atherosclerotic peripheral vascular disease; both these disorders result in ischemic damage to peripheral nerves with axonal degeneration and consequent peripheral neuropathy (50).

Nerve Fibers

Most peripheral nerves contain a mixture of myelinated and unmyelinated nerve fibers. As the axons are oriented longitudinally along the nerve, quantitative estimates of the number of fibers in the

nerve and their diameters are only adequately assessed in exact transverse sections. Staining techniques that can be used to identify nerve fibers and other components within peripheral nerves are summarized in Table 10.1. Longitudinal sections of peripheral nerve are less valuable than transverse sections, but teased nerve fibers (see Figure 10.15D) are very valuable for detecting segmental demyelination and remyelination and for assessing past axonal degeneration and regeneration (50).

In a transverse section of a human sural nerve, there are approximately 8,000 myelinated fibers/mm^2, whereas the unmyelinated axons are more numerous at 30,000 myelinated fibers/mm^2. Peripheral nerve fibers are classified as class A, class B, and class C fibers, according to their size, function, and the speed at which they conduct nerve impulses. Class A fibers are myelinated and are further subdivided into six groups covering three size ranges. The largest are 10 to 20 Âµm diameter myelinated fibers that conduct at 50 to 100 m/sec; myelinated fibers 5 to 15 Âµm in diameter conduct at 20 to 90 m/sec, and 1 to 7-Âµm diameter myelinated fibers conduct at 12 to 30 m/sec. Class B fibers are myelinated preganglionic autonomic fibers some 3 Âµm in diameter and conducting at 3 to 15 m/sec. Unmyelinated fibers are small (0.2 to 1.5 Âµm in diameter), conduct impulses at 0.3 to 1.6 m/sec, and include postganglionic autonomic and afferent sensory fibers, including pain fibers (57).

Myelinated Axons

Ultrastructure

Although myelinated nerve fibers can be demonstrated in paraffin sections (Figure 10.4), they are best visualized by light microscopy in 0.5- to 1-Âµm thick toluidine blueâ€“stained resin sections (Figure 10.5). They exhibit a bimodal

distribution of fiber diameter in the normal nerve, with peaks at 5 and 13 Âµm and a range of 2 to 20 Âµm. Most axons above 3 Âµm in diameter are myelinated. Although along much of its length a myelinated nerve fiber has a circular outline in cross section, there is considerable variation in shape within the normal nerve, especially in the perinuclear regions and in the regions around the node of Ranvier (paranodal regions) (Figure 10.7).

Table 10.1 Histologic Techniques for Peripheral Nerves

	Technique	Application
A.	General	
	1. Hematoxylin and eosin (H&E)	Detection of inflammation, myelin, and axons (Figure 10.2B, 10.4A)
	2. Hematoxylin-van Gieson	Collagen stains red; myelin black
	3. Reticulin stains	Basement membrane around each Schwann cell in normal (e.g., Gordon-Sweet) nerve and schwannomas (Figure 10.17C)
	4. Masson's trichrome	Fibrinoid necrosis in vasculitis

	5. Alcian blue	Glycosaminoglycans stain blue
	6. Toluidine blue	(a) Mast cells in paraffin section (b) general stain for 1Âµm resin sections, (c) metachromatic stain for sulfatide lipid
B.	Stains for myelin	
	1. Luxol fast blue	Myelin stains blue; can be combined with silver stains for axons
	2. Loyez	Myelin stains black
	3. Osmium	Myelin stains black
	4. Periodic acid-Schiff (PAS)	Myelin stains bright pink (good for detecting small number of nerve fibers in muscle biopsies)
	5. Polarized light (frozen section)	Normal myelin, birefingent; degenerating myelin isotropic (nonbirefingent)
	6. Marchi's	Degenerating myelin stains black (due to the presence of cholesterol esters); normal myelin is unstained.

	7. Oil red O	Degenerating myelin stains bright red; normal myelin, pink
C.	Stains for axons	
	1. Palmgren's or Bodian's (silver stains)	Axons stain black.
D.	0.5 to 1Âµm resin sections	
	1. Toluidine blue	Myelin stains black; axons unstained; Schwann cells and other cells, blue; collagen, blue (Figures 10.2A, 10.5, 10.12 and 10.14A, B)
	2. Toluidine blue and carbol fuschin.	Myelin stains black; axons, unstained; cells and collagen, pink/blue (Figure 10.14C)
	3. Immunohistochemistry can be performed on these sections.	
E.	Electron microscopy	(Figures 10.8, 10.9, 10.10, and 10.16)
F.	Teased fibers	
	1. Osmium tetraoxide stained	Myelin; nodes of Ranvier; demyelination and remyelination

	(Figure 10.14D)
2. Enzyme histochemistry	
a. Mitochondrial enzymes	Schwann cytoplasm; axoplasm
b. Acid phosphatase	Lysosomal activity associated with degenerating myelin
c. Polarized light	Myelin
3. Lipid histochemistry	
a. Sudan black B	Myelin
b. Oil red O	Normal and degenerating myelin
4. Immunohistochemistry	
a. S-100 protein	
b. CD57 (Leu-7)	Schwann cells (Figure 10.4); schwannomas
c. CD56 (NKH1)	Schwann cells; schwannomas

d. Calretinin	Schwann cells and some schwannomas
e. CD146 (Mel-CAM)	Schwann cells; some schwannomas
f. GFAP (glial fibrillary acidic protein)	Some schwannoma cells; possibly unmyelinated
g. Myelin basic protein	Myelin
h. Neurofilament protein	Axons (Figure 10.4C)
i. Epithelial membrane antigen/Glut-1/claudin-1	Perineurium (Figure 10.4B)
j. CD34 (QBend10)	CD34 positive endonerual fibroblasts
k. CD68 (KP-1/PGM1)	Endoneurial macrophages.
l. GAP 43	Regenerating axons (Figure 10.4F)

The axon itself is limited by a smooth plasma membrane (axolemma), that is separated from the encompassing Schwann cell by a 10 to 20 nm gap (periaxonal space of Klebs) (Figure 10.8). The axonal cytoplasm (axoplasm) contains mitochondria, cisternae of smooth endoplasmic reticulum, occasional ribosomes and glycogen granules, peroxisomes, and vesicles containing neurotransmitters. The most prominent components of the axoplasm, however, are the filamentous and tubular structures. Microfilaments, 5 to 7 Âµm in diameter, are composed of chains of actin and comprise approximately 10% of the total axonal protein. They are virtually confined to the cortical zone of the axoplasm immediately beneath the axolemma (15). Neurofilaments (Figures 10.4C, 10.8) are 8- to 10-Âµm diameter intermediate filaments of indeterminant length, and they constitute a major filamentous component in larger axons (58). They were described originally by RamÃ³n y Cajal and Bielschowsky as argentophilic neurofibrillae. In the neuronal perikaryon, neurofilaments tend to appear in multiple whorled bundles with no clear orientation to elements of the cell. In the axons, however, neurofilaments appear in longitudinal, mostly parallel orientation (59). Small armlike filaments are seen by electron microscopy. They project from the surface of the neurofilaments to form an irregular polygonal lattice. Neurofilaments are composed of protein triplets that are chemically and immunochemically distinct (59). Three major subunits are recognized and are classified according to their molecular weights of 68, 150, and 200 KDa. Within axons, neurofilaments are phosphorylated and are immunocytochemically distinct from the nonphosphorylated filaments within neuron cell bodies. Immunocytochemistry for neurofilament protein (Figure 10.4C)

is often valuable for detecting large- or medium-sized axons in normal nerves, in traumatic lesions, in tumors involving peripheral nerves, and occasionally for detecting axonal processes in neuronal tumors (58,59).

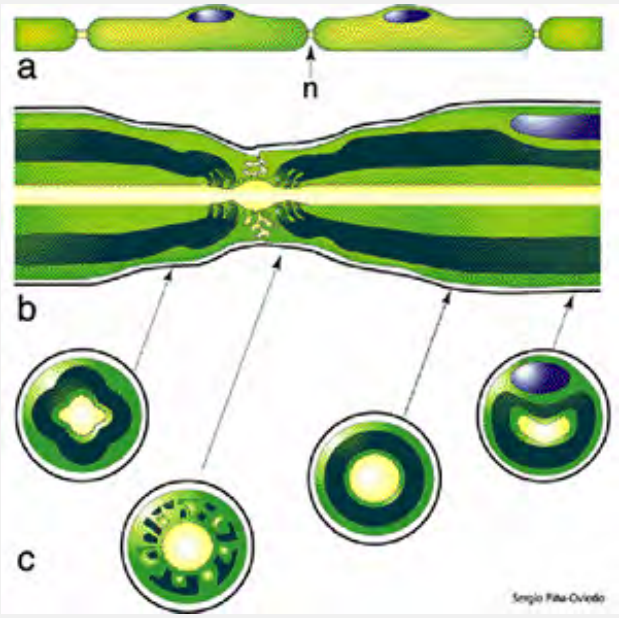

Figure 10.7 Diagram to show the relationships between (A) teased fibers, (B) nerve fibers in longitudinal section, and (C) nerve fibers in transverse section. A. In teased fibers, nodes of Ranvier (*N*) are separated by internodal portions of the Schwann cell and myelin sheath. The Schwann cell nucleus is roughly in the center of the internode. B. Longitudinal section through the node of Ranvier shows how the myelin sheath terminates as a series of end-loops. The axon narrows as it passes through the node of Ranvier. C. Transverse sections of peripheral nerve as seen in electron micrographs and 1 Âµm resin sections are here related to the different portions of the internode and the node of Ranvier. *From left to right,* the paranodal region shows crenation of both axon and myelin sheath in larger fibers. At the node of Ranvier, the axon is small and coated by radially arranged Schwann cell processes and myelin end-loops. Throughout most of the internode, the myelinated fiber is circular. In the region of the nucleus, the axon and the myelin sheath may be ovoid rather than circular in outline.

Figure 10.8 Transverse section of a myelinated nerve fiber in the perinuclear region. The axon contains mitochondria, small vesicles, and numerous neurofilaments and neurotubules cut in cross section (inset, *top left*). A distinct periaxonal space separates the axon from its encompassing Schwann cell. Myelin is compacted except at the external mesaxon (*EM*) and internally around the internal mesaxon near the axon itself. Part of a Schmidt-Lanterman incisure is seen on the inside of the myelin sheath. Abundant rough and smooth endoplasmic reticulum is seen in the perinuclear cytoplasm of the Schwann cell. A basement membrane (*BM*) surrounds the Schwann cell plasma membrane, and endoneurial collagen fibers are seen cut in cross section (*col*). (Electron micrograph, Ã—18,400); inset, Ã—40,000.)

The third â€œfilamentousâ€• component in the axoplasm is the microtubule (neurotubule). Microtubules are cylindrical (Figure 10.8), unbranched, longitudinally oriented, hollow tubules 24 nm in diameter and composed of globular subunits of tubulin 4 to 5 nm in diameter. Periodic radial projections of high-molecular weight proteins, which are part of the microtubule-associated proteins (MAPs), arise from the surface of the neurotubules. These armlike projections bind neurofilaments and actin filaments and together form neurotubule-neurofilament-actin filament lattices. The three-dimensional lattices form an ordered structure in the axoplasm that appears to play an important role in axonal transport and contributes directly to the axon's shape (60). Microtubules also direct the transport of vesicular organelles between the cell body and the axon and thereby determine, in part, the composition of the axon (60).

Axoplasmic Flow

In 1906, Scott proposed that neuron cell bodies secreted â€œgrowing substancesâ€• in order to maintain the function of the axon. He suggested that such substances pass down the axon cytoplasm to the axon terminals. This suggestion was endorsed by RamÃ³n y Cajal when he observed how regeneration occurs from the proximal stump of a damaged axon as long as continuity with the cell body is maintained (15). More definitive evidence of axonal transport was provided later by experimental studies using autoradiography and other techniques. Not only can labeled substances such as tritiated leucine be traced by autoradiography as they are transported along axons from the cell body, but the transport of organelles within the axon can also be directly observed by the use of dark-field microscopy or Nomarski optics (60). The term *axoplasmic flow* was coined by Weiss to describe the movement of different materials along the axoplasm. Axoplasmic flow and transport occur in two directions, away from the cell body

(anterograde) and toward the cell body (retrograde) (61).

Anterograde axoplasmic transport occurs at two velocities: fast and slow. Most organelles and large-molecular weight substances within the axon are conveyed by fast axoplasmic transport, up to 400 mm/day. If a ligature is placed around a nerve, transported material accumulates proximal to the ligature and to some degree distal to it, due to interference with anterograde and retrograde transport, which both occur at the same rate and by the same mechanisms. The filamentous lattice component of neurotubules, neurofilaments, and actin filaments is responsible for fast axoplasmic flow, and these three elements probably act as rails along which the various transported organelles and substances move. Fast axoplasmic transport is dependent on oxidative energy mechanisms and adenosine triphosphate (ATP); it also depends on calcium and magnesium ions and is blocked by calcium channel blocking agents. Some substances, such as trifluoperazine, that block calmodulin (calcium-activating protein) also block axoplasmic flow. Neurotubules, as an integral part of the axoplasmic transport mechanism, are depolymerized by cold and by colchicine; vincristine, and vinblastine are known to bind tubulin and prevent the normal assembly of neurotubules. Such substances block fast axoplasmic flow (60).

Retrograde axoplasmic transport may convey information and organelles back to the cell body. In immature nerves, nerve growth factor is taken up by nerve terminals and retrogradely transported to the cell body, where it may play a role in the maturation of neurons (62). It has been suggested that the transport of such growth factors may also influence the metabolism of mature neurons and that the absence of such signals from the distal part of the neuron when the axon is severed may trigger chromatolysis (61). Retrograde transport is also a pathway by which certain toxins (tetanus neurotoxin) and some metals (lead, cadmium, and mercury) may bypass the blood-brain barrier and accumulate in neurons (63). Neurotropic viruses such as herpes, rabies, and poliomyelitis may be transported to the

central nervous system by retrograde transport (64,65). In addition to toxic neuropathies, axonal transport is defective in diabetes, peroneal muscular atrophy, and probably in amyotrophic lateral sclerosis. Axoplasmic transport is reduced with age (66).

Slow axoplasmic transport at 1 to 3 mm/day concerns the distal movement of cytoskeletal elements such as neurofilaments, microtubules, and actin. It is a one-way process, and neurofilaments are broken down by calcium-activated proteases at the distal end of the axon. Similarly, microtubules are depolymerized distally (67). Various toxins such as hexocarbons and their derivatives may interfere with slow axoplasmic transport so that neurofilaments accumulate and form large swellings within the axon (34,68). It is thought that neurofilaments within an axon may act primarily to maintain the bulk and the shape of large axons; neurofilaments are less numerous in small axons.

The Periaxonal Space of Klebs

As the Schwann cell enwraps the axon, it leaves a space, 20 nm wide, between the Schwann cell membrane and the axolemma (Figure 10.8); this is the periaxonal space of Klebs (69). This space is in continuity with the extracellular space at the node of Ranvier through a narrow helical channel at the site where the terminal cytoplasmic processes of the Schwann cell approach the axolemma (14) (Figure 10.7). The maintenance of the periaxonal space of Klebs appears to be mediated by an intrinsic 100 KDa myelin-associated glycoprotein (MAG) in the periaxonal membrane of the Schwann cell (70). This protein has a heavily glycosylated

domain, with sialic acid and sulfate residues on the external surface of the plasma membrane extending into the periaxonal space; in fact, about half of the peptide of MAG is in the periaxonal space (71). Mutant mice that do not express MAG do not form a periaxonal space, and the Schwann cell membrane fuses with the axolemma.

Experimental studies with giant squid axons and mammalian nerve axons show that there is an increase in potassium concentration in the periaxonal space during repetitive conduction of nerve impulses. The full significance of the periaxonal space, however, is not clearly understood.

Schwann Cells

In his book on the microscopic structure of animals and plants published in Berlin in 1839, Theodore von Schwann identified a vague sheath of cells within nerve fibers; these cells have subsequently borne his name as Schwann cells. As described previously in the section on development of peripheral nerves, Schwann cells are derived from the neural crest and migrate with growing axons into the developing peripheral nerves (3,72). Schwann cells produce nerve growth factor both in development and during regeneration; and, as the nerves grow, Schwann cells divide axons into groups and eventually establish 1:1 relationships with the larger fibers that they will ultimately myelinate (15,25,72). Immature proliferating Schwann cells have a relatively large volume of cytoplasm compared with mature Schwann cells. The Schwann cytoplasm is rich in mitochondria, polyribosomes, Golgi cisternae, and rough endoplasmic reticulum (Figure 10.8). The cytoskeleton within the cells includes vimentin intermediate filaments and is particularly obvious during the active proliferative and migrating phases of development and regeneration.

Schwann cells in a normal adult peripheral nerve are associated with both myelinated fibers and unmyelinated fibers. In myelinated fibers the Schwann cytoplasm is divided into two compartments: (a) around the nucleus and on the outside of the myelin sheath, and (b) that thin rim of cytoplasm on the inside of the myelin sheath and around the internal mesaxon (Figure 10.8). Using electron microscopy, Schwann cells within a nerve can be identified by their relationship with myelinated or unmyelinated fibers. In damaged peripheral

nerves, however, Schwann cells can be identified most easily by the presence of an investing basement membrane (Figure 10.8). Other cells within the endoneurium, such as fibroblasts, do not have a basement membrane; and, although macrophages may invade the basement membrane tubes, they have a distinct ruffled border that distinguishes them from Schwann cells. Perineurial cells may be found in the endoneurial compartment, particularly in damaged nerves; they possess a basement membrane, but they can be distinguished from Schwann cells by the presence of tight junctions that are not a feature of Schwann cells (3,54,72). With increasing age, normal Schwann cells accumulate lipofuscin and lamellated structures in the paranuclear cytoplasm in the form of pi (Ï€) granules of Reich. Such granules are composed of wide-spaced lamellated structures and amorphous osmiophilic material; they are rich in acid phosphatase and stain metachromatically with toluidine blue in frozen sections (73). Other inclusions such as the corpuscles of Erzholz are seen in Schwann cytoplasm; these bodies are spherical, 0.5 to 2.0 Âµm in diameter, and stain intensely with the Marchi method. Few Pi granules remain in Schwann cells following nerve damage in which there has been extensive Schwann cell mitosis and proliferation (73).

In addition to an investing basement membrane, composed of laminin, fibronectin, and entactin/nidogen, Schwann cells also produce heparan sulfate, N-syndecan, glypican, collagens type I, III, IV, and V, Î²1 and Î²4 integrin, and the protein BM-40 (74). All these secreted products are incorporated into the basement membrane except type I and type II collagen (3,72). Schwann cells can be identified in paraffin sections by immunocytochemistry and by the presence of close investment by reticulin staining. There is a rich reticulin network investing each cell, not only in the normal peripheral nerve but also in Schwann cell tumors. The S-100 protein in the cytoplasm and nuclei of Schwann cells can be identified by immunocytochemistry (Figure 10.4D). This acidic protein, which is 100% soluble in ammonium sulfate at neutral pH, was described by

Blake W. Moore in 1965, is a calcium-binding EF-hand type molecule, and has no known function, but it is present in Schwann cells and not in fibroblasts or perineurial cells (37,75) (Figure 10.4). In vitro studies have reported the presence of Schwann cells that are weakly reactive for S-100 protein and that may correspond to the non-myelinating (Remak) cell population (76). Schwann cells are also immunolabeled using CD57 and CD56 but perineurial cells are again negative (37,77). Calretinin, the 29-KDa, calcium-binding protein that also belongs to the family of EF-hand proteins, is expressed in Schwann cells but not consistantly in schwannomas (78). Normal and some neoplastic Schwann cells also express the cell adhesion molecule CD146 (79). Occasionally, Schwann cells are labeled by anti-GFAP antibodies, but this may depend on the antibody used (37,80). GFAP immunoreativity in the peripheral nervous system has been demonstrated in enteric ganglia, olfactory nerve cells, and in Schwann cells in the sciatic, splenic and vagus nerves (81). Schwann cells also participate in the formation, function, and maintenance of neuromuscular junctions and Meissner corpuscles (82,83). These â€œterminal Schwann cellsâ€• may be identified by their expression of Herp-protein, which is not present in nonterminal myelinating Schwann cells (84). An interesting and peculiar intermediate glial cell type known as the olfactory ensheathing cell (OEC) is associated with neuronal processes of the olfactory bulb; OECs share astrocytic and Schwann cell phenotypes,

promote axonal regeneration, and are potentially useful cells for xenotransplantation procedures (85).

Myelin

Myelin sheaths appear as slightly basophilic rings in H&Eâ€“stained transverse paraffin sections of nerve (Figure 10.4). They can be more prominently stained by Luxol fast blue or by hematoxylin stains such as Loyez (Table 10.1). In frozen sections, myelin is well depicted by Sudan black staining; and, in unstained frozen sections,

myelin can be identified due to its birefringence in polarized light, a technique that is particularly suitable for identifying myelin in enzyme histochemical preparations (57).

Myelin is formed by the fusion of Schwann cell membranes and, by electron microscopy, it is seen as a regularly repeating lamellated structure with a 12 to 18 nm periodicity (86). On the outer and inner aspects of the sheath, external and internal mesaxons can be traced from the cell surface (Figure 10.8). The myelin membrane is divided into two structurally and biochemically distinct domains: the compact and the noncompact myelin, each of which is characterized by a unique set of proteins. Compact myelin, for instance, contains P0, PMP22, and MBP, whereas noncompact myelin contains MAG, Cx32, Î±6Î²4 integrin and E-cadherin (3,72).

As the external aspects of the Schwann cell membranes fuse to produce compact myelin, an interrupted interperiod line forms in the myelin. The more densely stained period line is formed by fusion of the cytoplasmic aspects of the cell membrane. A narrow cleft can be resolved between the components of the interperiod line. In myelinating Schwann cells, noncompact myelin is present in paranodal loops, Schmidt-Lanterman incisures, nodal microvilli, and the inner and outer edges of the myelin (87). Several types of cell junction, including tight, gap and adherens junctions, are seen between the myelin lamellae (known as autotypic junctions) (87).

Biochemically, myelin is 75% lipid and 25% protein. The major lipids are cholesterol, sphingomyelin, and galactolipids, which are present in a rather higher proportion than they are in other cell membranes. It is the arrangement of the lipids that produces the liquid crystalline fluid birefringent myelin sheath, and it is esterification of the cholesterol in degenerating myelin that can be detected by Sudan dyes, by oil red O, and by the Marchi technique (Table 10.1). As myelin degenerates and the cholesterol becomes esterified, the ultrastructural lamellated pattern of myelin is lost and replaced by the amorphous osmiophilic globules seen in electron micrographs.

More than half the protein in myelin is a transmembrane 28 to 30 KDa glycoprotein, P0 (88); other proteins are P1 and P2. The protein mediates homophilic adhesive interactions between Schwann cell plasma membranes, is a key structural constituent of both the major dense line and interperiod line of compact myelin, and is involved in myelin compaction (88). Numerous mutations in P0 have been described in a variety of demyelinating diseases (see below) (88).

Although the lipid composition of myelin in the peripheral nervous system (PNS) is very similar to that of the central nervous system (CNS), the protein components are markedly different. Central nervous system myelin has no P0 protein but has a proteolipid that is soluble in organic solvents; it also has an 18KDa basic protein that is probably homologous to the P1 protein of peripheral nerve myelin. These biochemical differences may account for differences in the structure between PNS and CNS myelin; for example, the spaces between the dense lines are less for CNS myelin (89). Biochemical differences in the proteins definitely account for the distinct antigenicities of peripheral and central nervous system myelin. Thus, injection of CNS myelin with Freund's adjuvant will produce allergic encephalomyelitis in experimental animals, with destruction of myelin in the brain and spinal cord (90), whereas injection of peripheral nervous system myelin with Freund's adjuvant will produce allergic neuritis with demyelination in the peripheral nervous system.

Myelin sheaths are essential for the normal functioning of the PNS; and, in those hereditary neuropathies in which myelination is defective, severe disability and retardation of development are seen (91). Acting as a biological electrical insulator, myelin allows discontinuous (saltatory) and very rapid conduction of a wave of depolarization along the nerve fiber. It appears that myelination is an evolutionary adaptation that allows increased conduction velocities without excessive increases in axon diameter (72).

Myelination in the PNS in humans occurs well in advance of that of the CNS (89). Although there is little myelin in human cerebral

hemispheres at birth, myelin sheaths have already started to form around peripheral nerves at this time. Myelination is initiated by contact between Schwann cells and future myelinated axons. The Schwann cell rotates around the axon and may form 50 or more spirals, resulting in formation of the myelin sheath.

As the Schwann cell differentiates and produces a basement membrane, it acquires polarity via interaction of its cytoskeleton and some basement membrane components (mainly laminin and fibronectin) (3,92). The Schwann cell then begins to extend processes around individual axons. Once the lips of the Schwann cell start to wrap around the axon, they generate traction to pull the whole cell around, and a spiral wrapping made up of many lamellae is formed (18). The importance of basement membrane formation as a prerequisite for the formation of myelin is emphasized by the lack of myelination when the basement membrane is deficient (92,93).

Myelin-associated glycoprotein also plays an important role in myelination (88). It is present in the membranes of Schwann cells around myelinated fibers but not in those cells associated with unmyelinated fibers. Myelin-associated glycoprotein

probably functions through its interaction with the Schwann cell cytoskeleton, and this facilitates process lengthening and rotation during myelination (71). Periaxin, a 47 KDa protein constituent of the dystroglycan-dystrophinâ€“related protein-2 complex that links the Schwann cell cytoskeleton to the extracellular matrix, is located in the periaxonal region of Schwann cell plasma membrane that possibly interacts with myelin-associated glycoprotein during myelination (94). Mutations in the periaxin gene result in the autosomal recessive demyelinating Charcot-Marie-Tooth (CMT4F) and DÃ©jÃ©rine-Sottas diseases (94) (see below). As myelination proceeds, cytoplasm is expressed from the spiral of Schwann cell processes and membranes compact to form the 12 to 18 nm lamellated structure of myelin.

The length of an embryonic Schwann cell is 30 to 60 Âµm, and it becomes associated with that length of axon in the developing nerve. As the nerve lengthens with growth of the body and limbs, so does the Schwann cell so that the length of the Schwann cell or internodal distance (Figure 10.7) in myelinated fibers reaches some 190 Âµm at 18 weeks gestation and 475 Âµm at birth. In the adult nerve, normal Schwann cells may extend for up to 1 mm in length along myelinated fibers. Schwann cells associated with unmyelinated fibers lengthen to reach approximately 250 Âµm in the adult sural nerve. Following damage to a peripheral nerve, Schwann cell lengths revert to their embryonic length, and thus give short internodes in regenerating and remyelinating nerve fibers (see Figures 10.12, 10.14).

Schmidt-Lanterman Clefts or Incisures

Once viewed as artifacts, the clefts or incisures described by H.D. Schmidt and A.J. Lanterman (Figure 10.9) are now known to be fixed components of the myelin sheath (24). Each Schmidt-Lanterman incisure (S-L I) consists of a continuous spiral of Schwann cytoplasm that runs from the outer (nuclear) to the inner (paraxonal) Schwann cell compartment in an oblique fashion at about 9 degrees to the long axis of the sheath. The cleft splits the cytoplasmic membranes at the major dense line and forms a route for the passage of substances from the outer cytoplasmic layer through the myelin sheath to the inner cytoplasm. This function was suggested by Ranvier as early as 1897. Near the external surface of the cleft, stacks of desmosome-like structures and gap junctions rich in connexin 32, are sometimes seen, possibly maintaining the integrity of the spiral (95). The cell junction proteins claudin-5, MUPP1, E-cadherin, as well as a 155-KDa isoform of neurofascin, have been selectively detected at the S-L I (31). Cytoplasm in the clefts contains membrane-bound dense bodies, lysosomes, an occasional mitochondrion, and a single microtubule (Figure 10.9) that runs circumferentially around the fiber; this microtubule may be associated with transport and with stabilization of the cytoplasmic

spiral (15). The number of S-L Is correlates with the diameter of the axon; the larger the fiber, the more clefts in the myelin sheath per Schwann cell. The presence of these clefts throughout myelogenesis suggests that they are an important functional part of the sheath (24). Balice-Gordon et al. (96) have suggested that the incisures may provide some degree of flexibility and may protect the peripheral nerve from mechanical stress during stretching and recoil. It also seems obvious that they are pathways of communication between the inner and outer Schwann cell cytoplasm, but their full significance remains to be elucidated.

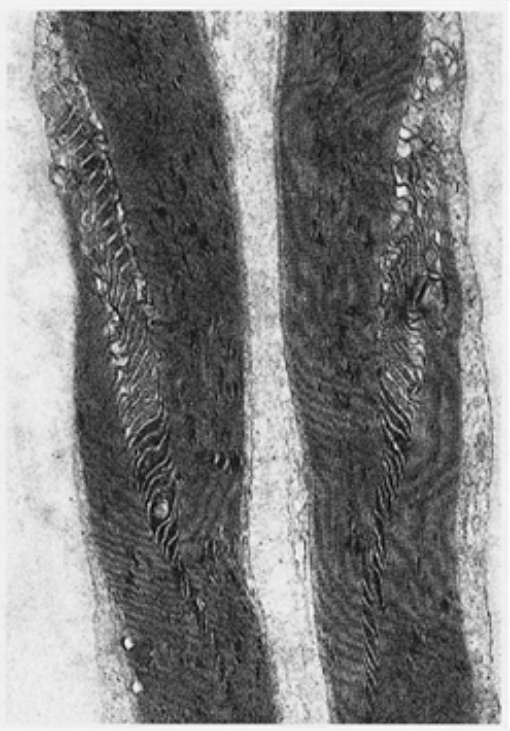

Figure 10.9 Longitudinal section of peripheral nerve: a Schmidt-Lanterman incisure. Blebs of cytoplasm are seen running through the myelin sheath. Densities in the cytoplasm (*top left*) suggest some form of junction between the spiral turns of the incisure. The axon is cut tangentially. (Electron micrograph, Ã—30,000). (Reprinted from

Node of Ranvier

With the introduction of techniques whereby individually separated or teased myelinated nerve fibers could be stained black with osmium tetroxide, a new view of nerve fibers was obtained. In his publication of 1876, Louis-Antoine Ranvier, Professor of Histology in Paris, described and illustrated the constrictions or â€œÃ©tranglements annulaires,â€• that are now known as the nodes of Ranvier (20,24). The functions of the node at that time were not known, but Ranvier did suggest that the constrictions may prevent displacement or flow of the semiliquid myelin along the nerve fibers (20,24). He also suggested that the gap in the myelin sheath at the node of Ranvier might allow diffusion of nutrients into the axon (15).

In teased fibers stained with osmium tetroxide or viewed in polarized light, the nodal gap is readily visible, as is the bulbous swelling of the fiber on either side of the node of Ranvier (see Figure 10.15D). The distance between each node along a myelinated fiber (Figure 10.7) is approximately proportional to the thickness of the myelin sheath. In a normal adult mammalian nerve, internodal segments between the nodes of Ranvier vary from 200 to 1500 Âµm in length; the Schwann cell nucleus is usually sited around the middle of the internode.

Histological study of 1-Âµm transverse resin sections of nerve and electron microscopic observations reveal a complex structure at the node of Ranvier and in the paranodal regions. As the axon approaches a node of Ranvier, it may become cruciform in cross section, especially in large fibers (Figure 10.7). Deep furrows

develop in the surrounding myelin sheath, and those furrows are filled with cytoplasm that is rich in mitochondria. As the axon passes through the node it is reduced to one-third or one-sixth of its internodal diameter. There may be a slight swelling at the midpoint of the node. Amorphous, osmiophilic material rich in ankyrin, Nr CRM, and neurofascin (97) may be deposited under the axolemma (98). Ankyrin-binding proteins are also localized in the initial segment of the axon, the voltage-dependent sodium channel, the sodium/potassium ATPase, and the sodium/calcium exchanger (97). These specialized areas of axon membrane may reflect the site of high ionic current density during transmission of a nerve impulse. Numerous ion channels are present in this region of the axolemma, and they are responsible for the changes in ionic milieu that occur during the conduction of nerve impulses (98).

There is considerable specialization of the Schwann cell and the myelin sheath at the node of Ranvier. The myelin sheath terminates by forming dilated looplike structures that are closely apposed to the axon surface (Figure 10.7). Occasionally, desmosome-like structures are formed between Schwann cell terminal loops. The tight junction protein claudin-2, and the ERM (ezrin, radizin, moesin) proteins have been identified as a ring that surrounds sodium channels at the node of Ranvier, possibly participating in the junctions formed at the outer collars of two adjacent Schwann cells at the node zone (31). The abundance of mitochondria in the paranodal cytoplasm is an indication of the high energy requirements of the node. Right in the center of the node, the myelin end-loops are replaced by multiple fingerlike Schwann cell processes (nodal villi) that contain f-actin and are 70 to 100 nm in diameter. The villi extend from the Schwann cells into the nodal gaps and interdigitate with processes of adjacent Schwann cells (98). This interlacing pattern of cell processes around the axon at the node of Ranvier is more prominent and complex in larger fibers.

Basement membrane from the two adjacent Schwann cells is continuous over the nodal gap. Around the villous Schwann cell

processes, there is an electron-dense polyanionic-rich material that constitutes the extracellular matrix of the node. This gap substance creates a ringlike structure (ring of Nemiloff) and may provide an ion pool necessary for nodal function. It has been demonstrated that the gap substance contains glycosaminoglycans with cation binding substances (95).

The myelin sheath acts as a biological insulator for the internodal portion of the axons. Conduction of impulses along myelinated fibers proceeds in a discontinuous manner from node to node (saltatory conduction). Numerous sodium channels with a suggested density of approximately 100,000/Âµm^2 are present on the axolemma at the node of Ranvier in contrast to the very low density of sodium channels (less than 25/Âµm^2) in the internodal axon membrane; the internodal membrane may be regarded as inexcitable (3,98). Potassium channels show a complementary distribution to that of the sodium channels; they are less common than in the nodal membrane but are present in the paranodal and internodal axon membrane. Potassium channels contribute to the stabilization of the axon by preventing repetitive firing responses to a single stimulus and also help to maintain the resting potential of the myelinated fiber (98).

In demyelinating diseases, when the myelin sheath is stripped from the axon, there is gross slowing or cessation of nerve conduction along the affected fibers. Spread of a continuous wave of depolarization along the axon membrane is prevented due to the absence of an adequate density of sodium channels in the internodal axon membrane. Furthermore, the exposure of the internodal axon cell membrane, which is rich in potassium channels, will also interfere with induction of the impulse (15,98).

Unmyelinated Axons

Unmyelinated fibers can be detected as unstained structures by light microscopy in toluidine blueâ€“stained 0.5-Âµm transverse resin sections of peripheral nerve (Figure 10.5) (99). However, at 1 to 3

Âµm diameter, they are almost at the limit of resolution and are only seen in good quality sections. Such fibers can be stained by silver techniques, such as Palmgren's or Bodian's, but are poorly visualized in immunocytochemical preparations using antineurofilament antibodies (Figure 10.4), probably because unmyelinated fibers contain few neurofilaments and a high proportion of microtubules.

The structure of unmyelinated fibers and their quantitation are most adequately studied by transmission electron microscopy (Figure 10.10). They are more numerous than myelinated fibers in mixed peripheral nerves by a factor of 3 or 4:1 (25,54) and were first recognized in 1838 by the Polish physician Robert Remak as â€œfibriae organicaeâ€•; the Schwann cells associated with unmyelinated axons are sometimes referred to as Remak cells (54). Schwann cells

have the potential to differentiate into either a myelinating or nonmyelinating ensheathing cell, depending upon the signals received from the axons that they contact. Schwann cells must form basal laminae in order to myelinate axons (24,54). Schwann cells around myelinated and unmyelinated axons may thus be regarded as originating from the same cell type but developing morphological, biochemical, and physiological differences (106).

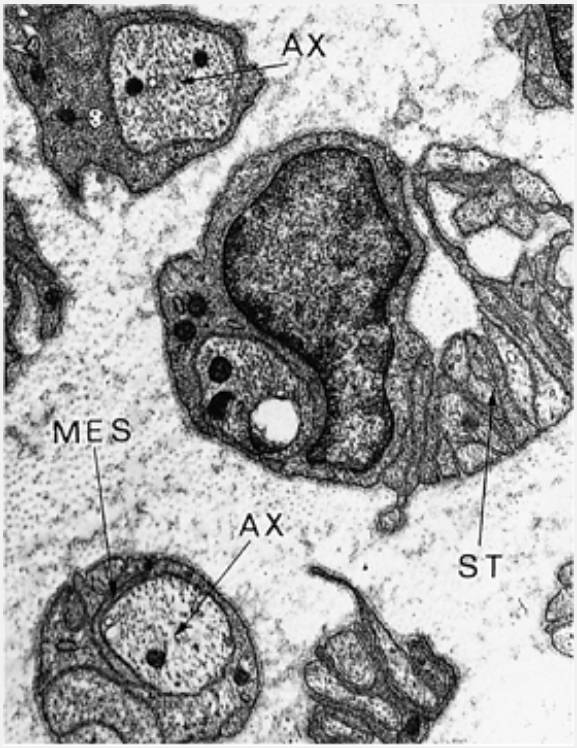

Figure 10.10 Unmyelinated axons (1.3 Âµm in diameter) cut in transverse section. The axons (*AX*) are surrounded by Schwann cells, Mesaxons (*MES*). Stacks of Schwann cell processes (*ST*) are commonly seen in adult nerves. (Electron micrograph, Ã—13,000.)

The cytoplasm of Schwann cells associated with unmyelinated fibers contains a Golgi apparatus, rough endoplasmic reticulum, mitochondria, microtubules, and microfilaments and may exhibit centrioles near the nucleus. Pi (Ï€) granules, however, are not present, although there are lysosomes containing acid phosphatase present in the cytoplasm (73). The nuclei of these cells are ellipsoid with one or more prominent nucleoli. A continuous basement membrane surrounds each cell (98). Schwann cells associated with unmyelinated fibers express different phenotypic characteristics from Schwann cells around myelinated axons. Although both types of

Schwann cell contain immunocytochemically detectable vimentin intermediate filaments and S-100 protein, and almost the same basement membrane components, Schwann cells associated with unmyelinated axons are more likely to express GFAP (101). Such cells also lack MAG, which is apparently necessary for segregation and myelination of axons. *Mycobacterium leprae* (Hansen's bacilli) colonize nonmyelinating Remak cells by attaching to laminin-2 and its receptor Î±-dystroglycan. Myelin-forming Schwann cells seem to be relatively free from infection by *M. leprae*. There is often a strong cell-mediated immune response with extensive inflammation and peripheral nerve damage that causes paralysis and loss of sensation and frequently leads to unintentional mutilation of hands and feet (102).

Electron microscopy of transverse sections of normal peripheral nerve show how numerous unmyelinated axons 0.2 to 3.5 Âµm in diameter are associated with a single Schwann cell. Short mesaxons extend from the surface of the cell (Figure 10.10), and the Schwann cell is separated from the axon plasma membrane by a space 10 to 15 nm wide that is analogous to the periaxonal space of Klebs seen around myelinated fibers. Although many axons may be gathered close to the cell body in the perinuclear region of the Schwann cell (24,54), away from the nuclear region, single axons become more widely separated and are enclosed by thin Schwann cell processes (Figures 10.3, 10.10). Each Schwann cell associated with unmyelinated axons in the sural nerve is between 200 and 500 Âµm in length. As axons pass from one Schwann cell to another, they are surrounded by flattened irregular, fingerlike processes that interlock and become telescoped into the adjacent Schwann cell. The surface of the axon is therefore always in contact with the Schwann cell. In young children, only a single thin layer of Schwann cytoplasm surrounds each axon away from the nuclear region; but the picture is more complex in adult nerves, with several Schwann cell processes stacked together and associated with each unmyelinated axon.

Pockets of collagen bundles are frequently invaginated into the

surface of Schwann cells associated with unmyelinated fibers (Figure 10.3), particularly in aging nerves and when there is loss of unmyelinated fibers. The pockets of collagen fibers are separated from the surface of the Schwann cell by a layer of basement membrane. The significance of this phenomenon is not fully known.

Endocrine cells have been identified within the perineurium in close contact with unmyelinated nerves in the lamina propria of the appendix (103). These cells were demonstrated in 1924 by Masson, and later AubÃ¶ck coined the term *endocrine cell-nonmyelinated fiber complex,* emphasizing the association between endocrine cells and unmyelinated fibers (104). These complexes are separated from the interstitial connective tissue by a common continuous basement membrane, leaving the cells in intimate contact with each other. It has been suggested that such endocrine cells could participate in the pathogenesis of the so-called neuromas of the appendix and appendiceal carcinoids (105,106). It is not known whether such endocrine cells exist in nerves other than those located in the wall of the appendix, but there are reports of extraepithelial carcinoid tumors in stomach, small intestine, and bronchus, which suggests that there may also be endocrine cells related to nerves in these regions (107).

Interesting immunological properties have been ascribed to Schwann cells. Numerous in vitro studies have shown that Schwann cells display a large repertoire of properties, ranging from the participation in antigen presentation, to secretion

of pro- and anti-inflammatory cytokines, chemokines, and neurotrophic factors (108). Schwann cells express Ia determinants on their membranes and are able to present foreign antigens to specific synergic T cells. When Schwann cells are exposed to inflammatory cytokines they have the capacity of inducing selective damage to T cells and have the potential of regulating the immune response in the peripheral nervous system (109). A role for Schwann cells has been suggested in myasthenia gravis (110).

Schwann cells also express complement receptor CR1 (CD35) and CD59, a 19 to 25 KDa glycoprotein that binds to complement proteins C8 and C9 in the assembling cytolytic membrane attack complex. This may indicate that regulation of complement activation by these proteins is important in neural host defense mechanisms and may be implicated in the complement-mediated damage occurring in inflammatory demyelinating diseases such as Guillain-BarrÃ© syndrome (111,112).

Correlation of Normal Histology with the Pathology of Peripheral Nerves

Handling and Preparation of Peripheral Nerve Biopsy and Autopsy Specimens

The sural nerve is the nerve that is most commonly biopsied in the investigation of peripheral neuropathies. It is a sensory nerve so that in some motor neuropathies it may be totally normal, in which case examination of small branches of motor nerves within a muscle biopsy may be more fruitful (48,54,54). At autopsy, a wider range of motor and sensory nerves may be sampled, depending on the clinical picture. Whether taken at biopsy or autopsy, peripheral nerves are very easily damaged. The myelin sheaths are semiliquid and may be crushed by indelicate handling (Figure 10.11). The specimen should be gripped at only one end and then gently dissected free before laying it, very gently stretched, on a piece of dry card and placing it in fixative or in liquid nitrogen for snap freezing. Fresh, frozen nerve should be used for enzyme and lipid histochemical studies whereas formalin-fixed nerve can be embedded in paraffin for the application of routine stains and immunocytochemistry (see Table 10.1). Although formalin-fixed material can be used for the preparation of 0.5- to 1-Âµm resin-embedded sections and for electron microscopy, ideally the tissue should be fixed in glutaraldehyde and postfixed in

osmium for ultrastructural studies. Teased fibers can be prepared from either glutaraldehyde- or formalin-fixed material (24,54).

The method of preparation really depends on the information sought. Frozen sections are ideal for detecting abnormal lipids, such as sulfatide in metachromatic leukodystrophy, and for detecting the cholesterol ester droplets of degenerating myelin by staining for Sudan red or oil red O. Increased lysosomal enzyme activity as in Krabbe's leukodystrophy or in human and experimental neuropathies in which axonal degeneration or segmental demyelination is suspected can be detected in frozen sections stained histochemically for acid phosphatase (54). Brief formalin or glutaraldehyde fixation can be used in some cases for electron microscopic enzyme histochemistry (54,113). Frozen sections can also be used for immunofluorescence for the detection of immunoglobulin binding to myelin sheaths in paraproteinemias. Transverse frozen sections of nerve are ideal for these purposes although they are often more difficult to prepare than longitudinal sections.

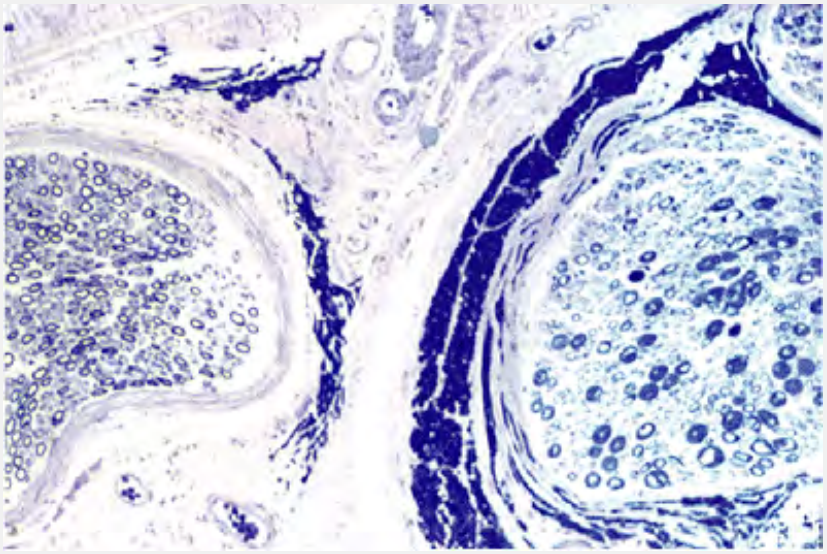

Figure 10.11 Histologic artifact in a peripheral nerve. In this transverse 1-Âµm resin section, the fascicle to the left of the picture is well-preserved. However, there is extensive recent

hemorrhage (*center*) that occurred during the biopsy procedure; the myelinated axons in the nerve fascicle are squeezed and distorted (*right*) (toluidine blue, Ã—40.)

There is a variety of methods of preparing and examining fixed specimens of peripheral nerve, and each method reveals different information (24,54). Ideally, exact transverse sections should be cut from the peripheral nerve; occasionally, longitudinal sections are also useful, particularly for detacting regenerating axons by immunocytochemistry (Figure 10.4F). Paraffin-embedded sections can be stained for a variety of histological stains and for immunocytochemistry to reveal nerve components (Table 10.1). Blood vessels and inflammatory exudates are ideally studied in paraffin sections, but quantitation of nerve fibers, the detection of axon degeneration and regeneration, and the assessment of segmental demyelination and remyelination are more satisfactory in 0.5- to 1-Âµm toluidine blueâ€“stained resin sections or by electron microscopy. The presence of amyloid in the endoneurium or giant axons in some hereditary neuropathies and in some toxic neuropathies can be detected both in paraffin- and in resin-embedded sections. Teased preparations are most useful for detecting segmental demyelination and remyelination and

for assessing whether axonal degeneration and regeneration have occurred within the nerve in the past (24,56).

Peripheral Neuropathies

The pathological diagnosis of a peripheral neuropathy usually requires close clinicopathologic correlation and knowledge of the electrophysiologic data, such as nerve conduction velocities and electromyography. Moderate slowing of nerve conduction velocities usually indicates loss of large myelinated fibers, whereas excessive slowing of conduction velocity suggests that segmental demyelination

has occurred. Although there are a number of specific histopathological features that aid in the diagnosis of peripheral neuropathy [e.g., amyloid, the presence of *M. leprae* bacilli, abnormal lipids such as sulfatide within the nerve, giant axons, and vasculitis (15,56)], for the most part, assessment of peripheral nerve pathology depends on detection and quantitation of general pathological features and good clinicopathological correlation.

General Pathology of Peripheral Nerves

The general pathological reactions of peripheral nerves are, for most practical purposes, limited to (a) axonal degeneration and regeneration and (b) segmental demyelination and remyelination. Hypertrophic changes with onion-bulb formation occur most commonly as a result of recurrent segmental demyelination and are most often seen in hereditary neuropathies.

Axonal Degeneration and Regeneration

If a neuron in the anterior horn of the gray matter of the spinal cord or in a dorsal root ganglion dies, its axon degenerates and no regeneration occurs. Such neuronal destruction is seen in poliomyelitis, motor neuron disease (amyotrophic lateral sclerosis), spinal muscular atrophy, and infarction of the spinal cord. Dorsal root ganglion cells may be lost in viral infections such as varicella zoster or in a variety of hereditary sensory neuropathies. If an axon in a peripheral nerve is injured, for example, by trauma, entrapment, or ischemia, the distal end of the axon degenerates and subsequently regeneration occurs from the proximal stump of the damaged axon (Figure 10.12). The success of the regeneration depends on the distance of the site of damage from the nerve end organ (either motor endplate or sensory nerve ending) and the amount of scarring or other obstruction laid in the path of the regenerating axons.

Axonal degeneration was described by Waller in 1850 in London and the eponym *wallerian degeneration* is still used. Much of the

fundamental work on nerve degeneration and regeneration, however, was performed by RamÃ³n y Cajal in the early part of the twentieth century. Twenty-four hours after nerve injury, most myelinated and nonmyelinated axons start to show degenerative changes. There is retraction of myelin from the nodes of Ranvier and dilatation of Schmidt-Lanterman incisures in the proximal as well as in the distal stump. By 48 hours, myelin and axon changes become more obvious as the axon disintegrates and myelin sheaths become disrupted and form globules (Figure 10.13) in which axon fragments are enclosed. Disintegration of the myelin appears to start with dilatation of the Schmidt-Lanterman incisures during the first day or two after injury (24,54). Myelin debris is initially birefringent and has a lamellated ultrastructure, as does normal myelin. But, as proteins break down and lysosomal enzymes become active around the myelin debris (54,113,114), cholesterol within the myelin is esterified to cholesterol esters, and lipid debris loses its birefringence in polarized light and its lamellated ultrastructure to become amorphous globular lipid, which now stains strongly with Sudan dyes and oil red O. The Marchi technique also differentiates between normal myelin and degenerating myelin (56).

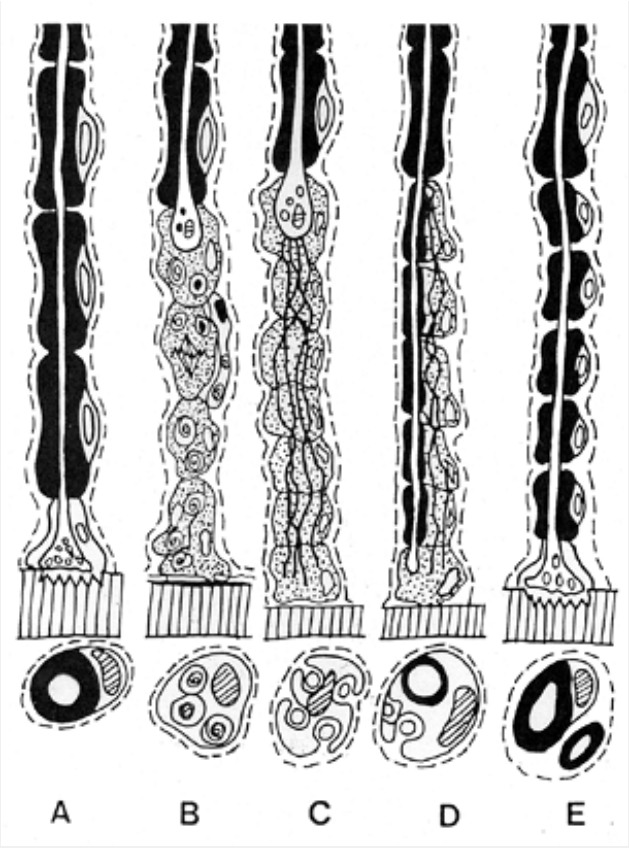

Figure 10.12 Diagram summarizing the events occurring during axonal degeneration and regeneration. A. Normal nerve. B. By seven days after axonal damage, Schwann cells containing axon and myelin debris have divided to form bands of BÃ¼ngner. C. Axon sprouts grow from the swollen end bulb of the proximal axon. D. An axon becomes myelinated. E. Connection with the end organ is reestablished; regenerated internodes are short. (Reprinted from:
Weller RO, Cervos-Navarro J. *Pathology of Peripheral Nerves: A Practical Approach*. London: Butterworths; 1977
with permission.)

During the second week after nerve injury, much of the myelin debris is removed from the distal part of the nerve, and regenerative

features become more prominent. Axon fragments and myelin debris are broken down by both

Schwann cells and macrophages (116). Schwann cells directly attract macrophages by secretion of different proteins, probably regulated by autocrine circuits involving the neuropoietic cytokines, IL-6, and leukemia inhibitory factor (113). Macrophages, in addition to their phagocytic function may help to promote nerve repair through the elaboration of Schwann cell mitogens and may also affect neurons and axonal growth directly through the release of neurotrophins (115,117,118,119).

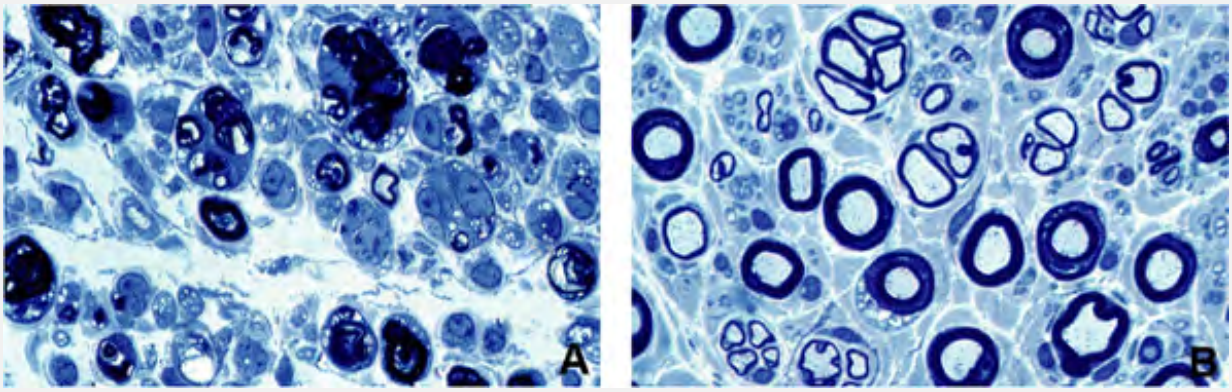

Figure 10.13 Axonal degeneration and regeneration in transverse sections of peripheral nerve. A. Axonal degeneration four days after nerve section. Few axons are visible and myelin is forming globules in Schwann cells and macrophages (1-Âµm section, toluidine blue, Ã—310). B. Axonal regeneration in a human nerve biopsy. Normal myelinated fibers are interspersed with clusters of closely associated thinly myelinated regenerating fibers (*top and bottom right*) (1-Âµm section, toluidine blue, Ã—310).

Although Schwann cell mitoses are seen as early as 24 hours after nerve injury, the peak of proliferation is between 3 and 15 days after nerve damage (120). As Schwann cells proliferate, they form columns (bands of BÃ¼ngner) surrounded by basement membrane (Figure 10.12); often redundant, old Schwann cell basement membrane is associated with these bands. Regenerating axons grow along the bands of BÃ¼ngner; and, if regeneration fails, the bands shrink and Schwann cells may disappear and become replaced by fibrous tissue (121).

â€œImportinsâ€• are proteins involved in the retrograde transport of substances collectively known as *injury signals*; such transport is through a complex of proteins acting in association with neurotubules and into the cell nucleus, where gene transcription subsequently occurs (122).

Several easily detectable histological changes occur during axonal regeneration The neuron cell bodies in the anterior horns of the spinal cord or in the dorsal root ganglia show changes of chromatolysis during the first three weeks after axonal injury (120). The nerve cell perikaryon swells by some 20%, and the nucleus becomes eccentric, as does the nucleolus. Nissl substance (a mixture of rough endoplasmic reticulum and polyribosomes) is dispersed so that the cytoplasm becomes pale when stained by H&E or by the Nissl stain (24,54). During this stage of chromatolysis, there is a marked increase in polyribosomal ribonucleic acid (RNA) with an upregulation of a number of regeneration-associated genes, including those encoding growth-associated protein-43 (GAP 43), cytoskeleton protein-23, and Î²-tubulin, and in peptides such as galanin and vasoactive intestinal polipeptide (VIP), reflecting the metabolic events involved in axon regeneration (122,123,124). Regenerative changes in axons are seen within the first few hours after nerve damage but are most easily detected 5 to 20 days after injury. Using immunocytochemistry, GAP 43 can be identified in regenerating axons 4 to 21 days after injury (125) (Figure 10.4F). The proximal stump of the axon swells to create a balloonlike structure, often 50

Âµm in diameter and 100 Âµm in length. The balloons are filled with organelles and fibrils, which can be detected by electron microscopy; they can be visualized by light microscopy using immunocytochemical stains for neurofilament protein, GAP 43, or silver stains such as were used by RamÃ³n y Cajal when he first described them. Myelin sheaths become stretched around the swollen axon balloons (114,126).

Starting around the fourth day after injury, multiple nerve sprouts, or neurites, extend from the axon balloon (growth cone) and grow distally at 1 to 2.5 mm/day. As the neurites enter the bands of BÃ¼ngner, they become invaginated into the surface of the Schwann cell and, if growth continues, they become myelinated. Unmyelinated fibers regenerate in a similar way, but they are smaller and no myelin sheaths form around them. Regenerating neurites can be detected in the classical way by silver staining; but, in cross sections of peripheral nerve, they are best demonstrated in 0.5- to 1-Âµm resin sections or by electron microscopy. Characteristically, regenerating axons form clusters encircled by a single basement membrane. In the light microscope, these clusters (Figure 10.13) are recognized by the close association of small, thinly myelinated axons within the nerve; myelinated nerve fibers in a normal

nerve are well-separated from each other by endoneurial collagen (Figure 10.5).

Axon growth and regeneration are stimulated by nerve growth factor that is synthesized by Schwann cells, fibroblasts, and macrophages and transported back along the axon by retrograde axoplasmic transport to stimulate nerve cell protein synthesis (60,126,127,128). In addition to growth factors, there appears to be topographical affinity between regenerating axons and certain pathways; for example, it appears that regenerating tibial nerve axons grow toward the distal tibial nerve rather than toward the distal peroneal nerves. Connective tissue elements may also play a role in guiding regenerating axons (10). Neurite outgrowthâ€“promoting factors on

cell surfaces (cell adhesion molecules) or in the extracellular matrix promote extension of the axon by providing an appropriate â€œadhesivnessâ€• in the substrate (129). Both neurotrophic and neurite outgrowthâ€“promoting factors are essential for axonal growth after injury (129).

The success of regeneration, with axons reaching effective end organs, may be influenced by several factors. If the injury is far proximal from the end organ, few regenerating axons may make effective reconnections. But, regeneration over short distances may be very effective in the peripheral nervous system. The presence of scar tissue or discontinuity of anatomical pathways may also inhibit regeneration. A number of grafting techniques are employed to overcome this problem (13,120). If regeneration to the distal stump of a nerve is blocked by scar tissue, axons may grow outside the original course of the nerve and even back alongside the proximal stump (terminals of Perroncito); thus, small bundles of regenerating neurites, often surrounded by perineurial cells, form amputation neuromas. Microscopically, there are interlacing bundles containing axons surrounded by myelin sheaths and with fine perineurial coverings. Immunocytochemistry for neurofilament proteins (axons), EMA, and Glut-1 (perineurial cells), and S-100 (Schwann cells) may be very useful in establishing the structure and identity of the nerve bundles in an amputation neuroma. Immunohistochemical and radioimmunoassay data have shown a focal accumulation of sodium channels within the tips of injured axons that may be responsible, in part, for the ectopic axonal excitability and the resulting abnormal sensory phenomena (pain and paresthesia) which frequently complicate peripheral nerve injury (130). Macropaghes migrate into the neuroma within the first two weeks after the injury, and later they are seen with numerous large cytoplasmic vacuoles filled with myelin fragments. This suggests that macrophages may also participate in the genesis of chronic pain after the neuroma has formed possibly by: (a) creating demyelinating axonal regions susceptible to external stimuli; (b) by releasing substances that

influence regeneration of axons; or (c) by direct action on the denuded remodelling membranes (131).

Axon degeneration, often with regeneration, is a feature of numerous peripheral neuropathies, including those associated with diabetes, amyloidosis, infections (such as leprosy), sarcoidosis, paraneoplastic syndromes, vascular disease, and metabolic diseases (24,54,132,133). Most toxic neuropathies (34,68) result in chronic axonal degeneration at the extreme distal ends of sensory and motor nerves (distal axonopathies). The distal ends of long tracts in the spinal cord (dorsal columns and corticospinal tracts) are often affected as well as the peripheral nerves. Timely withdrawal of the toxin may allow effective regeneration to occur, but only in the peripheral nerves, not in the spinal cord. Many peripheral neuropathies induced by the diseases itemized above are slowly progressive, so that nerve biopsies in these conditions do not usually reveal the early stages of axonal degeneration and regeneration. More frequently, the histological picture is characterized by loss of large myelinated axons and, to a lesser extent, loss of small myelinated and unmyelinated axons. Nerve root or peripheral nerve compression and trauma to peripheral nerve trunks result in axonal degeneration. Regeneration may be recognized in transverse sections of peripheral nerve by the presence of clusters (Figure 10.13). In teased fiber preparations, short internodes in the distal part of the nerve indicate that axonal degeneration and regeneration have occurred in the past (121).

Segmental Demyelination and Remyelination

When demyelination occurs in peripheral nerves, it has a segmental distribution with each segment representing the internodal portion of an axon myelinated by one Schwann cell (Figures 10.7, 10.14). Such segments can be contiguous, and thus demyelination may occur over long lengths of the nerve or in short sporadic segments (55,118).

The axon remains intact except in severe demyelinating neuropathies in which secondary axonal degeneration occurs. Remyelination is often rapid and effective, with restoration of nerve function. Demyelination may occur as a result of direct interference with Schwann cell metabolism, as in diphtheria; myelin sheaths are broken down through the lysosomal action of Schwann cells, although macrophages are later involved in the destruction of myelin debris (116,120). Another mechanism that is seen in the commonest acute demyelinating neuropathy, Guillain-BarrÃ© syndrome, in which there is an immunological attack on peripheral nerve myelin by lymphocytes and macrophages; segmental demyelination occurs and is followed by remyelination (Figures 10.14, 10.15). Functional recovery occurs following both types of demyelination except in the most severe cases (134).

The first stages of segmental demyelination are seen at the node of Ranvier, where the nodal gap becomes widened; subsequently, the whole internode of myelin may be broken down (135). This destruction results in severe slowing of conduction of nerve impulses across the demyelinated segment and the onset of symptoms for the patient. Preserved axons remain invaginated within Schwann cells as the

myelin sheaths are broken down (Figures 10.15 and, 10.16). Schwann cells proliferate and within a few days start to remyelinate the demyelinated axons by a similar mechanism to that seen during myelination in the fetus. Remyelination may be well advanced by two weeks after demyelination as the thickness of myelin sheaths increases and conduction velocities return to normal.

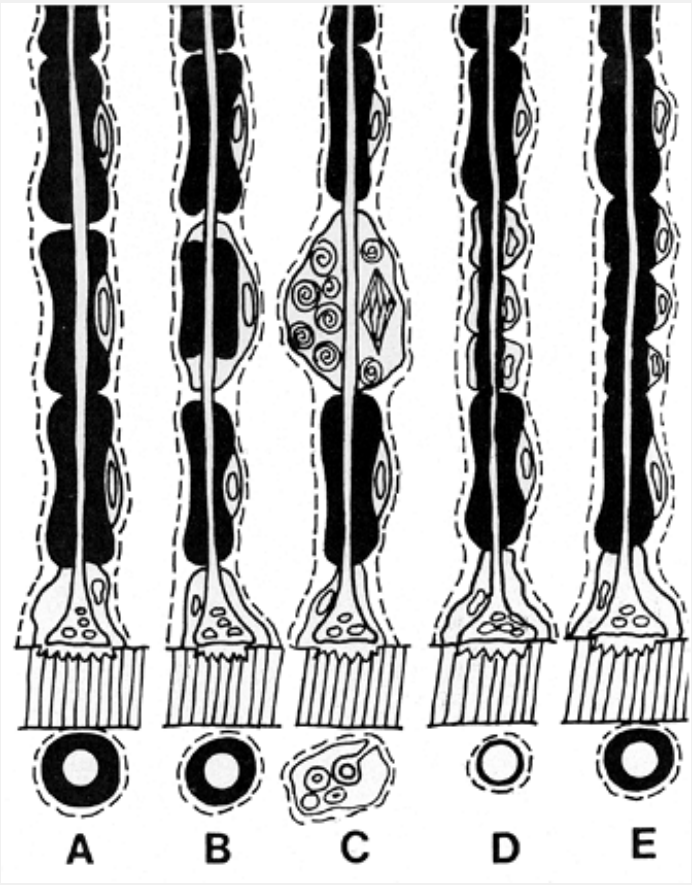

Figure 10.14 Summary of the events occurring in primary segmental demyelination and remyelination. A. Normal nerve. B. Early segmental demyelination; retraction of paranodal myelin with widening of the nodal gap. C. Destruction of myelin sheath and Schwann cell mitosis. D. and E. Remyelination; intercalated short segments. (Reprinted from:
Weller RO, Cervos-Navarro J. *Pathology of Peripheral Nerves: A Practical Approach*. London: Butterworths; 1977
with permission.)

Classically, segmental demyelination can be detected in teased nerve fibers, first by the presence of widening of the gap of the node of Ranvier and then by the presence of axons devoid of myelin sheaths.

Intercalated thin myelin sheaths along the axon are seen as remyelination proceeds (Figure 10.15). In electron micrographs or in resin-embedded light microscope sections, naked axons can be recognized in transverse section and remyelinating fibers detected by the presence of inappropriately thin myelin sheaths (Figures 10.12,10.13,10.14). Segmental demyelination is a feature of a number of peripheral neuropathies (132,133), particularly mild vascular damage to peripheral nerves as in rheumatoid arthritis (136), diabetes (24), Guillain-BarrÃ© syndrome, occasional toxic neuropathies (131), and metabolic neuropathies such as metachromatic leukodystrophy (15,56) (Figure 10.15). Throughout the range of neuropathies, however, segmental demyelination is less common than axonal degeneration.

Hypertrophic Neuropathy

Recurrent segmental demyelination is a feature of a number of chronic hereditary neuropathies, particularly Charcot-Marie-Tooth (CMT) disease, DÃ©jÃ©rine-Sottas disease (hereditary motor and sensory neuropathy types I and III), and Refsum's disease (138,139). In such diseases, repeated segmental demyelination appears to be responsible for a florid proliferation of Schwann cells and the formation of onion-bulb whorls (139,140) (Figures 10.14, 10.15), giving a distinctive histological picture of hypertrophic neuropathy to these peripheral neuropathies. So far, at least 16 genetic loci and 9 caustive genes have been identified for primary heritable demyelinating neuropathies (HDN); therefore, although histopathological analysis is still important for the diagnosis of HDN, it is gradually being replaced by molecular diagnosis (139,141).

Traumatic Lesions of Peripheral Nerve

An understanding of the structure and staining reactions of normal peripheral nerve is essential for unraveling the complexities of traumatic lesions of nerve. Identification of cell types, recognition of

patterns of organization, and the detection of normal elements within a traumatic lesion allow a more confident diagnosis and description to be formulated.

Amputation neuromas may develop as painful swellings at the distal ends of amputated limbs or at sites of nerve damage without amputation. They consist of disoriented bundles of axons surrounded by Schwann cells and divided into compartments by perineurial cells. In H&Eâ€“stained paraffin sections, the tubular formation of the perineurial compartments can be recognized (56). By immunocytochemistry, axons can be stained with antibodies to neurofilament protein and GAP 43; the Schwann cells associated with them contain S-100 protein, and the perineurial cells are EMA-, Glut-1â€“, and claudin-1â€“positive but do not contain S-100 protein (142). Silver stains can also be used to identify the twisted and disoriented axons. The histological picture reflects the processes seen in the normal regeneration of peripheral nerve; but in amputation neuromas, appropriate regeneration along the distal part of the nerve is prevented.

In 1876, Thomas G. Morton, from Pennsylvania, described a neuroma that involves the plantar interdigital nerves, almost always between the third and the forth toes (Morton's metatarsalgia), and consists of small painful swellings on the nerves. Histologically, there is fibrosis and edema of the endoneurium and perineurium and the accumulation of mucosubstances similar to endoneurial glycosaminoglycans. The detection of axons and Schwann cells by immunohistochemistry is often a useful adjunct to the diagnosis of this lesion (142).

A pseudocyst or nerve sheath ganglion, containing mucinous material that stains with Alcian blue, may form on a

peripheral nerve, generally at a site of repeated trauma. Although the fibrous capsule of the cyst and its mucinous contents may dominate the picture, damaged nerve components can usually be

detected adjacent to the cyst (142).

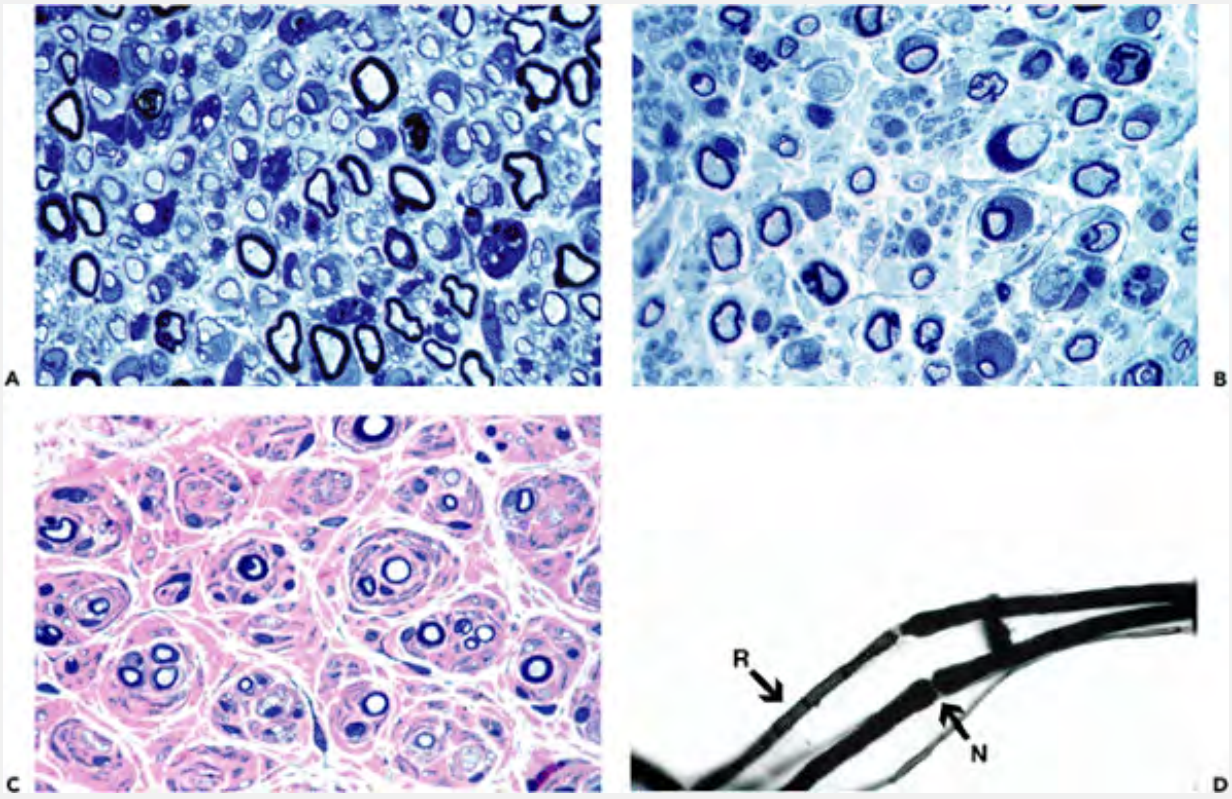

Figure 10.15 Segmental demyelination and remyelination. A. Transverse section of peripheral nerve showing early remyelination in an experimental animal. There are normal, large myelinated fibers with axons 8 to 10 Âµm in diameter and axons 3 to 5 Âµm in diameter, which have thin myelin sheaths and are remyelinating. Myelin debris is seen in Schwann cells and macrophages (1-Âµm resin section, toluidine blue, Ã—310). B. Nerve biopsy from a child with metachromatic leukodystrophy (sulfatide lipidosis). Large axons with either thin myelin sheaths (remyelination) or with no myelin sheath at all (demyelinated) (*right of center*) are seen in the biopsy. Unmyelinated fibers (*center*) are unaffected (1-Âµm resin section, toluidine blue, Ã—310). (Reprinted from
Ahmed AM, Weller RO. The blood-nerve barrier and reconstitution

of the perineurium following nerve grafting. *Neuropathol Appl Neurobiol* 1979;5:469â€“483
with permission.) C. Hypertrophic neuropathy (Charcot-Marie-Tooth disease-HSMN type I). Demyelinated and remyelinated axons are seen at the centers of onion-bulb whorls formed by Schwann cell processes; there is abundant endoneurial collagen (pink) (1-um resin section, toluidine blue and carbol fuchsin, Ã—240). D. Teased fibers. Normal fiber (*lower*) with a normal node of Ranvier (*N*). The fiber above has a thin, remyelinating segment (*R*) on one side of the node and a normal segment on the other side (osmium stain, Ã—200). (Reprinted from: Weller RO. *Colour Atlas of Neuropathology*. Oxford: Oxford University Press and Harvey Miller; 1984
with permission.)

Compressive lesions of peripheral nerves have resulted in some debate regarding their origin. Because of the resemblance of whorls within these lesions to those seen in hypertrophic neuropathies, they have been labeled *localized hypertrophic neuropathy* (36). Such lesions usually occur at sites of compression over the fibula or on the posterior interosseous nerve (137), although some lesions present with no obvious nerve compression. Although there is well-marked onion-bulb formation, ultrastructural studies have shown that the onion bulbs are formed not by Schwann cells, as in hypertrophic neuropathies, but by perineurial cells (141,143). Such compressive lesions should not be confused with perineuromas in which immunocytochemistry has confirmed that the cell whorls are formed by EMA-, Glut-1â€“, and claudin-1â€“positive perineurial cells (40,143), and there are abnormalities of chromosome 22. (143,144).

In 1972, Reed described a small (1â€“15 mm), typically solitary neuroma that presents in adults and affects the face,

with no clinical manifestations of neurofibromatosis or MEN-IIb

(multiple endocrine neoplasia). This lesion is known as solitary circumscribed neuroma (SCN) (palisaded encapsulated neuroma) and is currently viewed as a form of true neuroma. Histologically, SCN appears as one or more circumscribed nodules in the dermis, sometimes partially encapsulated by a delicate compact EMA-positive perineurial layer. The process consists of a solid proliferation of tightly interwoven fascicles of Schwann cells, sometimes separated by narrow gaps that create a characteristic appearance of the lesion at low magnification. The Schwann cells are often arranged as palisades, and there may be numerous axons scattered troughout the lesion, which are best demonstrated with Bodian's silver stain or by immunohistochemistry for neurofilament proteins (145).

Figure 10.16 Demyelination. A large diameter axon (*top*) is

demyelinated and devoid of a myelin sheath. A small onion-bulb whorl has formed around this axon with the encirclement by Schwann cell processes (*S*), one of which contains an unmyelinated fiber (*UM*). Thickly myelinated fibers are seen at the bottom of the picture. (Electron micrograph,Ã—6,600.)

Tumors of the Peripheral Nervous System

A variety of cells and structures may be identified in tumors of the peripheral nervous system; they include perineurial cells, Schwann cells, axons, and neurons (142,146,147). The diagnosis frequently depends on the histologic analysis of the tumor and thus the detection of cellular components forming the tumor and their relationship with normal nerve structures (142).

Perineurioma is a rare true perineurial neoplasm (135). Perineuriomas can arise in a wide variety of sites and may exhibit different histological patterns with extra and intraneural forms (29,148). Histologically, *intraneural perineuriomas* affect individual fascicles with concentric proliferation of spindle cells around nerve fibers in the endoneurium; extraneural (soft tissue) perineuriomas show paucicellular to cellular forms (with some cases showing dense collagenizationâ€“*sclerosing perineurioma*) with proliferation of spindle cells with extremely thin and elongated profile resembling normal perineurial cells (148). The key diagnostic finding is that the proliferation cells are labeled with EMA, Glut-1 and claudin1 but fail to stain for S-100 protein, neurofilaments, and CD34 (39,40,41,142). Perineuromas may be closely related to cutaneous meningioma since shared histologic features, and positive staining for vimentin and EMA in both conditions, suggest close similarities between these lesions (41).

Schwannomas are tumors of peripheral nerves composed almost

entirely of Schwann cells (28,142,146). Neoplastic Schwann cells may produce and respond to trophic factors, particularly to the growth factorâ€“like polypeptides known as neuregulins, in an autocrine and/or paracrine fashion to promote proliferation. In fact the presence of neuregulins in certain schwannomas has been demonstrated by immunohistochemistry (149).

Histologically, schwannomas show the classical patterns of spindle cells in a compact (Antoni type A) or loose (Antoni type B) arrangement. Neoplastic Schwann cells may exhibit different morphologies (Figure 10.17) (142,146,150,151,152). Occasionally, the Schwann cells have an epithelioid appearance (epithelioid schwannomas) (152), are surrounded by an abundant myxoid stroma (nerve sheath myxoma) (153), have a high nuclear-cytoplasmic ratio (cellular schwannoma), exhibit a plexiform pattern (plexiform schwannoma), contain copious melanin (melanotic schwannoma) or exhibit xanthomatous change with many foamy cells containing oil red Oâ€“positive neutral lipid (142,146,154). Schwannomas usually grow on the sides of

nerves and do not infiltrate nerve bundles (54). Thus, normal nerves may be seen within the fibrous capsule that is usually present around schwannomas.

Figure 10.17 Panel showing the different morphology that the Schwann cells may present in schwannomas. A. Benign schwannoma, showing the typical biphasic appearance. B. Benign schwannoma with Verocay bodies. C. Reticulin (Gordon-Sweet) stain in a benign schwannoma, showing the positive basement membrane. D. Cellular schwannoma with uniform fascicular growth pattern. E. Granular cell schwannoma. Note the granular cells are originating from a nerve fascicle (*N*) (anti-S-100 protein). (Photograph supplied by Dr. Javier Baquera.) F. Melanotic schwannoma. G. Nerve sheath myxoma. H. Malignant peripheral nerve sheath tumor (malignant triton tumor) with rhabdomyoblastic differentiation (*arrowheads*).

Histologically, the tumor cells have elongated nuclei and long eosinophilic processes, often forming palisades first described by the Uruguayan-born pathologist JosÃ© Verocay and known today as Verocay bodies (155). The palisades are parallel arrays of tumor nuclei separated by the eosinophilic, periodic acid-Schiff (PAS)â€“positive processes of Schwann cells. The basement membrane investing each Schwann cell in the tumor is well-demonstrated by electron microscopy but can also be demonstrated in reticulin stains by light microscopy (54,142). Collagen bundles within schwannomas may have a distinctive long spaced appearance (Luse bodies) (156). Immunocytochemistry shows the presence of S-100 protein, CD57 (Leu-7), CD56, and calretinin in schwannoma cells, but they are negative for EMA (37,38,157). Some schwannomas associated with the spinal cord and those deep in the body or close to major joints stain by immunocytochemistry for GFAP, while the superficial, subcutaneous schwannomas are negative (158). Schwann cells associated with unmyelinated fibers are more likely to express GFAP, and it has been proposed that the GFAP-positive schwannomas may arise from unmyelinated nerves (158).

Melanin may be seen in schwannomas; and, by electron microscopy,

premelanosomes and melanosomes may be identified (142,145). Such structures emphasize the common origin of Schwann cells and melanocytes from the neural crest (159,160). There are two types of melanotic schwannomas.The *conventional type* is composed of plump spindle and epithelioid cells arranged in whorls and streaming fascicles containing melanin pigment. *Psammomatous melanotic schwannomas* are mainly in autonomic/visceral locations with the same cell arrangement as melanotic schwannomas but with the additional feature of PAS-positive, von Kossa-positive, mineralized, laminated calcospherites (161). Approximately 50% of patients with psammomatous melanotic schwannomas may have evidence of Carney's syndrome, which includes primary pigmented nodular adrenocortical disease; pituitary-independent, primary adrenal form of hypercortisolism; lentigines; ephelides and blue nevi of the skin and mucosae; and a variety of nonendocrine and endocrine tumors, such as myxomas, pituitary adenomas, testicular Sertoli cell tumor, and other benign and malignant neoplasms (including tumors of thyroid and ductal adenomas of the breast) (161).

Granular cell tumor (GCT, or Abrikosoff tumor) is not a specific entity. Granular cytoplasmic change is the expression of a metabolic alteration occurring often, but not exclusively, in Schwann cells (162). The tumor cells have abundant granular cytoplasm and a small eccentric nucleus; they invade small nerve branches in the skin. Immunocytochemical studies have shown that the tumor cells express S-100 protein, CD57, CD68, neurospecific enolase (NSE), Protein Gene Product PGP9.5, and also occasionally myelin (P0 and P2) and myelin-associated proteins (28,163). Expression of calretinin has been demonstrated in GCT. As this calcium-binding protein is typically expressed in neurons, ganglion cells, and Schwann cells, GTC expression may further support a neuronal origin or differentiation of these tumors (157). Interestingly, calretinin positivity may be increased in the pseudoepitheliomatous hyperplasia of the squamous epithelium overlying the tumor cells seen in some cases of GCT, which may indicate a role of calretinin in the

interaction between GCT cells and hyperplastic epithelium (157). Granular cells have also been described in nerves undergoing wallerian degeneration (162).

Neurofibromas are complex benign lesions frequently associated with neurofibromatosis (147). As distinct from schwannomas, neurofibromas are diffuse lesions in the skin or around peripheral nerves that invade the peripheral nerve endoneurium and enlarge nerve branches (54,142,147). They also diffusely invade surrounding tissues and may cause bone destruction. Histologically, neurofibromas are as a rule not encapsulated, and they contain a variety of cells that are associated with peripheral nerves; unlike schwannomas, neurofibromas are not predominantly composed of Schwann cells. Mast cells are frequently seen in the stroma and can be identified using toluidine blue or Giemsa or by anti-triptase, CD117, and calretinin immunohistochemistry (51,52,152). Mast cells induce factor XIIIa-positive fibroblast-like cells to synthesize the large amount of extracellular matrix in neurofibromas, and mast cells are one of the inflammatory cell types involved in tumor promotion (52,164,165,166). It has been hypothesized that when mast cells are lost, as seen in cases of malignant peripheral nerve sheath tumors, there may be a diminution of the anti-cancer effect of mast cells in maintaining the benign nature of some of these proliferations (51,52). By immunocytochemistry, S-100- and CD57 (Leu-7)-positive Schwann cells can be detected within neurofibromas, in addition to EMA-, Glut-1â€“, and claudin-1â€“positive perineurial cells and CD34 endoneurial fibroblasts (37,38). Entrapped axons can be seen coursing through neurofibromas in immunocytochemical preparations for neurofilament protein or in silver-stained sections. All of these cellular components are set in a variable fibromyxoid stroma that in some cases may be so prominent (the myxoid part) that it may be mistaken for a myxoma or myxoid liposarcoma. Distorted structures resembling Wagner-Meissner or pacinian corpuscles are some times seen (pacinian neurofibromas), and melanin may be found in pigmented neurofibromas (167).

Neurofibromatosis is an autosomal dominant disease that is part of the group of neurocutaneous disorders collectively known as phacomatoses (137,142,168). It presents as two major diseases, peripheral (type 1, or von Recklinghausen's disease; NF1) and central (type 2; NF2) (163). Both type 1 and type 2 are inherited as autosomal dominant traits, but many cases are new mutations. Over 90% of cases

of neurofibromatosis are type 1 (peripheral); a gene defect has been located on the long arm of chromosome 17 (17q11.2; *NF1* gene) near the centromere and has been linked to the locus encoding nerve growth factor (147,168). There is an increase in nerve growth factor in the serum of patients with this disorder (169). The *NF1* suppresor gene, which spands over 350 kb of genomic DNA and contains 60 exons, encodes a ubiquitous protein known as neurofibromin. This 2818 amino acid protein has been shown to be associated with cytoplasmic microtubules and functions as a GTPase-activating protein for *ras* (170,171).

A wide variety of disorders occur in patients with NF1, including elephantiasis neuromatosa, in which there are redundant folds of skin associated with plexiform neurofibromas (24,162,168,170,171) and, more commonly, multiple cutaneous neurofibromata. Other tumors, such as gliomas, carcinoid tumors, pheochromocytomas, neuroblastomas, gastrointestinal stromal tumors, Wilms' tumors, and pigmented hamartomas of the iris (Lisch nodules), are also seen in patients with this disorder (142,167).

Central, or type 2, neurofibromatosis is much less common than NF1 and is characterized by bilateral vestibular schwannomas; skin lesions are uncommon. Approximately 40% of the vestibular schwannomas in NF2 tend to have a lobular grapelike pattern, while this arrangement is extremely uncommon in sporadic schwannomas (169,172). A proportion of these patients have multiple tumors, including meningiomas, intramedullary spinal ependymomas, and glial microhamartomas of the cerebral cortex (169,170). A gene

deletion on chromosome 22q12 (*NF2* gene) was identified in 1993 in patients with this disorder, and it is associated with abnormalities of glial growth factor and nerve growth factor activity (169). The *NF2* gene spans 110 kb and encodes a membrane-cytoskeleton linking protein that is a member of the protein 4.1 family, known as merlin, (for *m*oezin-*e*zrin-*r*adixin-*l*ike prote*i**n*). Merlin, also known as schwannomin, may be detected immunohistochemically in the cytoplasm of many cells, including Schwann cells, and it is believed to act as a tumor suppressor gene, the loss of function of which is a fundamental event in the genesis of schwannomas (172,173,174). Normal Schwann cells express merlin, which is known to play a crucial role in cytoskeleton-associated events. Since merlin is a tumor suppressor gene, and all schwannomas lack merlin, it is proposed that the mutation of *NF2* may cause tumor formation through disruption of cell shape, cell matrix, and cell-cell communication or signaling functions, attributed to actin-cytoskeleton-plasma membrane interaction (173,174). Sporadic schwannomas from non-*NF2* individuals also have *NF2* mutations (175).

Neuronal tumors such as ganglioneuromas occur in association with autonomic ganglia in the peripheral nervous system. Histologically, neurons can be identified within these tumors; axons and Schwann cells may be identified by immunocytochemistry. Electron microscopy reveals the presence of 100-nm dense-core vesicles resembling catecholamine granules in the neurons. In addition to well-differentiated ganglioneuromas, primitive neuroectodermal tumors such as neuroblastoma and ganglioneuroblastomas arise within the abdomen and thorax (172). Cell types within the more primitive tumors may be difficult to identify by immunocytochemistry, but electron microscopy usually reveals the presence of 100-nm dense-core catecholamine vesicles within the tumor cell cytoplasm (142,176).

Malignant peripheral nerve sheath tumors (MPNST, or malignant schwannomas) (142) are derived from specialized cells of the

endoneurium and perineurium and show great histological variation and many similarities to other soft tissue tumors (28,142). The term *MPNST* incorporates previously used terms such as neurofibrosarcoma and malignant schwannoma. Mutation in the *NF1* tumor suppressor gene is the most important molecular genetic event in the development of MPNST (177). Malignant change in a benign scwhannoma is an extremely rare event (142); however, two forms of neurofibroma, plexiform and localized intraneural neurofibroma, are significant precursors of MPNST (178). Immunocytochemistry has demonstrated EMA-, S-100â€“, and CD57-positive cells in MPNST (154,177), and occasional tumors that are EMA-positive and S-100â€“negative have been described as MPNST with perineurial cell differentiation (179). This suggests that cells of MPNST may produce proteins characteristic of perineurial cells or of both perineurium and Schwann cells. Neurospecific enolase, neurofilament protein, and myelin-basic protein have also been occasionally identified in MPNST (17,180). Heterogeneity is common, and so histological sampling should include wide areas of tumor (142,181). Unusual elements (such as cartilage, bone, squamous elements, and muscle) may be encountered occasionally. Malignant peripheral nerve sheath tumors may also present with malignant glands (glandular malignant schwannoma) or rhabdomyosarcoma, features that may be highlighted by immunocytochemistry for cytokeratins and desmin, respectively. In an attempt to explain the occurrence of malignant muscle differentiation (rhabdomyosarcoma) in malignant schwannomas, Pierre Masson suggested that endoneurial cells might differentiate into muscle cells under the inductive influence of nerve cells, a situation that was thought to be operative in regenerating limbs in triton salamanders, hence the name *triton tumor* (malignant schwannoma with rhabdomyoblastic differentiation) (182).

Central Nervous System

Gregory N. Fuller
Peter C. Burger

Introduction

The central nervous system (CNS) is unparalleled among natural systems in terms of structural and functional complexity. As a consequence of its intricate regional architecture, heterogeneous cellular constituents, and an associated extensive and somewhat arcane lexicon, the nervous system is often viewed as a formidably Byzantine realm by many nonneuropathologists; and yet, a working familiarity with the normal morphology of this complex organ must precede optimal evaluation of the many disease states that afflict it. To this end, this chapter will present the salient features of regional neuroanatomy followed by a description of the essentials of microscopic anatomy of the CNS, with special emphasis on those aspects that constitute potential diagnostic pitfalls, including normal anatomic variations, alterations associated with advancing age, reactive changes, and common artifacts.

Regional Neuroanatomy

We have limited this discussion of regional neuroanatomy to those

principles of structural organization that are of practical value to the diagnostician, emphasizing the rudiments of neuroembryology by which the basic organization

of the nervous system is best understood. Further details about topographical neuroanatomy can be found in the list of suggested readings provided at the end of the chapter.

Organization of the Spinal Cord and Brainstem

Embryologically, the nascent CNS is a hollow tube formed by the invagination of the neural plate ectoderm. This primitive cylinder is subdivided functionally into a dorsal sensory (alar) plate and a ventral motor (basal) plate. The two are separated by a lateral groove, termed the sulcus limitans, along which develops the efferent autonomic system (Figure 11.1). This primitive organizational pattern is retained, essentially unaltered, in the mature spinal cord. The central gray matter consists of: (a) dorsal horns that receive sensory input from the dorsal roots; (b) ventral horns that contain motor neurons whose axons are conducted to the somatic periphery by the ventral roots; and (c) the lateral autonomic gray matter. Spinal autonomic neurons are confined to thoracic (sympathetic) and sacral (parasympathetic) levels, forming the intermediolateral cell columns. The axons of these preganglionic neurons exit the spinal cord through the ventral roots, ultimately to synapse on postganglionic neurons in the peripheral autonomic ganglia. The sympathetic intermediolateral cell column produces a third horn of gray matter in the thoracic cord, termed the lateral horn (Figures 11.1,11.2). The parasympathetic intermediolateral cell column occupies a similar lateral position in the sacral cord (at the S2, S3, and S4 levels) but does not form a distinct horn.

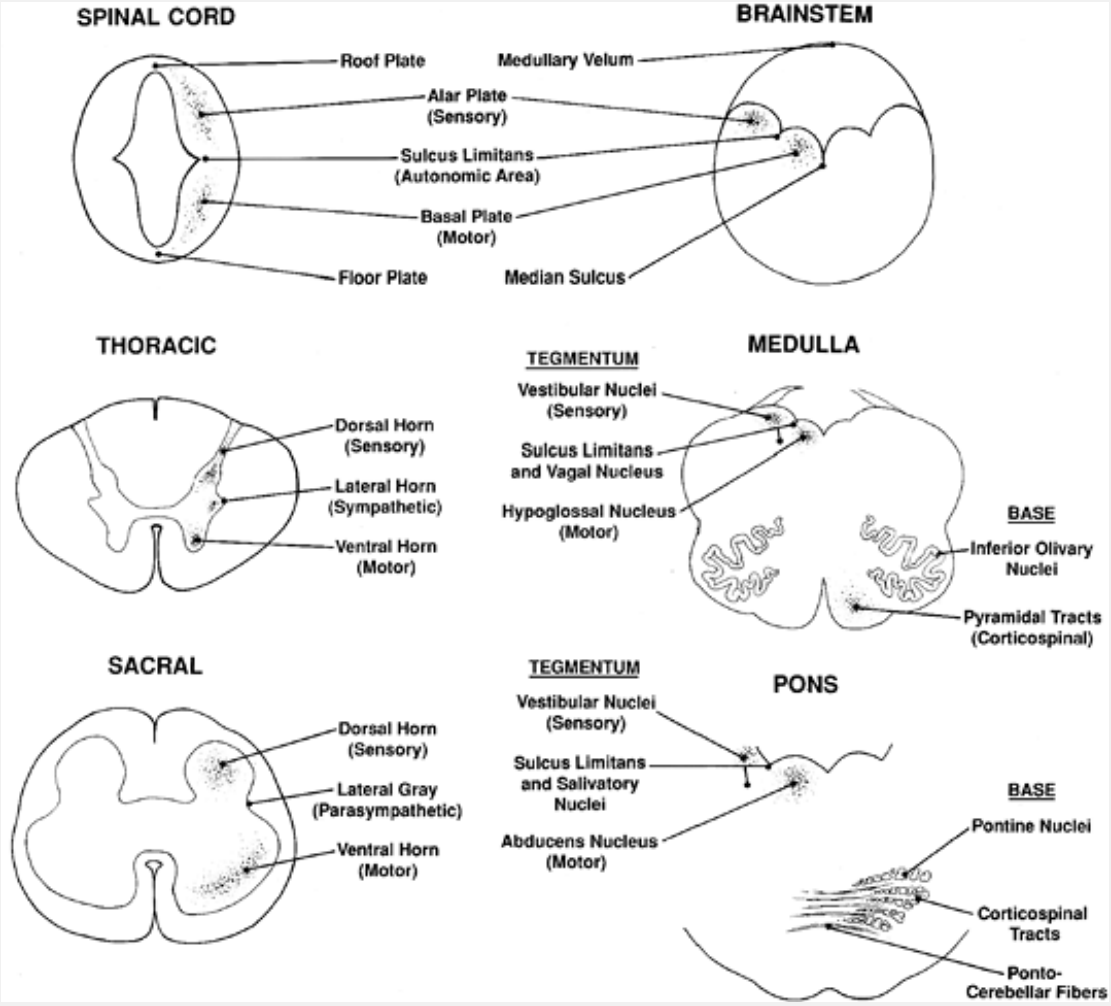

Figure 11.1 Structural organization of the spinal cord and brainstem. (See text for discussion.)

Spinal Cord

The anatomy of the spinal cord varies according to the level (Figure 11.2). Two enlargements of the ventral horns, one in the cervical region (Figure 11.2A) and another in the lumbosacral region (Figure 11.2C), provide motor innervation for the upper extremities and lower extremities, respectively. In contrast, the ventral horns of the

thoracic cord provide innervation for the more limited axial musculature of the trunk and are, accordingly, much smaller (Figure 11.2B). As mentioned earlier, the lateral horns of the gray matter (sympathetic neurons) are a unique feature of the thoracic cord. The thickness of the surrounding white matter fiber bundles (termed funiculi) also varies with cord level, being greatest in the cervical cord, where the thickness reflects the summated accrual of ascending fiber tracts that have successively entered at lower levels, as well as the maximum content of descending tracts that are en route to lower levels, and thinnest in the lumbosacral cord. The terminus of the spinal cord, the filum terminale, is composed primarily of meningeal connective tissue in the human and is discussed separately with the pia-arachnoid (Figure 11.56).

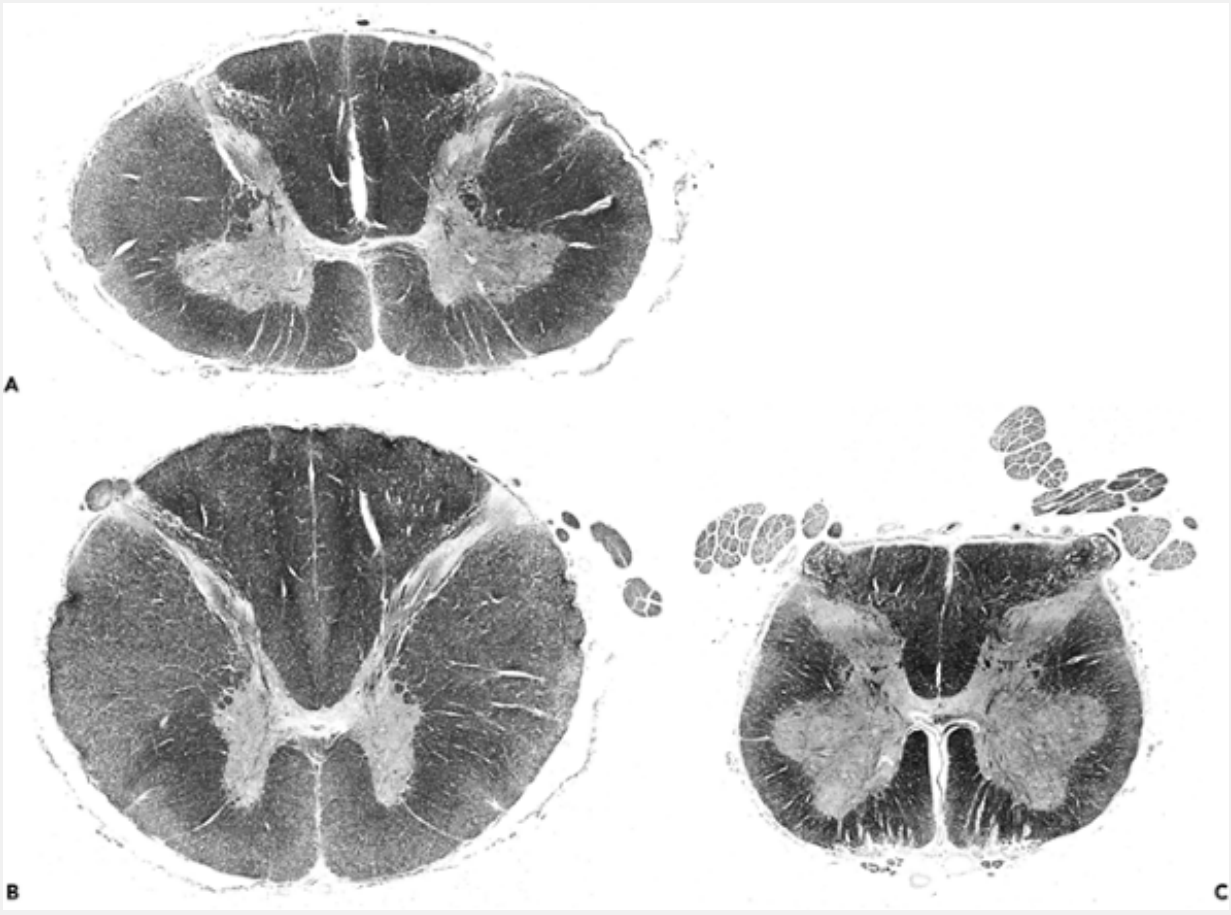

Figure 11.2 Spinal cord: regional variation of spinal cord structure is illustrated in these cross sections taken from the cervical enlargement (A), midthoracic cord (B), and lumbosacral enlargement (C). The cervical enlargement (A) is typified by an oval shape with large white matter funiculi and prominent, broad anterior gray horns that contain the motor neurons that innervate the upper extremities. In contrast, sections from thoracic cord (B) have a more rounded profile and exhibit small, slender, peglike anterior gray horns. In addition, lateral horns, which house the intermediolateral cell column neurons of the sympathetic nervous system, are unique to thoracic segments (see Figure 11.1). The lumbosacral cord (C) has very large anterior gray horns (motor supply to the lower extremities) like those of the cervical enlargement but only a very small surrounding mantle of white matter (see Figure 11.1).

Brainstem

The brainstem is innately more complex than the spinal cord, but its basic organization is readily understood when viewed as a slightly modified version of the basic plan. Thus, the stem is also a neural tube but one that has been stretched dorsally and splayed out laterally so that the ventrally located embryonic motor plate is now medial and the dorsal sensory plate is lateral (Figure 11.1). Therefore, within the brainstem, the cranial nerve motor nuclei are located medially, the sensory nuclei laterally, and the autonomic nuclei are intermediate in position.

The brainstem can be further subcategorized in cross section into tectum, tegmentum, and base. The tectum is the roof of the ventricular system, as exemplified by the superior and inferior colliculi (corpora quadrigemina) of the midbrain and the superior medullary vela of the pons and medulla. The tegmentum forms the

floor of the cerebral aqueduct and fourth ventricle and is divisible into the medial motor and lateral sensory areas discussed previously (Figure 11.1). The â€œbaseâ€• is located subjacent to the tegmentum and is the most ventral portion of the stem. It is composed principally of the so-called long tractsâ€”that is, the descending motor pathways and ascending sensory pathways that link the spinal cord with higher neural centers. The combination of long tract signs with dysfunction of specific cranial nerves allows the precise anatomic localization of brainstem lesions by clinical examination.

Cerebellum

Embryologically, the cerebellum arises as a dorsal outgrowth of the fetal brainstem and remains connected to it in the adult by the three pairs of cerebellar peduncles: the superior (brachium conjunctivum), middle (brachium pontis), and inferior (restiform body). They join with the midbrain, pons, and medulla, respectively. The cerebellum is composed of three structural and functional compartments: cortex, medulla, and deep nuclei. The cortex

displays three distinct laminae: an outer hypocellular molecular layer, an intermediate single-cell thick Purkinje cell layer (described below), and a deep hypercellular granular cell layer (Figure 11.3). Before one year of age, the cerebellar cortex is conspicuous for remnants of a fourth layer of small neurons, the fetal external granular cell layer, which is located immediately subjacent to pia (Figure 11.3C). The external granular cells are gradually depleted during the first year of life as they descend the processes of Bergmann glia to reach their final position in the internal granular cell layer. Embedded within the white matter of the cerebellar medulla are four pairs of nuclei, from medial to lateral: fastigial, globosus, emboliform, and dentate. The dentate is by far the largest and is usually the only deep nucleus seen on routine sections. Its serpiginous profile is strikingly similar to that of the inferior olivary

nucleus of the medulla oblongata (illustrated in Figure 11.1) which is a major source of afferent fibers to the cerebellum.

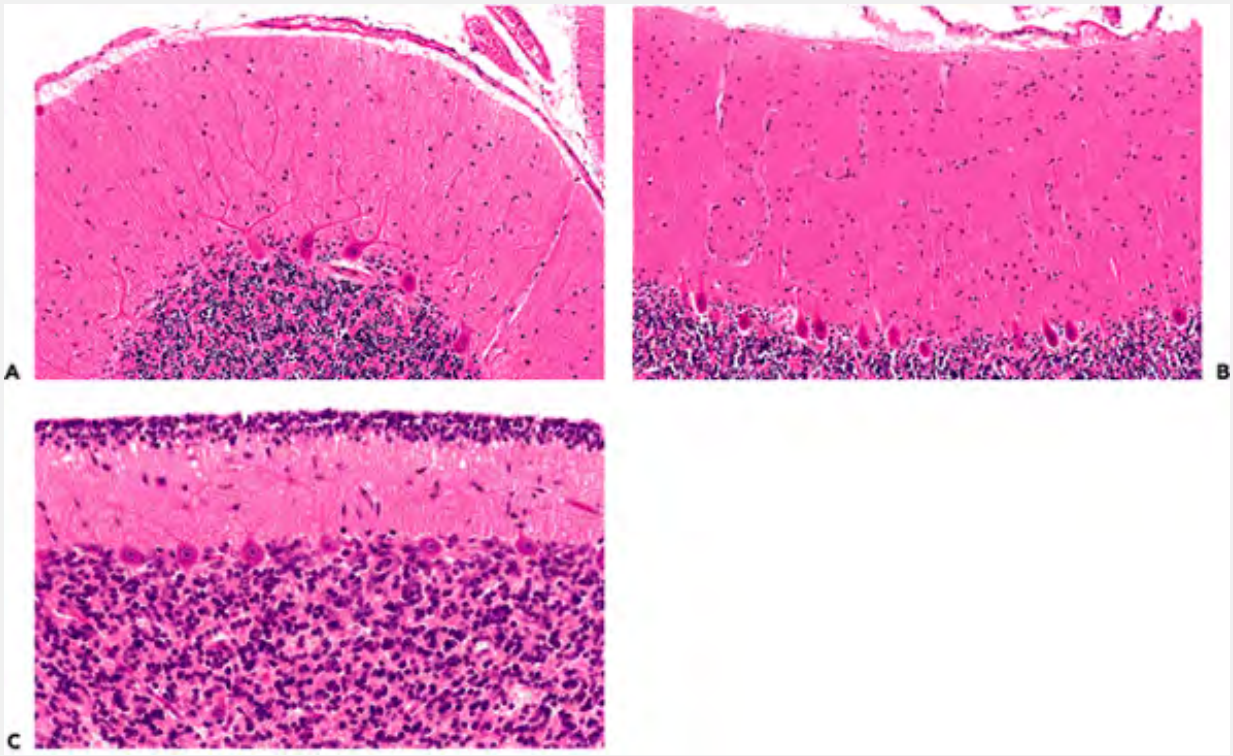

Figure 11.3 Cerebellar cortex. The adult cerebellar cortex is composed of three layers: an outer hypocellular molecular layer, middle Purkinje cell layer, and inner densely populated granular cell layer. Whereas the Purkinje cells are prototypically neuronal in appearance, the small cells of the granular layer are hardly recognizable as neurons by traditional histologic criteria (see Figure 11.7). A. A cross section of a cerebellar folium shows the typical broadly branching Purkinje cell dendritic arbor. B. However, sections taken parallel to the folia reveal the streamlined â€œon edgeâ€• appearance of the arbor, which should not be interpreted as pathological pruning. C. The fetal cerebellum has an additional cortical lamina, the external granular layer, applied to the surface of the cortex. This pool of cells populates the internal granular cell layer during

development and is, thereby, depleted by the end of the first year of postnatal life.

The Purkinje cell dendritic arbor extends into the molecular layer like a hand with outstretched fingers. Its broad, flat palm and radiating fingers are oriented perpendicular to the long axis of the cerebellar convolutions (folia). Thus, routine folia cross sections show the typical, elaborate dendritic branching pattern, whereas longitudinal sections present a dramatically different â€œon edgeâ€• view of the arbor (Figure 11.3). This should not be mistaken for pathologic dendritic tree â€œpruningâ€• seen in some disease states.

Diencephalon

The diencephalon is interposed between the brainstem (midbrain, pons, and medulla) and the cerebrum. Four major divisions are recognized: epithalamus (pineal gland and habenula), thalamus, subthalamus, and hypothalamus. The medial and lateral geniculate nuclei of the thalamus are sometimes considered together as the metathalamus.

The strategic location of the thalamus is related to its major role in processing and relaying information passing between the cerebral cortex and brainstem and spinal cord. All sensory data (with the exception of olfaction) are processed by specific thalamic nuclei before distribution to the primary sensory cortices.

Of clinical significance to the pathologist, certain portions of the diencephalon immediately subjacent to the third ventricle (in particular, the large dorsomedial nuclei of the thalamus and the mammillary bodies of the hypothalamus) are often prominently involved in Wernicke's encephalopathy. The lesions at these sites are postulated to account for the memory disturbance that accompanies this disorder.

Cerebrum

Supratentorially, the CNS becomes so much more complicated that it is difficult to describe in terms of any general pattern of orientation. It remains a hollow structure, but

one that is no longer easy to consider as a tube with foldings and regional overgrowths. In light of this complexity, it is appropriate to review only those areas that are of particular diagnostic relevance.

Basal Ganglia

The term *basal ganglia* refers to the deep gray matter masses of the telencephalon and encompasses the caudate nucleus, putamen, globus pallidus, and amygdala (Figure 11.4). The term *ganglion* was formerly used interchangeably with *nucleus,* and *ganglion cell* was synonymous with *neuron* to earlier neuroanatomists. With the exception of the basal ganglia, the current definition of a ganglion is now generally restricted to mean a collection of neuronal cell bodies located outside the CNS, namely, the sensory and autonomic ganglia of the peripheral nervous system. Reference to CNS neurons as *ganglion cells* is still occasionally encountered, and this historical sense of the term is reflected in the names of such neoplastic entities as *ganglioglioma, ganglioneuroma,* and *ganglion cell tumor.*

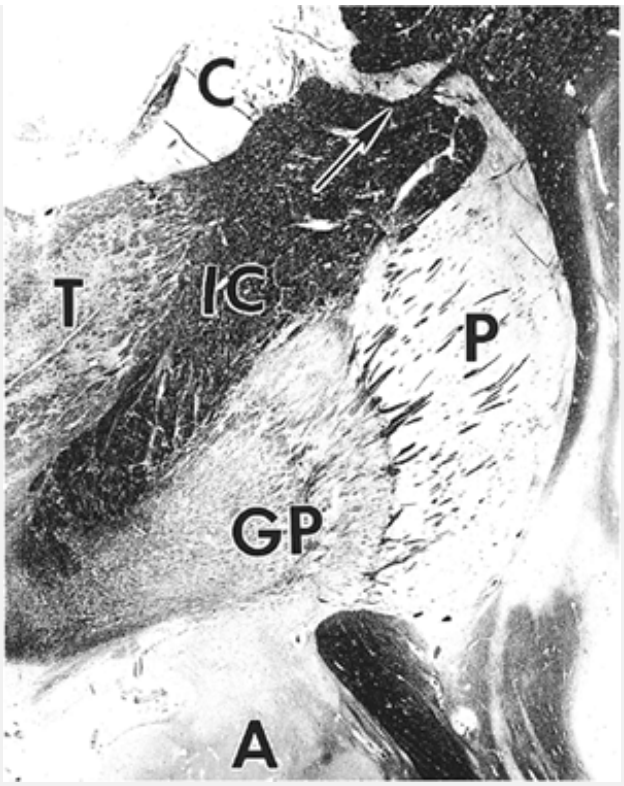

Figure 11.4 Basal ganglia. The gray matter of the telencephalon is broadly divisible into two componentsâ€”the superficial cortical gray matter mantle and the deep gray nuclei. The latter are known as the basal ganglia and consist of the caudate nucleus (*C*), putamen (*P*), globus pallidus (*GP*), and amygdala (*A*). The lenticular nucleus is composed of the medially situated, diffusely myelinated globus pallidus and the laterally placed putamen, whose myelinated fibers are grouped into slender fascicles known as the pencil bundles of Wilson. The internal capsule (*IC*) separates the lenticular nucleus from the caudate and the thalamus (*T*). Gray matter bridges (*arrow*) occasionally span the capsule to connect the caudate and putamen, a reflection of the close functional relationship between these two nuclei. The lenticular nucleus receives its blood supply from several lenticulostriate arteries, which are direct branches of the middle cerebral artery, and is the most common site of intracerebral hypertensive hemorrhage and lacunar infarction. The large

lenticulostriate artery coursing through the lateral putamen was known in former times as Charcot's artery, or, more colorfully, as the artery of internal hemorrhage. The lenticulostriate vessels are often surrounded by dilated perivascular spaces that should not be mistaken for lacunar infarcts.

The amygdala (archistriatum) is located in the mesial temporal lobe immediately rostral to the hippocampus and is functionally related to the limbic system. The remaining nuclei of the basal ganglia play an integral role in the modulation of motor function and probably participate in other higher neural systems as well. The caudate nucleus, as the name implies, has a long tapering tail that intimately follows the curvature of the lateral ventricle. The caudate is morphologically and functionally closely related to the putamen. These two nuclei are appropriately referred to collectively as the neostriatum, or simply the striatum. For descriptive purposes, the putamen and the medially situated globus pallidus (paleostriatum, or pallidum) are collectively referred to as the lenticular (lentiform) nucleus. The putamen and globus pallidus are separated from one another by the external medullary lamina of the globus pallidus, whereas the globus pallidus is itself divided into medial and lateral segments by the internal medullary lamina. The globus pallidus (pale globe) is so named because of its pallor in the fresh state compared to the putamen. This contrast is attributable histologically to the dense meshwork of myelinated fibers in the globus pallidus. In contrast, myelinated axons in the putamen are grouped into slender fascicles (pencil bundles of Wilson) that project medially to the globus pallidus and to the substantia nigra. The histologic appearance of the lentiform nucleus is distinctive and permits unambiguous identification of even very limited amounts of tissue from this site.

The basal ganglia are prominently involved in a variety of pathological processes, including kernicterus (literally, nuclear

jaundice) in the neonate and lacunar infarction in adults. Carbon monoxide poisoning classically produces selective necrosis of the inner segment of the globus pallidus. A frequent incidental finding of no diagnostic significance on routine sections of the lentiform nucleus is micronodular mineralization of small blood vessels, which is typically most prominent in the globus pallidus. Histologically, similar micronodular mineralization is also commonly seen in the hippocampus (Figure 11.5C).

Hippocampal Formation

The hippocampal formation comprises the subiculum, Ammon's horn (hippocampus proper), and dentate gyrus (Figure 11.5). In coronal sections of the medial temporal lobe, the subiculum forms the inferior base of the hippocampal formation, joining the parahippocampal

gyrus with Ammon's horn. Ammon's horn, routinely abbreviated CA (for cornu Ammonis), is divided into four regions, CA1 through 4, based on cytological architecture and synaptic connectivity. (This nomenclature was introduced by Lorente de No in 1934.) The superiorly arching CA1 is joined by CA2 to form the medial floor of the temporal horn of the lateral ventricle. The dorsally situated CA2 is usually recognizable by the greater compactness of the pyramidal cell layer, as compared to CA1, and CA3 forms a descending medial arch that terminates in the hilus of the dentate gyrus. The final segment of Ammon's horn, CA4, lies within the hilus of the dentate gyrus and is often referred to as the end-plate. Essentially equivalent to Sommer's sector, CA1 is the zone that is most sensitive to various insults, including seizures, ischemia, and Alzheimer's disease changes. In contrast, the adjacent CA2 segment is known as the dorsal resistant zone, in recognition of its relative sparing compared to the other three sectors. The exquisite sensitivity of CA1 to injury, with sparing of the adjacent CA2, is routinely observed as mesial

sclerosis of the hippocampus, which is seen in many temporal lobes resected for intractable epilepsy. The classic histologic description of the pattern of neuronal loss in Ammon's horn was based on observations made on the brains of such epileptic patients by Wilhelm Sommer in 1880; E. Brotz coined the term *Sommer's sector* in 1920.

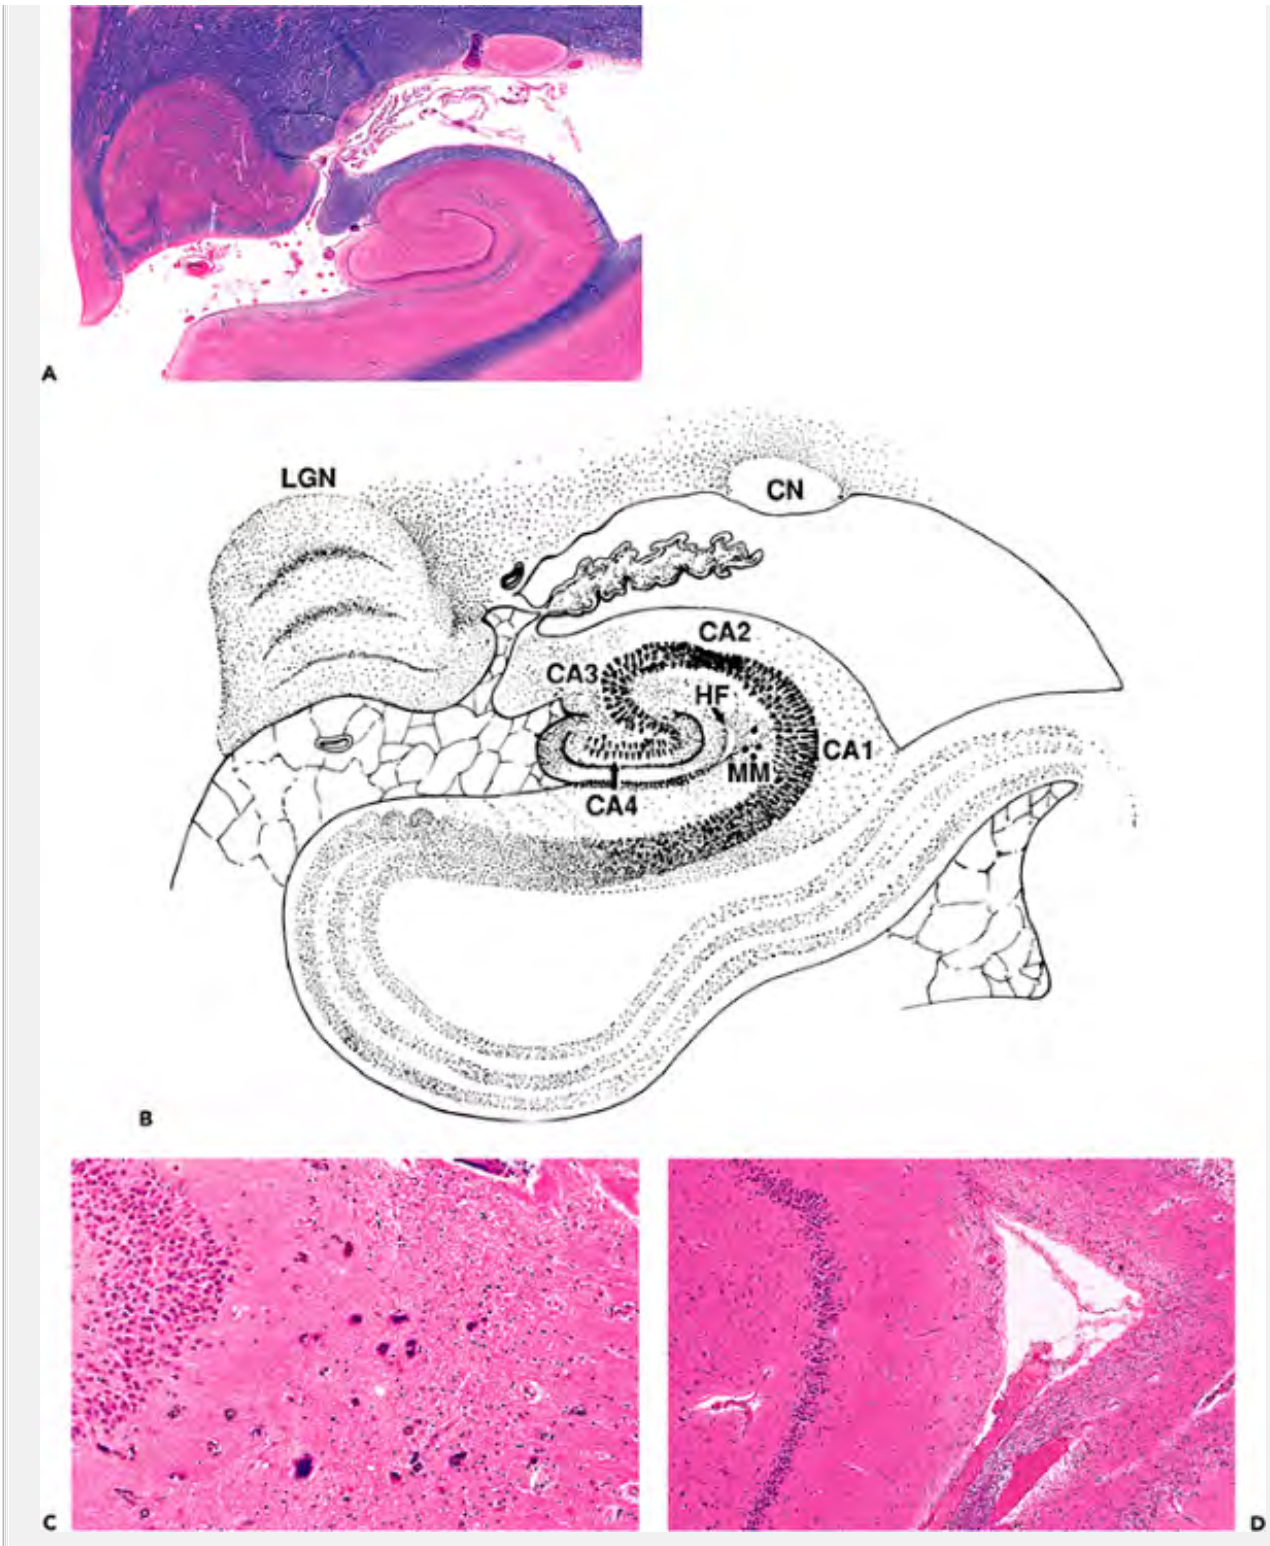

Figure 11.5 Hippocampal formation. The hippocampal formation is composed of the subiculum, Ammon's horn (cornu Ammonis,

abbreviated CA; divided into regions CA1â€“CA4), and the dentate gyrus (A, B). CA1 is equivalent to Sommer's sector and is the region of the hippocampus that is most sensitive to a variety of insults. In contrast, the adjacent CA2 region is known as the dorsal resistant zone. Two common incidental findings are also illustratedâ€”micronodular mineralization (B, C), which is also seen in the globus pallidus, and a residual hippocampal fissure (B, D), which should not be misinterpreted as a healed infarct. [*CN,* tail of the caudate nucleus; *HF,* residual hippocampal fissure; *LGN,* lateral geniculate nucleus (note the â€œNapoleon's hatâ€• profile and distinctive lamination); *MM,* micronodular mineralization.

There are several notable features that are frequently encountered incidentally in the examination of routine hippocampal sections and can be mistakenly interpreted as evidence of disease. One is an asymptomatic micronodular mineralization comparable to that seen in the globus pallidus. In the hippocampal formation, it is most commonly seen just outside the apex of the dentate gyrus (Figure 11.5B, C). A second common finding is a residual hippocampal fissure, which produces a rarefied lamina or cystic cleft that can be mistaken for a healed infarct (Figure 11.5B, D). In addition, pyramidal neurons of the CA are often dark and shrunken in autopsy material, and care must be taken not to overinterpret such changes as evidence of ischemia (Figures 11.16, 11.17).

Cerebral Cortex

From antiquity, neuroscientists have sought to divide the cortical mantle into discrete, functionally significant units. Early efforts yielded fanciful maps akin to those of phrenology and physiognomy. More recently, the application of light microscopy and special staining techniques for cell bodies (Nissl stains), dendritic arbors and unmyelinated axons (Golgi's stains), and the myelin sheaths of

myelinated axons (myelin stains such as the Weil's, Weigert's, and Luxol fast blue methods) have permitted a more scientific approach, although the details are beyond the scope of this chapter. In brief, the parcellation of the cortex is based on regional variation in the relative number, composition, and distribution of cortical neurons and their processes (cytoarchitectonics and myeloarchitechtonics). Various neuroanatomists have divided the cortex into a number of regions, varying from 20 to more than 200 and depending on the particular morphologic criteria and degree of subtlety employed. Currently, the most popular cortical map is that devised by Korbinian Brodmann in 1909. Brodmann's map and the classical nomenclature for the gross anatomy of the cerebral sulci and gyri are the two systems most commonly used at present for reference purposes in the neuroanatomic and clinical literature.

Within the context of even the simplest cortical map, it is generally not possible to assign a given histologic section of cortex to a precise anatomic locus without prior knowledge of the section's provenance. However, two cortical areas do exhibit distinctive features: primary motor cortex and primary visual cortex. The motor cortex, located on the precentral gyrus of the frontal lobe, is distinguished by the presence of the giant pyramidal cells of Betz. Pyramidal cells generally range from 10 to 50 mm in soma height from base to origin of the apical dendrite. By comparison, Betz cells may exceed 100 mm in soma height. The primary visual cortex, located on the banks of the calcarine fissure of the medial occipital lobe, is remarkable for the presence of a prominent external band of Baillarger, termed the line (or stria) of Gennari. This myelinated stratum located in lamina IV is usually visible to the naked eye and permits exact delineation of the primary visual cortex (Brodmann area 17) from the adjacent visual association cortex (Brodmann area 18).

Cellular Constituents of the Central Nervous System

Gray Matter and White Matter

By volume, most of the central nervous system is composed of gray matter and white matter. Specialized types of CNS tissues include the choroid plexus, pineal gland, circumventricular organs, and the infundibulum and neurohypophysis (discussed later). The hallmark of gray matter (Figure 11.6A) is the presence of neuronal cell bodies embedded within a finely textured eosinophilic background termed neuropil (Figure 11.6B, C). Neuropil (literally, nerve felt) is an interwoven meshwork of neuronal and glial cell processes. The individual neurites that compose the neuropil are not generally distinguishable in routine hematoxylin-eosin (H&E)â€“stained sections (Figure 11.6B) but are resolvable at the ultrastructural level (Figure 11.6C). White matter, in contrast, is composed primarily of myelinated axons and the supporting cells, oligodendroglia, that produce and maintain the myelin sheaths (Figure 11.6D).

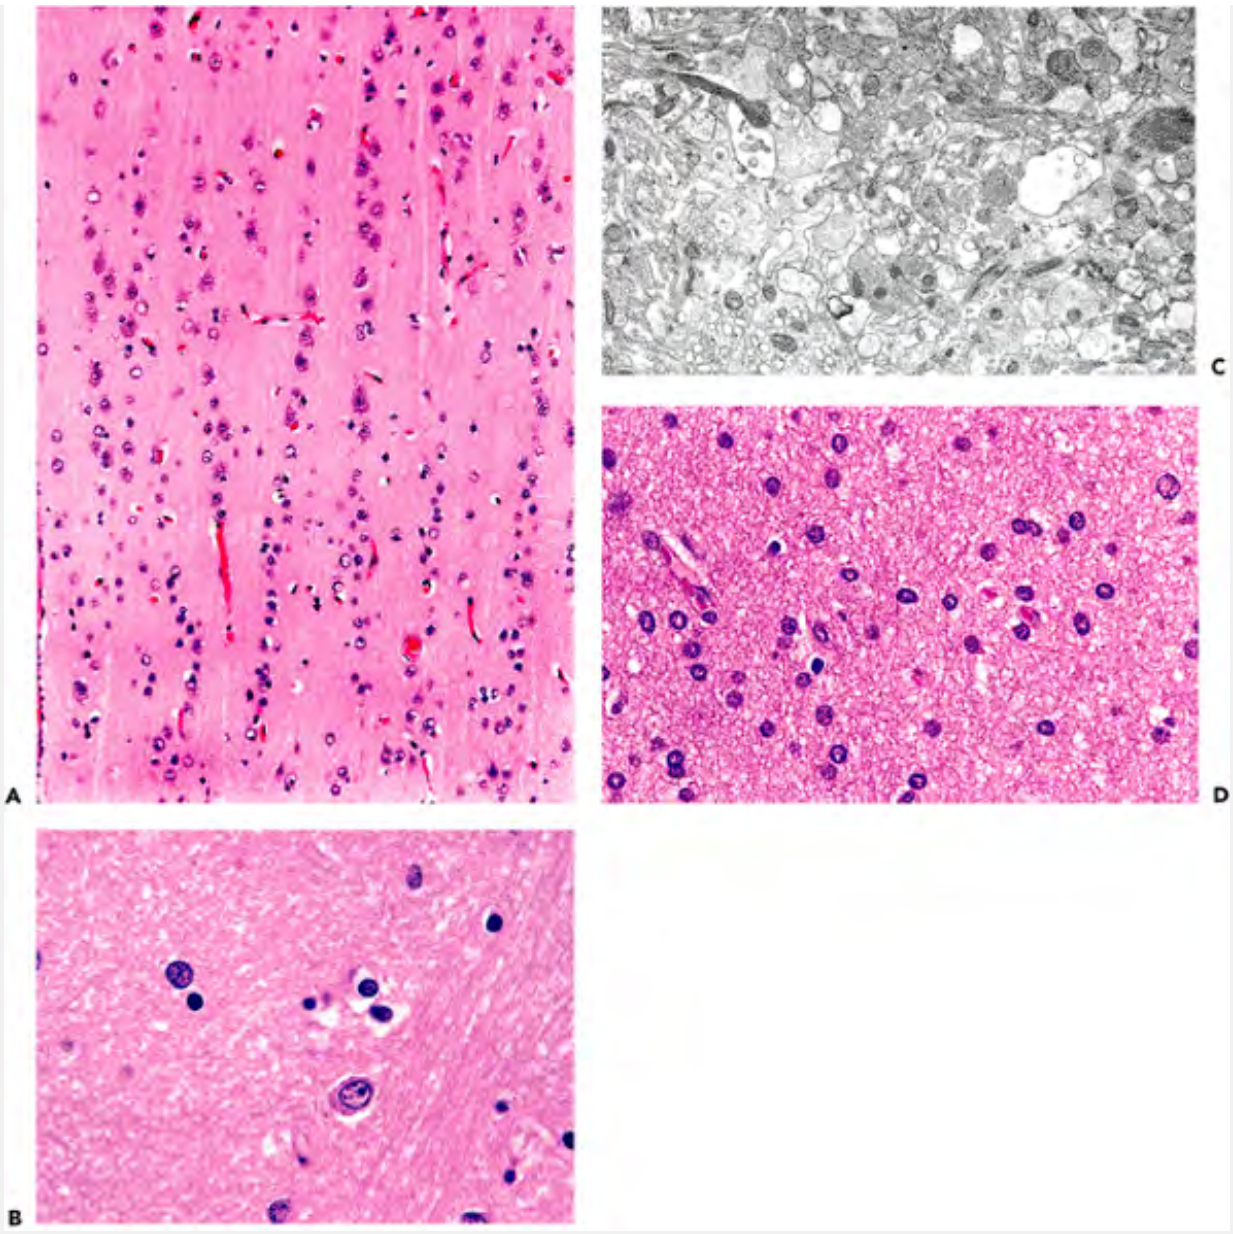

Figure 11.6 Gray matter and white matter. A. Gray matter contains abundant neuropil surrounding large neurons and smaller astrocytes and oligodendroglia. B. Neuropil is the term used for the fine amorphous eosinophilic background matrix of the central nervous system that fills the space between the cell bodies of the various cellular constituents as seen on H&E stains. C. Ultrastructural examination shows the neuropil to be composed of myriad intimately intermingling processes of the

cellular constituents. D. White matter, in contrast, is composed primarily of oligodendroglia and the axons that they myelinate, and it displays a much more uniform appearance.

Neurons

Normal Microscopic Anatomy

The prototypical neuron is exemplified by the large multipolar Betz cells of the motor cortex, the Î± motor neurons of the ventral horn of the spinal cord, and the Purkinje cells of the cerebellum. These neurons are characterized by large perikarya (cell bodies or somas) with abundant Nissl substance (rough endoplasmic reticulum), robust dendritic arborizations, and large nuclei with prominent single nucleoli (Figure 11.7A). Such large multipolar forms, however, represent only one type of neuron; the diapason of neuronal morphologies is remarkable. This is readily apparent by comparison of a motor neurons with granular cell neurons (Figure 11.7A, D). These two neuronal populations typify the classical dichotomous subdivision of CNS neurons into large extroverted projection neurons with long axons (Golgi type I neurons) and small introverts that function regionally with restricted connections (Golgi type II

neurons). Between these two poles is a full spectrum of neuronal sizes and shapes, with an equally impressive variety of dendritic arbor configurations. The details of the latter are generally appreciable only with special stains for neuronal processes. The cell processes of neurons are separated into two categories: axons (Figure 11.7Aâ€“C), of which each neuron only has one, and dendrites (Figure 11.7A), which are often multiple.

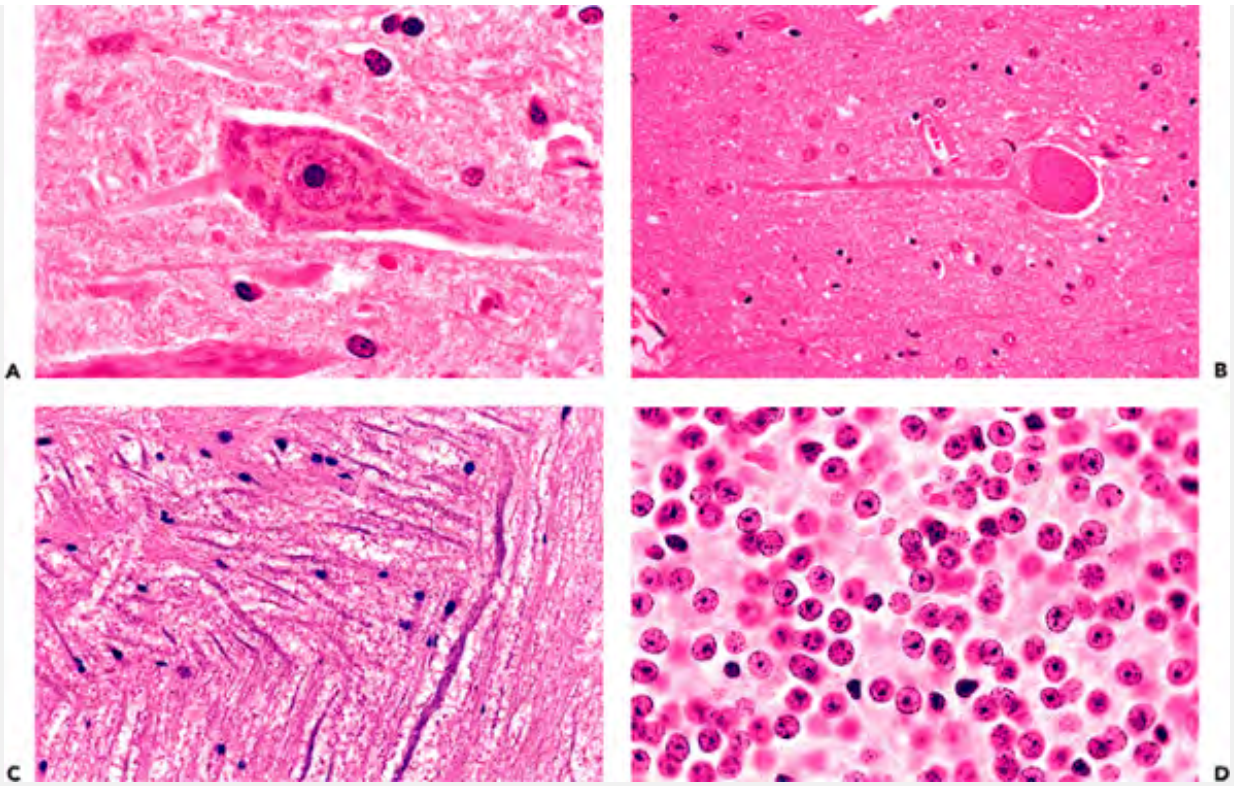

Figure 11.7 Neurons. A. Classical neuronal features, as illustrated by a motor neuron from the ventral horn of the spinal cord, include a large cell body (soma, perikaryon) with abundant cytoplasmic Nissl substance (rough endoplasmic reticulum, the â€œtigroid substanceâ€• of early microscopists), cytoplasmic processes, and a large nucleus with a single prominent nucleolus. The large process extending to the right is clearly recognizable as a dendrite by its content of Nissl substance, whereas, in this fortuitous section, the smaller process extending to the left is identified as the neuron's axon by its lack of Nissl substance. B. Axons are further distinguished from dendrites by their nontapering profile. C. The nontapering profile of axons is easily recognized in white matter. The extremes of neuron size and shape are readily apparent from a comparison of a large motor neuron (A) with the small granular cell neurons of the cerebellar cortex (D) that are approximately the same size as a motor neuron's nucleolus!

With respect to morphologic variants, one unique population of CNS neurons merits brief mention. The mesencephalic nucleus of the trigeminal nerve, which is concerned chiefly with the mediation of jaw proprioception, is composed of true primary (first order) sensory neurons that possess only a single process emanating from the cell body (Figure 11.8A). This nucleus constitutes the only intraparenchymal example of this class of neurons; all other primary sensory neuronal perikarya are gathered outside the CNS in the spinal and cranial nerve ganglia (Figure 11.8Bâ€“D).

Immunohistochemistry

Antibodies have been raised against a wide variety of the many unique neuronal proteins that are being isolated and characterized at an ever-increasing rate. A majority of these markers are confined to use for research purposes but several have found utility in the diagnostic laboratory. One of the earliest such markers, neuron specific enolase (NSE), has proven notoriously unreliable as a marker of neuronal differentiation. Its use for this purpose in evaluating neoplasms of the central nervous system is not recommended.

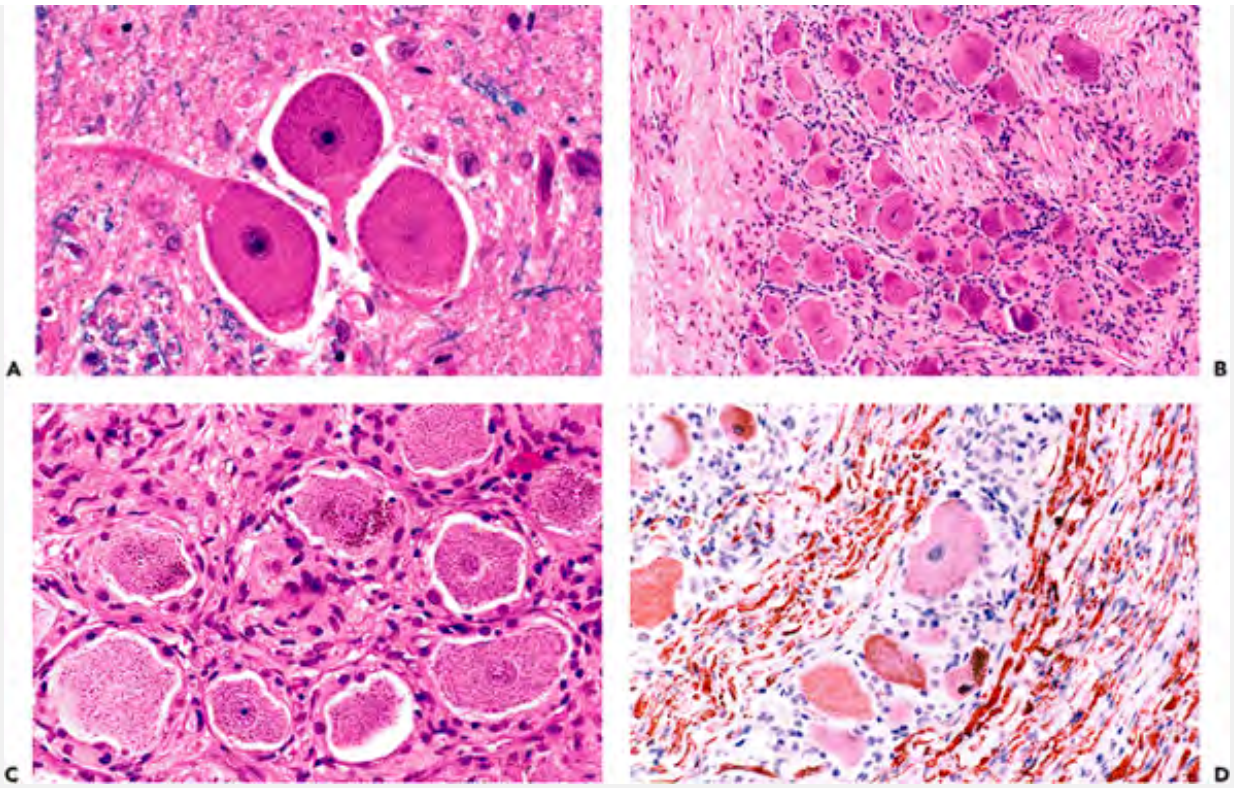

Figure 11.8 Unipolar neurons. Another neuronal morphologic variant is the unipolar (pseudounipolar) neuron. These large neurons possess only a single cell process, an axon, but no dendrites. A. Unipolar neurons are primary sensory neurons, and the only example of this class of neuron within the central nervous system is the mesencephalic nucleus of the trigeminal nerve in the upper pons and midbrain lateral to the periaqueductal gray matter. B. All other unipolar neurons are located in the peripheral nervous system ganglia. The dorsal root ganglia of the spinal cord provide a good example, with large unipolar neurons surrounded by satellite cells (B). C. Ganglionic neurons typically display cytoplasmic pigment. D. Their cell bodies and axons are strongly positive for phosphorylated neurofilament proteins.

Antibodies directed against epitopes on the constituent proteins of

neurofilaments, which are major cytoskeletal elements of the neuronal perikaryon and cytoplasmic processes, have been used extensively in both experimental and clinical studies (Figure 11.9).

One of the most useful and widely employed neuronal markers is synaptophysin. Synaptophysin is an integral membrane protein of synaptic vesicles. In the normal nervous system, antisynaptophysin antibodies yield a diffuse, finely granular pattern throughout the gray matter neuropil (Figure 11.10A). In addition, punctate granular decoration is seen along the cell bodies and proximal dendrites of several types of large, projection class neurons, including the Purkinje cells of the cerebellum, Î± motor neurons of the spinal cord, extraocular motor neurons of the brainstem, and Betz cells of the precentral gyrus (Figure 11.10B).

Age-Related Neuronal Inclusions

A variety of inclusions, largely intracytoplasmic, appear with increasing frequency as we age. By far, the most common is lipofuscin (lipochrome, or aging pigment), whose yellow-to-pale-brown color is unaltered by most histologic procedures, including the H&E method (Figure 11.11). Its autofluorescence and partial avidity for the acid-fast stain can be used to visualize differentially this â€œwear-and-tearâ€• pigment, although little functional significance is generally assigned to lipochrome accumulation in normal aging. In larger neurons, lipofuscin may accumulate to such an extent that it displaces organelles and creates an appearance similar to the cell swelling of central chromatolysis, described below (Figure 11.18). The lateral geniculate body provides an example of a densely populated nucleus whose constituent neuron's prominent accumulation of lipofuscin

is often discernible macroscopically as a distinctly mahogany hue compared to adjacent cortex. Interestingly, lipofuscin accumulation is not simply a function of cell size because some classes of large

neurons appear comparatively immune to significant accrual (e.g., the cerebellar Purkinje cells).

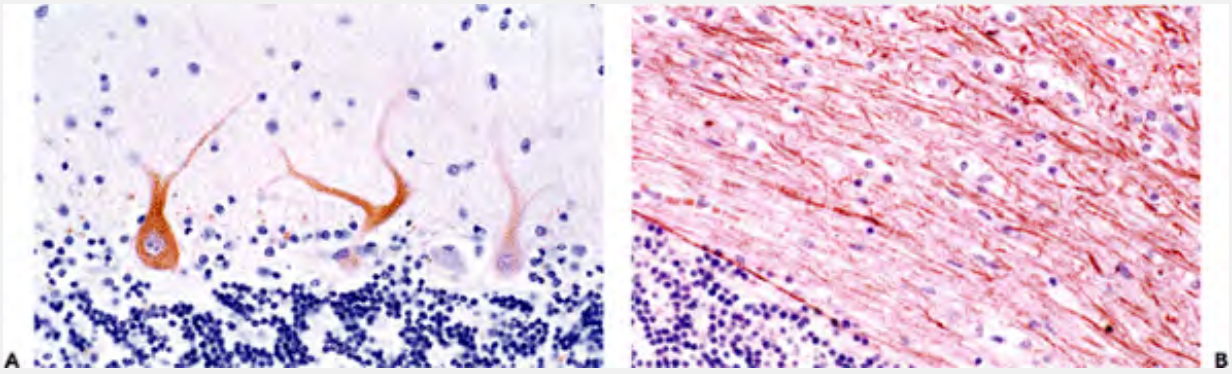

Figure 11.9 Neurofilament proteins (NFPs). Antibodies directed against neurofilament protein epitopes illuminate the cytoskeleton of neurons and their processes. As illustrated in the cerebellar cortex, specific antibodies directed against either nonphosphorylated (A) or phosphorylated (B) NFPs differentially identify cell bodies and dendrites or axons, respectively.

Functionally more significant neuronal inclusions that may be seen in asymptomatic individuals are those associated with Alzheimer's disease. They are neurofibrillary tangles, neuritic plaques, granulovacuolar degeneration, and Hirano bodies. These illustrate the often ill-defined distinction between health and disease, because these changes can be seen in the elderly, albeit in limited numbers, in the absence of antemortem disturbances of mentation.

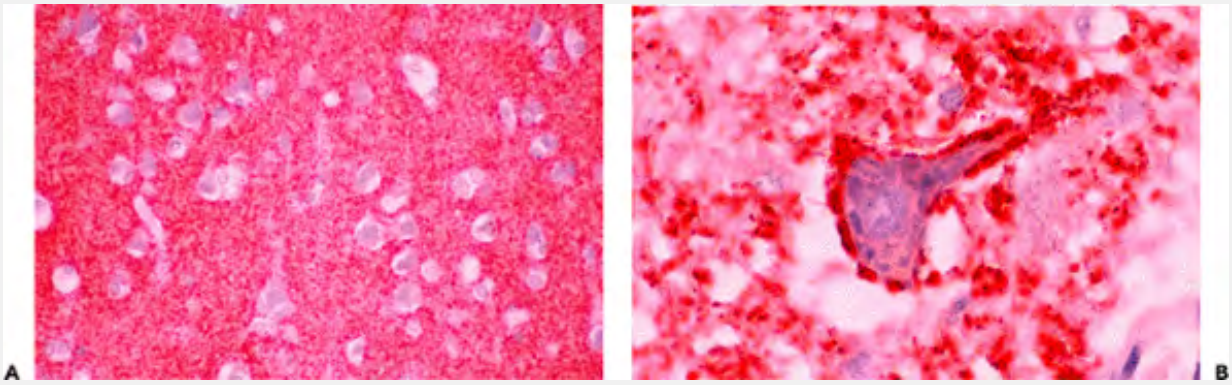

Figure 11.10 Synaptophysin is one of the most useful and widely employed markers of neuronal differentiation. A. The neuropil of gray matter, which is rich in synaptic contacts, shows a diffuse, finely granular pattern. B. Several specific types of large projection class neurons show prominent punctate decoration of the cell body and proximal dendrites, as illustrated here by a motor neuron in the hypoglossal nucleus of the medulla. Other groups of large neurons exhibiting this pattern of synaptophysin immunopositivity include Purkinje cells of the cerebellum, motor neurons of the ventral horn of the spinal cord, and Betz cells of the precentral gyrus in the cerebral cortex.

In some cases, neurofibrillary tangles may be found in asymptomatic individuals in occasional neurons of the subiculum or CA. Although silver stains greatly aid visualization and quantitation, these structures may be identified on routinely stained H&E sections if the observer is familiar with their appearance. In pyramidal cells, they appear as a slightly basophilic wisp of faintly fibrillar material that extends out into cell processes, most notably the apical dendrite, and they are often more prominent on one side of the nucleus (flame-shaped tangle; Figure 11.12A). This morphology reflects the fact that tangles generally conform to the shape of the cell body. For example,

in the pigmented neurons of the locus ceruleus, which are multipolar and lack the dominant apical dendrite of pyramidal neurons,

tangles that are globular in shape are occasionally encountered as an incidental finding.

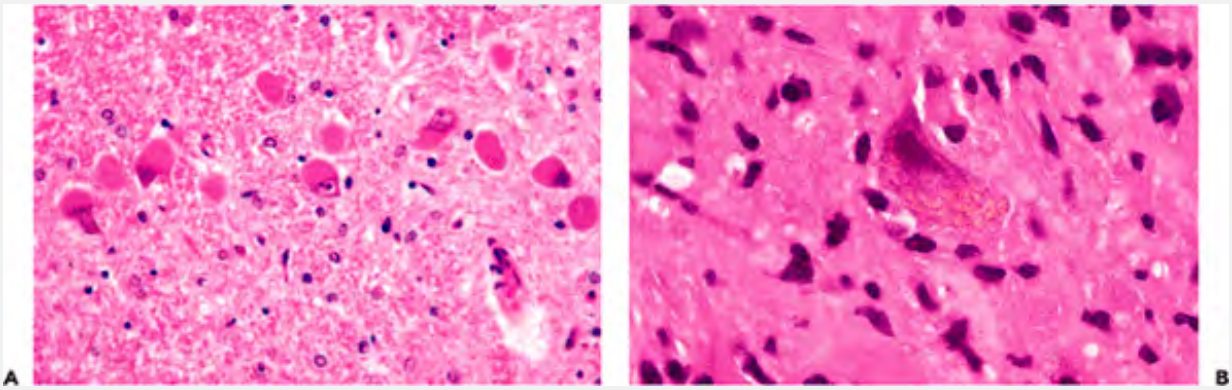

Figure 11.11 Lipofuscin. A. Prominent accumulation of lipofuscin pigment in large neurons with increasing age, as seen for example in the lateral geniculate nucleus, can result in peripheral displacement of the nucleus and Nissl substance, mimicking central chromatolysis. B. As a practical application of normal neurohistology, the presence of lipofuscin can sometimes aid in the identification of neurons in intraoperative frozen sections. As illustrated here, a neuron, identified by its lipofuscin content, is surrounded by tumor cells, thereby supporting a diagnosis of infiltrating glioma.

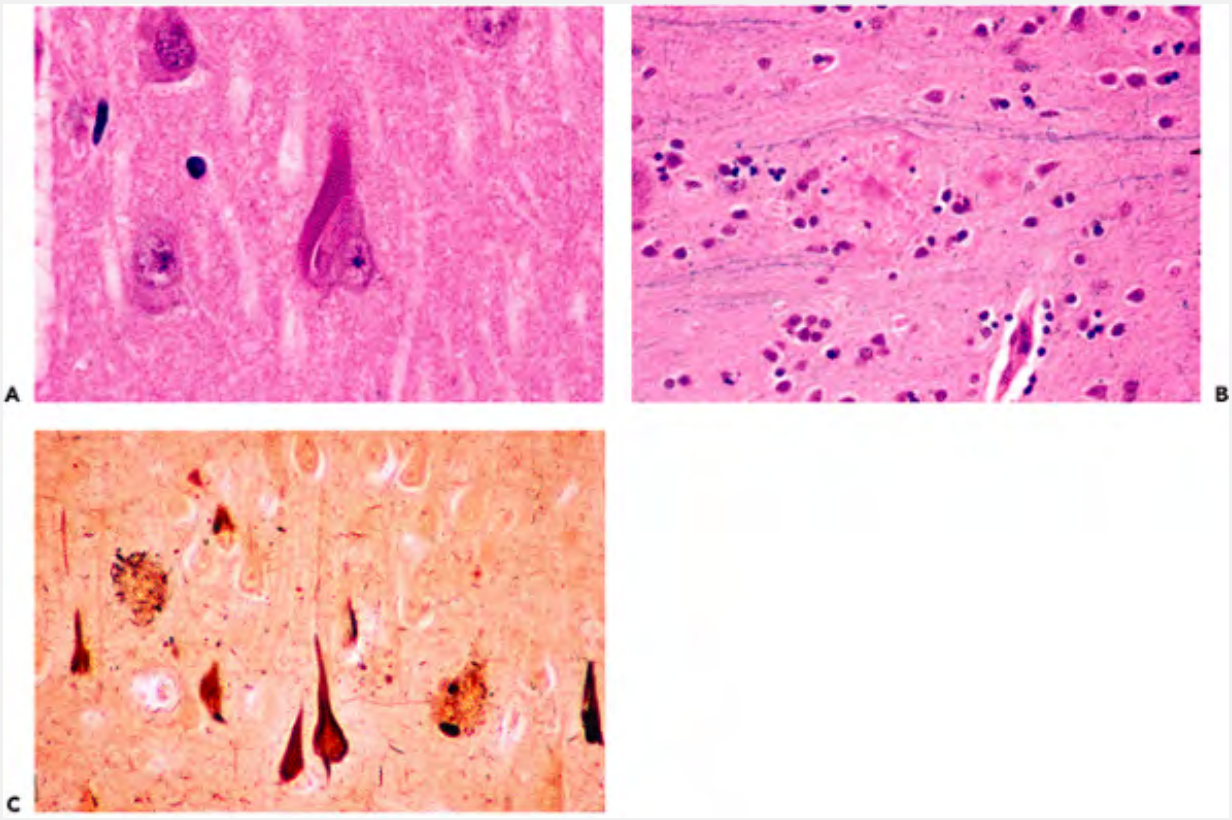

Figure 11.12 Neurofibrillary tangles and neuritic plaques. Neurofibrillary tangles (A) may be seen sporadically in the hippocampal formation of aging brains and have a fibrillary texture in H&E-stained sections. Mature senile (neuritic) plaques (B) deform the smooth texture of the neuropil and appear in H&E-stained sections as spherical, somewhat granular foci with a central eosinophilic core that is composed of amyloid. Note that adjacent myelinated axons are focally displaced as they pass by the plaque. In earlier stages, the plaques are less well defined and are not identifiable in H&E-stained sections. Although both neurofibrillary tangles and large mature neuritic plaques can be seen in H&E-stained sections, use of special techniques, such as silver stains (C), greatly facilitates visualization and quantitation.

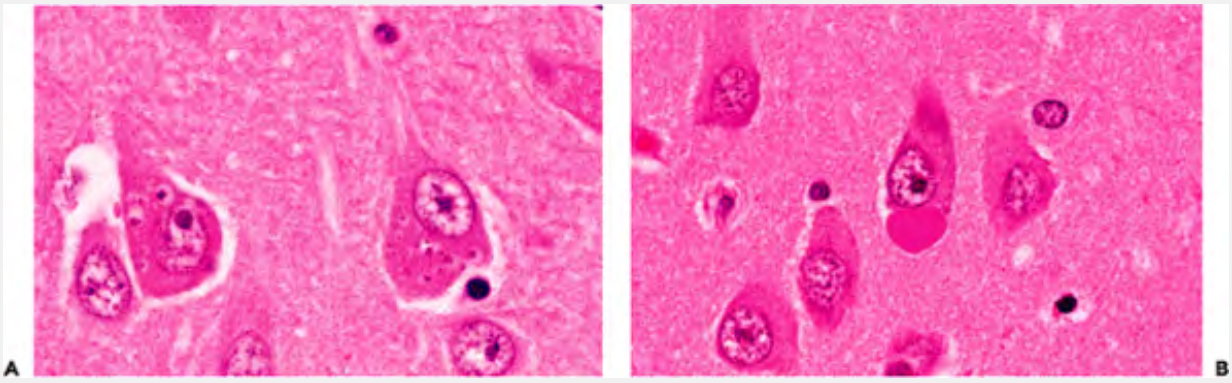

Figure 11.13 Granulovacuolar degeneration (of Simchowitz) (A) and Hirano bodies (B). Like neurofibrillary tangles, both of these intracytoplasmic inclusions can occasionally be seen in the hippocampal formation of normal older individuals. However, although these alterations are not pathognomonic for dementing illness, an appreciable number of affected cells should prompt a search for evidence of Alzheimer's disease in the form of a thorough examination for senile (neuritic) plaques and neurofibrillary tangles.

The senile plaque is also a manifestation of cell injury, but one that, like slight atherosclerosis, is not an unexpected finding in the brains of asymptomatic adults. In such individuals, the plaque is usually seen in its primitive form as a somewhat ill-defined, roughly circular region of abnormal argyrophilic neurites that is not visualized in the H&E-stained section. As the plaques mature they become visible in the latter preparation, particularly when a central core of eosinophilic amyloid appears (Figure 11.12B). The latter can be more readily seen by Congo red or periodic acid-Schiff (PAS) staining. As noted earlier, both neurofibrillary tangles and neuritic plaques are more easily identified and quantitated with special techniques such as immunofluorescence or silver stains (Figure 11.12C).

Two additional intraneuronal inclusions that are seen in Alzheimer's disease, but only rarely in nondemented individuals, are granulovacuolar degeneration (GVD) and Hirano bodies (Figure 11.13). As the name implies, the inclusion of GVD consists of a dark, basophilic granule inside a small, clear vacuole. Clusters of these cytoplasmic inclusions may be present within a single neuron (Figure 11.13A). Depending on the plane of section, Hirano bodies appear in H&E-stained sections as brightly eosinophilic oval, elliptical, or elongated rodlike refractile inclusions that are located either in very close apposition to a neuronal perikaryon (Figure 11.13B) or within the neuropil. Ultrastructural examination supports a localization in neuronal cell bodies and processes, and immunohistochemical studies reveal the presence of actin and actin-associated proteins. Unlike neurofibrillary tangles and neuritic plaques, both GVD and Hirano bodies exhibit a very limited neuroanatomic distribution and are, in fact, virtually confined to the hippocampal formation. Encountering more than one or two cells with these alterations should raise the issue of Alzheimer's disease and prompt a search for other attendant histologic features.

A particularly striking cytoplasmic inclusion occasionally encountered in routine sections of the hypoglossal nuclei of the medulla (less often in the ventral horn motor nuclei of the spinal cord) is the hyalin (colloid) inclusion (Figure 11.14). These inclusions, which consist of ectatic cisternae of endoplasmic reticulum, are rarely seen in the first few decades of life but appear with increasing

frequency thereafter. They are occasionally mistaken by the uninformed for viral inclusions.

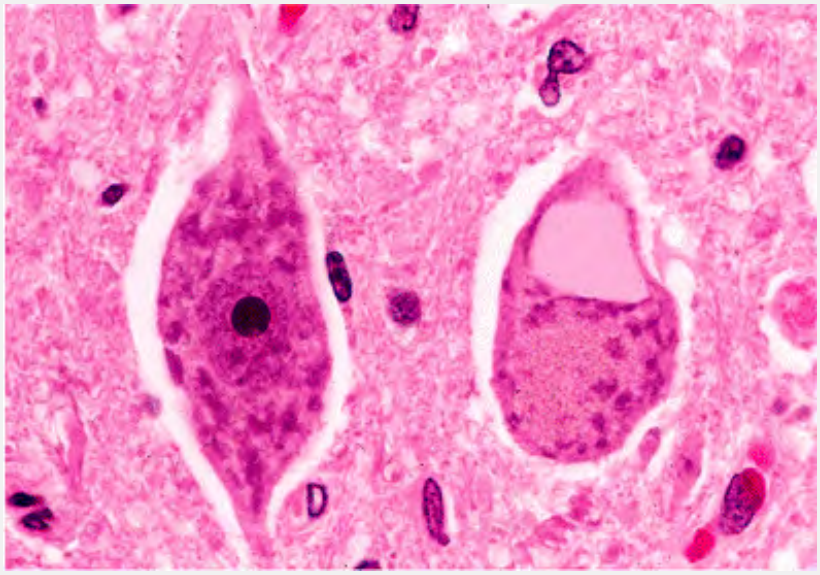

Figure 11.14 Hyalin (colloid) inclusion: these eye-catching inclusions, as seen in the neuron on the right, may be observed sporadically throughout the neuraxis but are most commonly encountered in the large motor neurons of the hypoglossal nuclei in the medulla (as in this micrograph). Less frequently, they may be seen in the motor neurons of the ventral horn of the spinal cord. Electron microscopic examination reveals ectatic cisternae of endoplasmic reticulum.

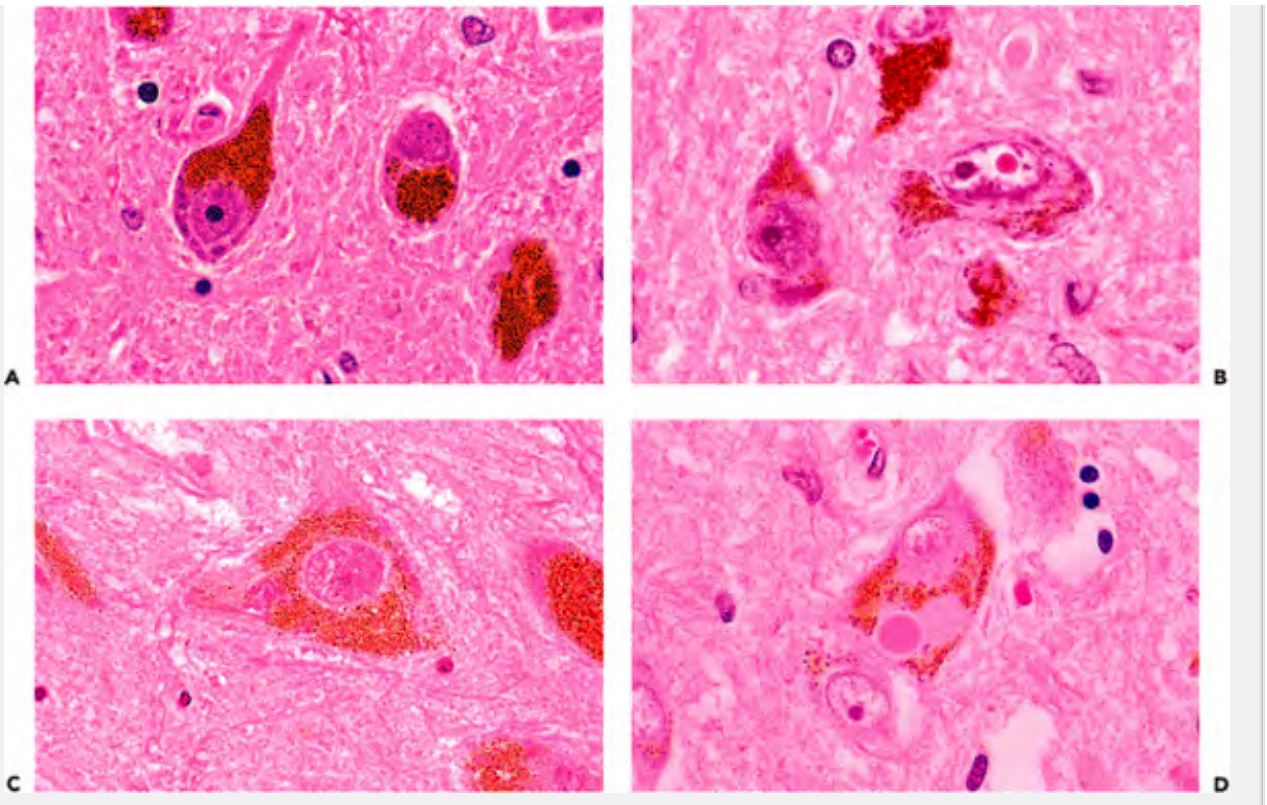

Figure 11.15 Pigmented neurons of the brainstem. A. Neuromelanin is a coarse, dark brown cytoplasmic pigment that is formed as a byproduct of catecholamine synthesis and is frequently encountered microscopically in scattered catecholaminergic neurons distributed widely throughout the brainstem. Two large populations are visible grossly: the substantia nigra (black substance) of the midbrain and the locus ceruleus (blue spot) of the pons. B. Marinesco bodies are eosinophilic, spheroidal, paranucleolar bodies that are often observed in the nuclei of pigmented neurons, especially those of the substantia nigra. The number of Marinesco bodies increases with advancing age and can be quite striking in some individuals. They should not be mistaken for intranuclear viral inclusions. C. Clusters of minute intracytoplasmic eosinophilic granules, seen in this micrograph to the left of the nucleus, may occasionally catch the eye of an obsessive observer. They have no known pathologic significance and are much smaller than Lewy bodies (D), which

are the characteristic intracytoplasmic inclusions of Parkinson's disease.

Catecholaminergic neurons throughout the brainstem gradually accumulate neuromelanin as a byproduct of neurotransmitter synthesis. The largest and most densely populated of these nuclei is the substantia nigra (black substance), which contains dopaminergic neurons. The locus ceruleus (blue spot), which is also seen by the unaided eye, is a collection of noradrenergic neurons in the rostral pontine tegmentum. It is of practical importance that the Lewy bodies of Parkinson's disease can be found in both of these neuroanatomic locales. Of the smaller and more diffusely distributed pigmented neurons, those in the vicinity of the dorsal motor nucleus of the vagus nerve in the medulla oblongata are most commonly encountered during routine histologic examination. Microscopically, neuromelanin appears as coarse, dark brown granules (Figure 11.15A) and should not be confused with melanocytic melanin. The latter is also present in the central nervous system but is confined to leptomeningeal melanocytes as discussed below (see Figure 11.57).

Several eosinophilic inclusions may be seen in pigmented brainstem neurons. The most striking of these are the commonly encountered Marinesco bodies (Figure 11.15B). These bright red, hyalin-appearing structures are located within the nucleus, often adjacent to and about the same size as a nucleolus (an alternative designation is paranucleolar body). Multiple Marinesco bodies may occur within a single nucleus, and, in some cases, a large percentage of pigmented neurons exhibit these eye-catching inclusions. In such cases, they may raise concern about a viral infection to the unaccustomed observer but are not

pathologic and have yet to be correlated with any significant process except advancing age. Two types of eosinophilic inclusions may be encountered in the cytoplasm of pigmented neurons. Clusters of

diminutive acidophilic granules are occasionally noted (Figure 11.15C) but have no pathologic significance. Lewy bodies, in contrast, are much larger, notably displace the cytoplasmic neuromelanin from which they are separated by a small clear halo, and are associated with Parkinson's disease (Figure 11.15D).

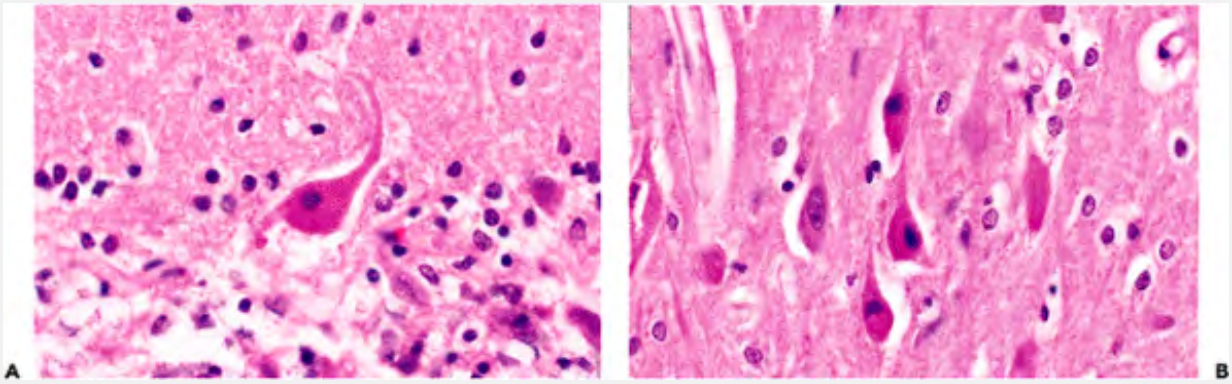

Figure 11.16 Ischemic injury: the sine qua non of ischemic damage to the nervous system is the so-called red neuron. As illustrated here by a Purkinje cell of the cerebellum (A) and pyramidal neurons of the hippocampal CA1 region (B), the soma (cell body) is shrunken, the cytoplasm is intensely eosinophilic, and the nucleus is pyknotic with no discernible nucleolus. It is largely the pronounced eosinophilia that distinguishes this cellular alteration from autolytic neuronal condensation, in which the cytoplasm is dark and basophilic (Figure 11.17).

Autolysis and Basic Neuronal Reactions to Injury

As captured in their normal state by perfusion fixation or rapid immersion fixation, neurons are generally rotund with lightly eosinophilic cytoplasm that is stippled with basophilic Nissl substance

in the case of the larger neurons. The surrounding glia are inconspicuous, and few clear vacuoles are seen. This perfection in fixation is rarely achieved in human material, however; and, in virtually all autopsy and surgical specimens, autolysis alters this ideal appearance to a greater or lesser extent. Neurons are, thereby, rendered somewhat contracted and basophilic. Nuclei are also somewhat condensed. Simultaneously, the processes of glia that surround neurons and blood vessels imbibe water to produce clear vacuoles (Figure 11.29). The neuronal response to injury overlaps in some cases with these autolytic changes, and it may not be possible to distinguish agonal hypotensive injury from autolysis in autopsy specimens. In the former setting, the neuronal contraction is pronounced, and the perineuronal and perivascular spaces are exceptionally prominent.

There are, however, three neuronal changes that provide unequivocal evidence of antemortem injury. One is the â€œredâ€• neuron, which is the sine qua non of ischemic damage. The second is central chromatolysis, and the third is ferruginization. The red neuron is characterized by a shrunken cell body and intense cytoplasmic eosinophilia with complete loss of Nissl basophilia (Figure 11.16). The nucleus is dark and usually lacks a distinguishable nucleolus but may be pale and demonstrate early karyolysis. At times, it has a somewhat fragmented look suggesting karyorrhexis, although clearly defined karyorrhexis is rare. In surgical specimens, tissue-handling artifact (â€œcrushâ€• artifact) also results in dark, shrunken neuronal perikarya; however, as with autolytic autopsy specimens, these cells lack the distinctive cytoplasmic eosinophilia of ischemia (Figure 11.17).

Central chromatolysis, the second unequivocally abnormal finding, consists of a loss of central basophilic staining of the cell body with peripheral margination of the Nissl substance (Figure 11.18). It is seen in a number of pathologic

states (the ballooned anterior horn cells of poliomyelitis being the

classical example). There are numerous mimickers that lie in wait for the unwary. For example, some normal neuronal populations, such as the supraoptic and paraventricular nuclei of the hypothalamus and the dorsal nucleus of Clarke of the thoracic spinal cord, display Nissl substance that is preferentially distributed peripherally in the soma. Other neurons, such as those of the mesencephalic nucleus of the trigeminal nerve discussed previously (Figure 11.8), have large, exquisitely rounded somas and, hence, mimic that aspect of chromatolysis. The giant pyramidal cells of Betz in the motor cortex are so large in comparison to surrounding neurons, that at low magnification they may give an initial impression of chromatolytic swelling. Finally, as discussed earlier, one must be careful not to mistake the accumulation of various substances that displace the Nissl substance peripherally, such as lipofuscin, for central chromatolysis (Figure 11.11).

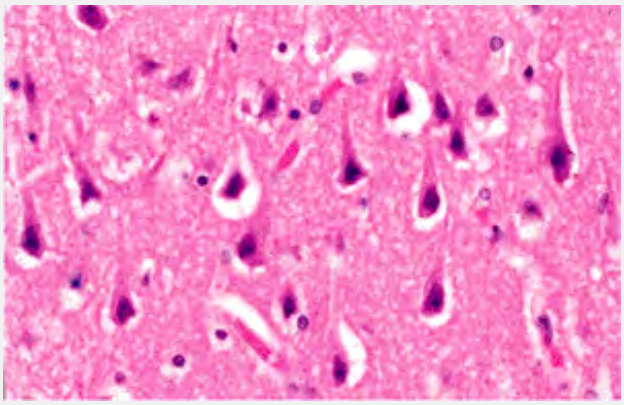

Figure 11.17 Neuronal contraction as a tissue-handling artifact. In contrast to ischemic insult (Figure 11.16), in â€œcrushâ€• artifacts the cytoplasm is dark and basophilic rather than brightly eosinophilic.

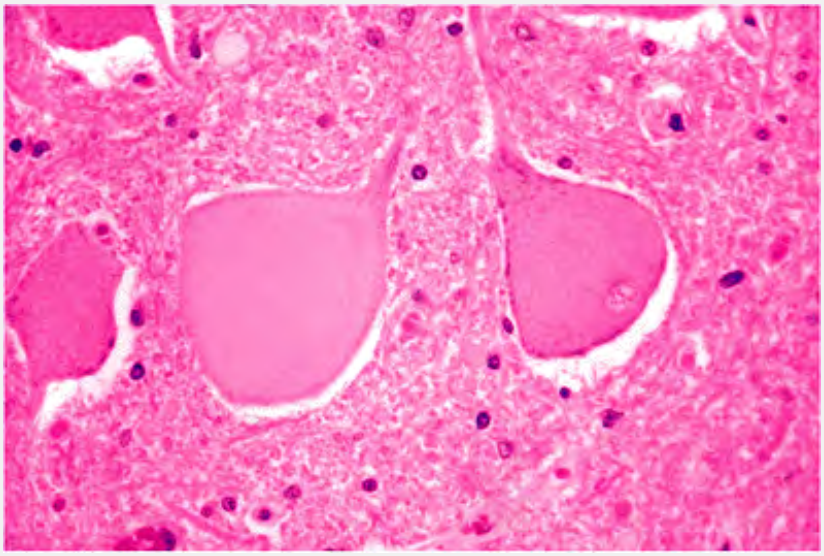

Figure 11.18 Central chromatolysis. Cytoplasmic hyalinization and swelling with peripheral displacement of the nucleus and lipofuscin can be a response to either intrinsic neuronal disease (such as in poliomyelitis or other viral infections) or to interruption of the axon in close proximity to the cell body. In the latter setting, the term *axonal reaction* is applied.

A striking finding sometimes encountered near old infarcts is the presence of ferruginized or fossilized neurons, in which both perikarya and axons are encrusted by blue-staining minerals (Figure 11.19). This arresting phenomenon is not limited to the vicinal tissue of old infarcts, although this is the most common context, nor is it confined to the adult nervous system, because prenatal insults may result in similar findings. Clusters of axons thus affected can be mistaken for fungal hyphae (Figure 11.20).

A common reaction of axons to injury seen in a wide variety of pathologic states is the formation of localized dilatations known as axonal spheroids or axon â€œretraction ballsâ€• (Figure 11.21A). Ultrastructural examination shows greatly distended axis cylinders

filled with bundles of neurofilaments and cellular organelles. A regional variant of this process may be observed in the granular cell layer of the cerebellum where focal dilatations of Purkinje cell axons are termed *torpedoes.* These structures are seen in a number of cerebellar degenerative diseases, as well as in normal aging. The most common site in the central nervous system where scattered axonal spheroids are routinely encountered as an incidental finding in aged individuals is in the rostral fasciculus gracilis of the medulla (Figure 11.21B). Spheroids in this location are often mineralized.

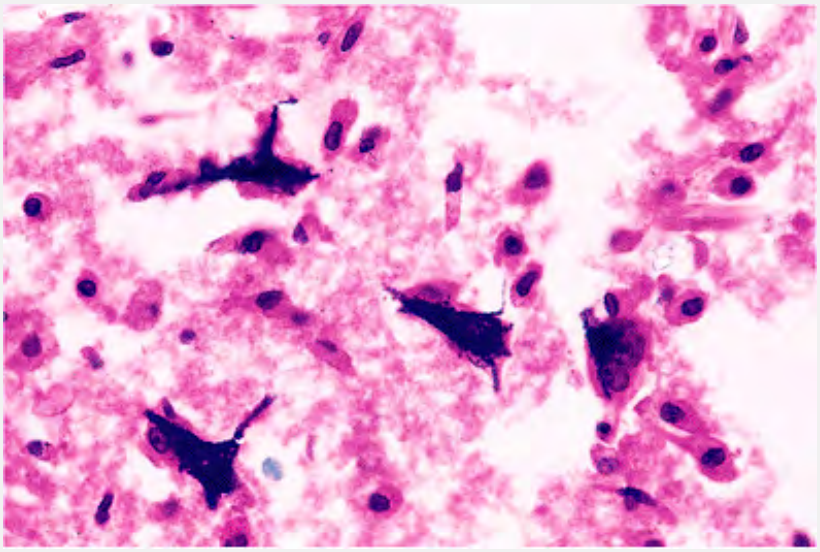

Figure 11.19 Mineralized (ferruginized) neurons. These encrusted relics resembling petrified tree trunks are most commonly encountered around the margins of old infarcts.

Astrocytes

Normal Microscopic Anatomy

Like neurons, astrocytes are also heterogeneous. The cells of one

class conform to the classic star shape and occur as either the fibrillary or protoplasmic form. Fibrillary astrocytes populate the white matter, whereas the latter inhabit the gray matter. Other important subtypes of astrocytes include the Bergmann astrocytes, which are distributed in a narrow lamina between the cell bodies of Purkinje neurons in the cerebellar cortex, and the â€œpilocyticâ€• astrocytes of the periventricular region, cerebellum, and spinal cord (Figure 11.22).

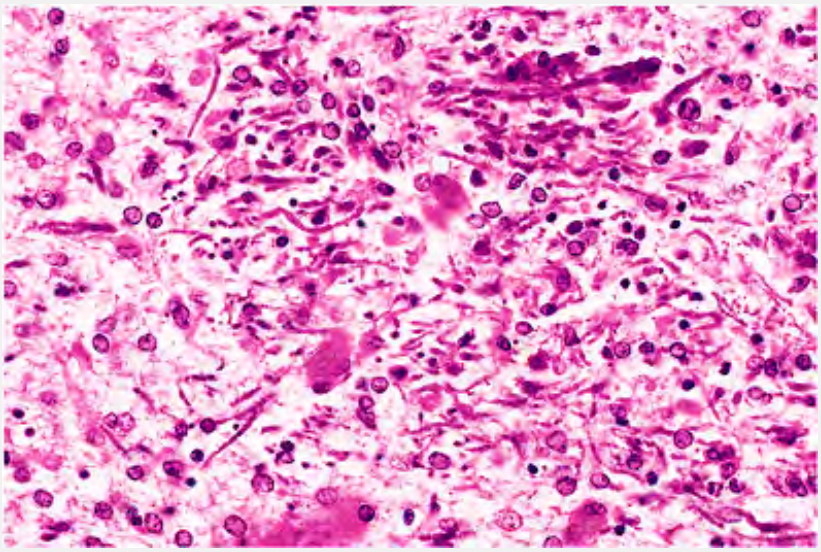

Figure 11.20 Mineralized axons. Clusters of mineralized axons have a superficial resemblance to fungal hyphae.

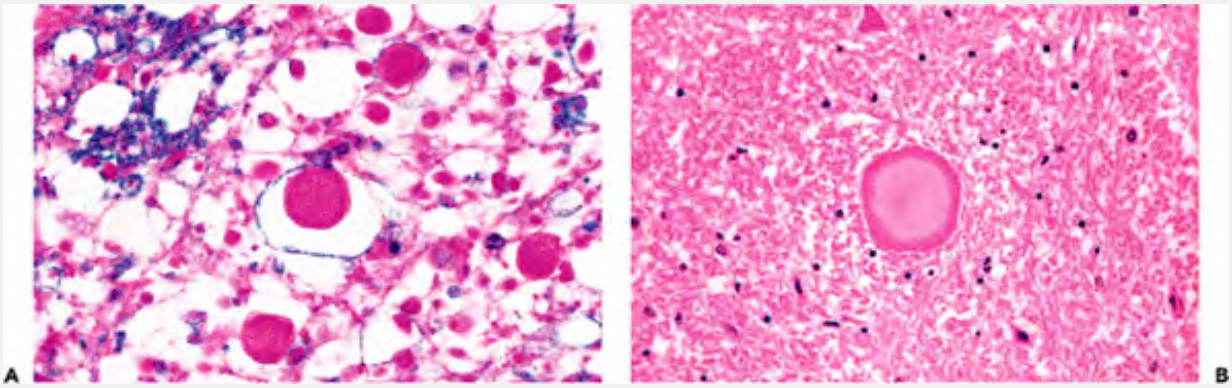

Figure 11.21 Axonal spheroids. A. Focal dilatations known as spheroids are a common axonal reaction to injury that are seen in a wide array of pathologic conditions, including radiation damage and posttraumatic diffuse axonal injury. B. Axonal spheroids are also frequently encountered incidentally in older individuals in the dorsal medulla oblongata (rostral fasciculus gracilis near the nucleus gracilis), where, as in this example, they are often mineralized.

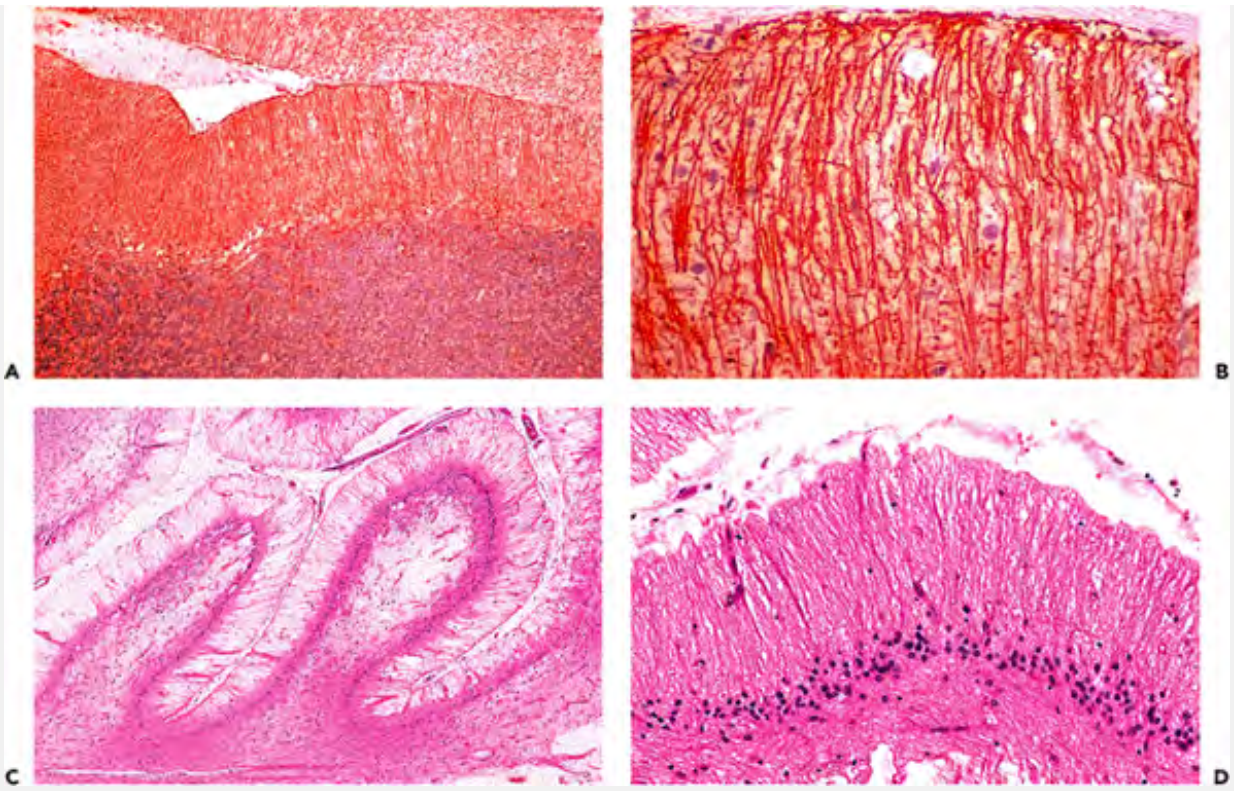

Figure 11.22 Bergmann glia. These astrocytes illustrate the fact that specialization is not confined to neurons. Bergmann astrocytes have cell bodies distributed in a narrow lamina of the cerebellar cortex coextensive with that of the Purkinje cells. Each cell sends an elongated process through the molecular layer to the subpial surface. A. and B. These processes are not usually well seen in healthy cerebellum with routine H&E staining (Figure 11.3A) but can be exquisitely visualized with immunohistochemistry for glial fibrillary acidic protein (GFAP). C. and D. An equally striking unmasking of this elegant architecture is often seen without the use of specialized staining techniques in areas of cerebellar cortex adjacent to healed infarcts, in which the degree of ischemia was sufficient to kill the indigenous neuronal populations but spared the more resistant Bergmann glia. Like other astrocytes throughout the central nervous system, Bergmann glia respond to ischemic insult by proliferating, resulting in an increased thickness of the cell body

lamina referred to as Bergmann gliosis (D).

In gray matter, nuclei of protoplasmic astrocytes cannot generally be distinguished from those of small neurons because the cytoplasm of both blends imperceptibly into the surrounding neuropil and is not normally discernible as a discrete entity. In white matter, it is usually difficult in H&E-stained sections to distinguish fibrillary astrocytes from the much more numerous oligodendroglia. The nuclei of oligodendrocytes are smaller and more hyperchromatic, but usually these two cell types do not fall into two clearly defined groups. In sections stained for myelin, a very small amount of eosinophilic cytoplasm may occasionally, but not invariably, be seen surrounding normal astrocytic nuclei. This helps distinguish this cell from the oligodendrocyte whose cytoplasm, other than the myelin sheath, is not usually apparent by conventional light microscopy (Figure 11.32). Astrocytic cytoplasm becomes much more prominent when astrocytes respond to CNS injury, culminating in the abundant glassy cytoplasm of the gemistocyte (Figure 11.24).

To appreciate the distinctive morphology of the star cell, one must visualize its radiating processes. These threadlike extensions reach out to define a sphere of influence that is many times greater in extent than one would have suspected by looking at an H&E-stained section alone. Historically, this tinctorial feat was achieved through the technically capricious metallic impregnations but now is accomplished with ease and predictability by the immunohistochemical localization of glial fibrillary acidic protein (GFAP) (Figure 11.24). In the case of the fibrillary astrocyte, processes branch infrequently, whereas those of the protoplasmic astrocyte are more numerous and divide more frequently. They are often less well stained with GFAP than the fibrillary types. Neither type of resting astrocyte is as apparent immunohistochemically as are reactive astrocytes.

The polar forms of astrocytes include the pilocytic and Bergmann types. The pilocytic astrocyte is not conspicuous in its native state but becomes so when responding as gliosis and forming Rosenthal fibers. The latter are hyaline, often corkscrew-shaped, eosinophilic structures that are wedged within one of the cell's bipolar processes (Figure 11.25). These structures are occasionally seen in normal brains in the hypothalamus or pineal gland but become much more prominent in gliosis about such lesions as craniopharyngiomas, pineal cysts, cerebellar hemangioblastomas, and chronic lesions of the spinal cord.

The Bergmann astrocytes are confined to a one-to-two-cell thick lamina. Their polar processes extend to the pial surface of the cerebellum and are only faintly seen with difficulty in standard sections. Yet, they are well visualized with immunohistochemistry for GFAP and at the margins of old cerebellar infarcts (Figure 11.22). The Bergmann glia provide an excellent illustration of astrocytic specialization. Their processes are a form of scaffold and serve as a reminder of the cooperative interplay between astrocytes and neurons during embryological development. At that time, the small neurons of the external granular cell layer spiral down the Bergmann processes to reach their final destination in the internal granular cell layer.

Age-Related Inclusions in Astrocytes: Corpora Amylacea

The ubiquitous corpora amylacea are, by far, the most salient astrocytic inclusions encountered in routine sections. These faintly laminated, slightly basophilic polyglucosan bodies accumulate with age and are observed in greatest numbers where astrocytic foot processes are most numerous, particularly around blood vessels and beneath the pia (Figure 11.23). The olfactory tracts of adults are also typically rich in corpora amylacea (Figure 11.45).

The similarity between corpora amylacea and fungal yeast forms such

as cryptococcus is a source of potential diagnostic error since both are strongly positive for methenamine silver, Alcian blue, and PAS (Figure 11.23).

In some individuals, corpora amylacea are strikingly numerous although no pathologic significance has yet been attributed to this abundance.

Astrocytic Reactions to Injury

Although normally among the most morphologically demure of nervous system constituents (only naked nuclei are typically visible on routine H&E histology), astrocytes respond rapidly and dramatically to CNS injury. This response typically consists of two components: hypertrophy and hyperplasia. The initial hypertrophic response, an increase in cell size and cytoplasmic prominence, occurs rapidly following CNS insult. Conspicuous cytoplasm is generally indicative of reactive gliosis and constitutes prima facie evidence of CNS injury. Reactive astrocytes display a broad range of cytoplasmic quantity, from just barely perceptible to robustly embonpoint (Figure 11.24). The latter cells are known as *gemistocytes* (literally stuffed cells). Gliosis may, of course, also present as an increase in the number and density of astrocytic nuclei (hyperplasia) without attendant cytoplasmic prominence. This chronic type of gliosis is frequently subtle and often requires special stains for confirmation and quantitation.

The end result of acute reactive astrogliosis, such as that accompanying cerebral infarction, is frequently a dense fibrillary gliosis (Figure 11.24D). The often-invoked analogy of the astrocyte as the â€œfibroblast of the CNSâ€• (i.e., a ubiquitously distributed cell with mitotic capability that responds with alacrity to a wide range of deleterious stimuli) is quite apt.

A distinctive cytoplasmic inclusion seen in fibrillary astrogliosis is the Rosenthal fiber (Figure 11.25). These strikingly eosinophilic, elongated, anfractuous structures are observed in a wide variety of

reactive states that share in common significant chronicity. Rosenthal fibers are also characteristic of several specific nosologic entities, including

Alexander's disease and, perhaps most widely known, pilocytic astrocytoma. It should be stressed, however, that Rosenthal fibers may be strikingly abundant in the chronically compressed glial stroma surrounding a large number of nonneoplastic conditions (such as syringomyelia) and slowly expanding nonglial tumors (such as craniopharyngioma).

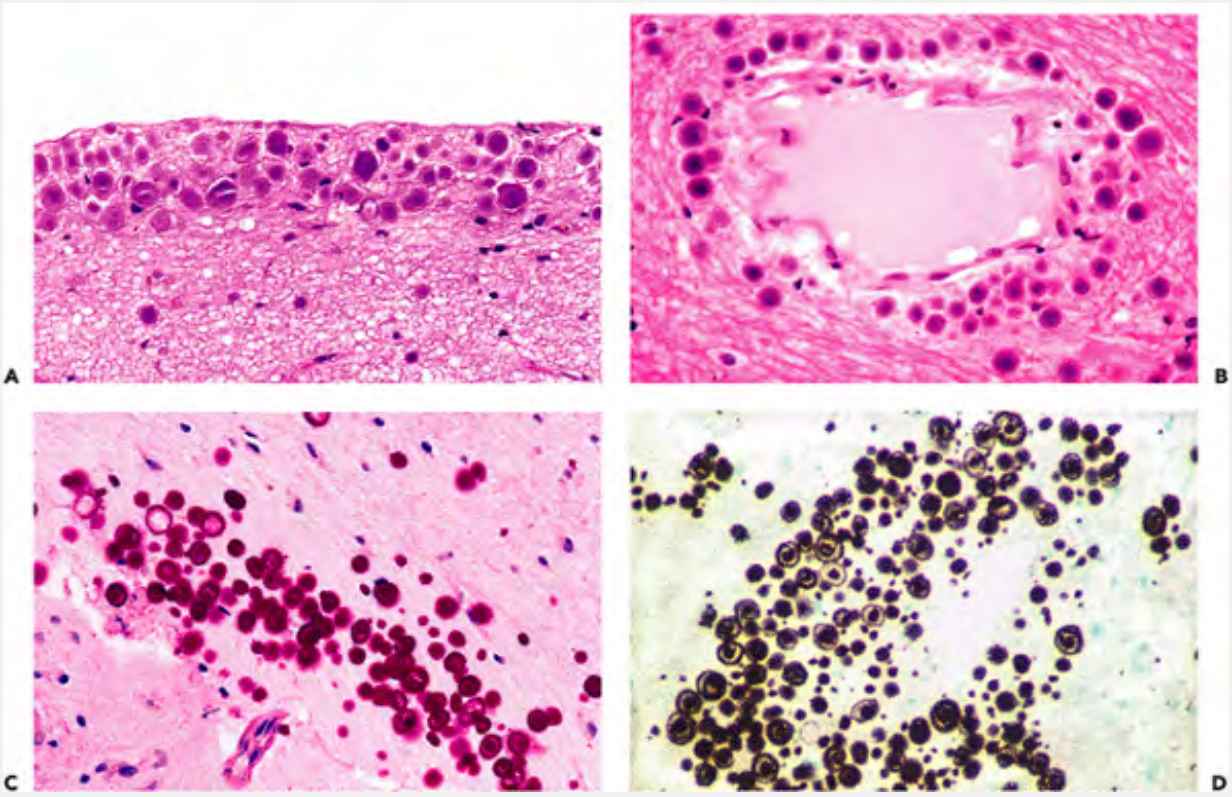

Figure 11.23 Corpora amylacea. These basophilic, lamellated polyglucosan bodies accumulate in astrocytic processes with age, most prominently in subpial (A) and perivascular (B) locations.

Corpora amylacea can resemble fungal yeast forms and show strong positivity for fungal stains such as PAS-fungus (C) and Gomori's methenamine silver (GMS) (D).

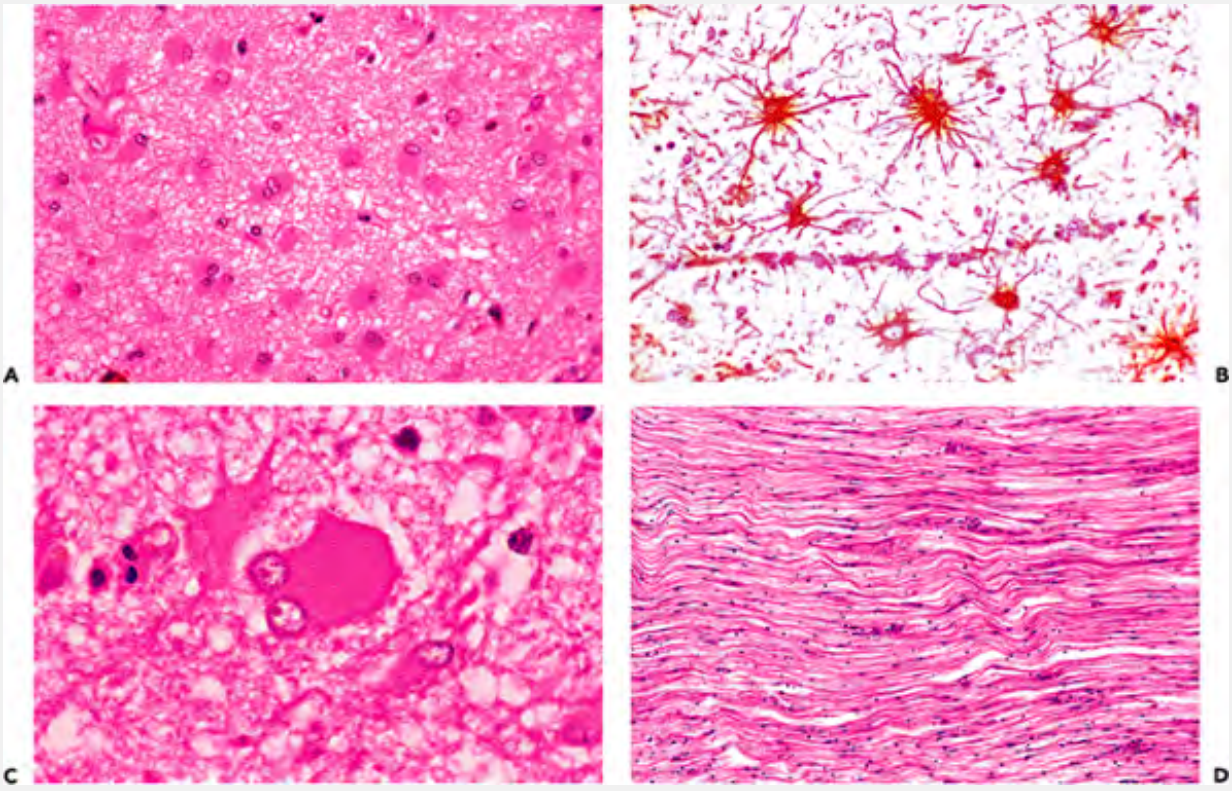

Figure 11.24 Reactive astrocytosis. The plainly visible cytoplasm and processes of the astrocytes (A) is proof of an insult to the nervous system. Under normal conditions, only bare nuclei are usually seen. The extensive, radiating cytoplasmic processes for which the astrocyte received its name are most readily appreciated when reactive astrocytes are immunostained for GFAP (B). Reactive astrocytes have been descriptively classified according to the amount and configuration of visible cytoplasm, and include the aptly named gemistocytic â€œladenâ€• or â€œstuffedâ€• cell (C), and pilocytic â€œhair cellâ€• (D) types. Reactive gemistocytes are typical of the acute astrocytic reaction

to CNS damage whereas dense fibrillary gliosis is commonly seen in longstanding lesions such as healed infarcts.

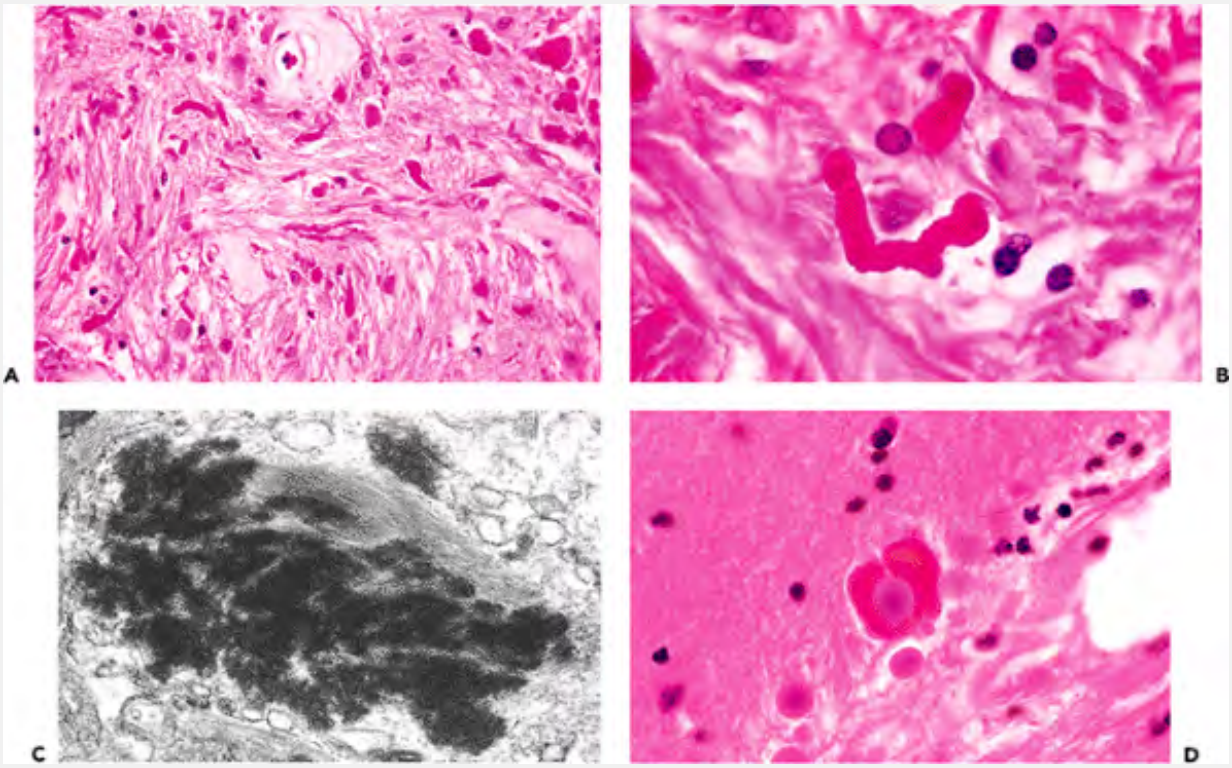

Figure 11.25 Rosenthal fibers. Chronic reactive fibrillary astrogliosis is often accompanied by Rosenthal fiber formation (A). Rosenthal fibers are brightly eosinophilic, lumpy, elongated structures (B) that, by ultrastructural examination, appear as electron-dense amorphous masses surrounded by and merging with dense bundles of glial filaments (C). Occasionally, the two most common intracytoplasmic inclusions of astrocytes (corpora amylacea and Rosenthal fibers) may coexist in the same astrocytic process (D).

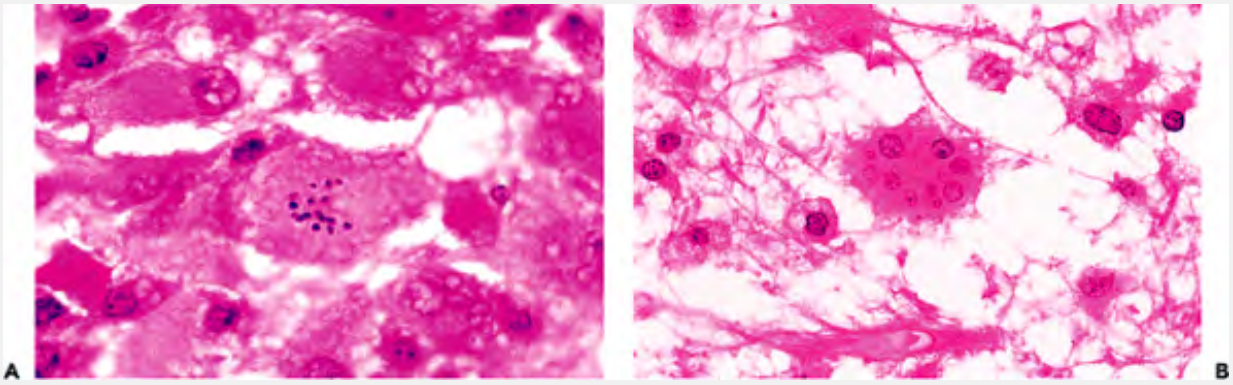

Figure 11.26 Granular mitoses (A) and Creutzfeldt astrocytes (B) in demyelinating diseases. These distinctive reactive astrocytes occur in a variety of pathologic conditions but are particularly characteristic of demyelinating diseases.

There are several specialized forms of reactive astrogliosis that deserve brief description. Reactive astrocytes with multiple small, variably sized, nuclei (micronuclei), termed Creutzfeldt astrocytes, may be seen in a number of reactive states but are especially typical of demyelinative processes (Figure 11.26). A specific type of astrocytic reaction to injury is seen in a variety of hepatic diseases that produce hyperammonemia. The reaction consists of nuclear changes exclusively: swelling with contortion of the nuclear membrane, chromatin clearing, and development of one or two prominent nucleoli (Figure 11.27). In sharp contrast to all of the other types of reactive astrocytes, these Alzheimer type II astrocytes fail to exhibit prominent (or even subtle!) cytoplasm by routine H&E microscopy. Alzheimer type II astrocytes may be seen throughout the neuraxis but are particularly prominent in certain locations, most notably the globus pallidus. Alzheimer type I astrocytes differ from type II astrocytes in displaying abundant eosinophilic cytoplasm (Figure 11.27) and are only seen with frequency in

Wilson's disease (hepatolenticular degeneration). As the eponyms imply, both types of reactive astrocytic morphologies were described by Alois Alzheimer and have no relationship to the dementing disease of the same ilk.

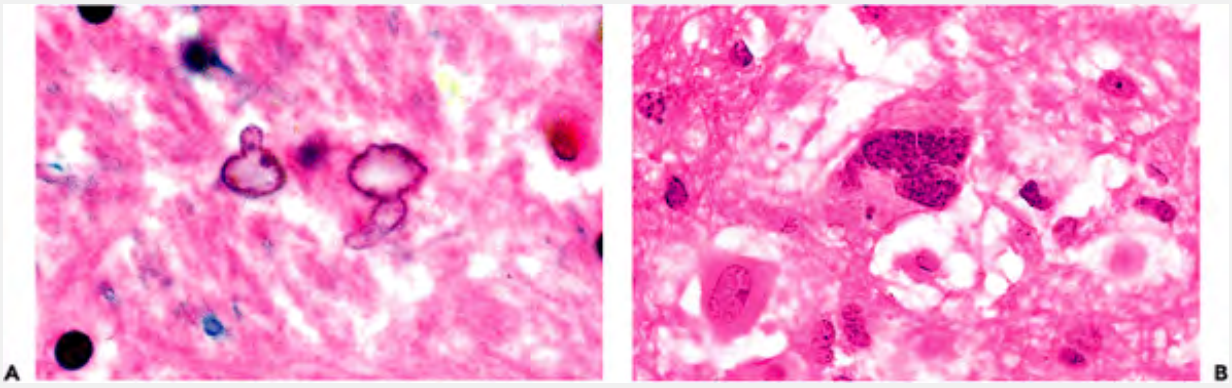

Figure 11.27 Alzheimer astrocytes in hyperammonemia. Two types of reactive astrocytic morphologies, termed Alzheimer type II and Alzheimer type I astrocytes, are associated with hyperammonemic conditions. They were described by Alois Alzheimer and bear his name but have nothing to do with the dementing disease that was also a subject of the famous neurologist's investigations. By far, the most frequently encountered are Alzheimer type II astrocytes (A). Typical features include an enlarged pale nucleus with an irregular contour and one or more small nucleoli. In marked contrast to other types of reactive astrocytes, visible cytoplasm is lacking. Alzheimer type II astrocytes are commonly seen in a wide variety of diseases that result in increased blood ammonia. In contrast, Alzheimer type I astrocytes (B) have large, irregularly lobulated or multiple nuclei and clearly discernible eosinophilic cytoplasm. These cells are not seen in most hyperammonemic diseases, with the exception of hepatolenticular degeneration (Wilson's

disease).

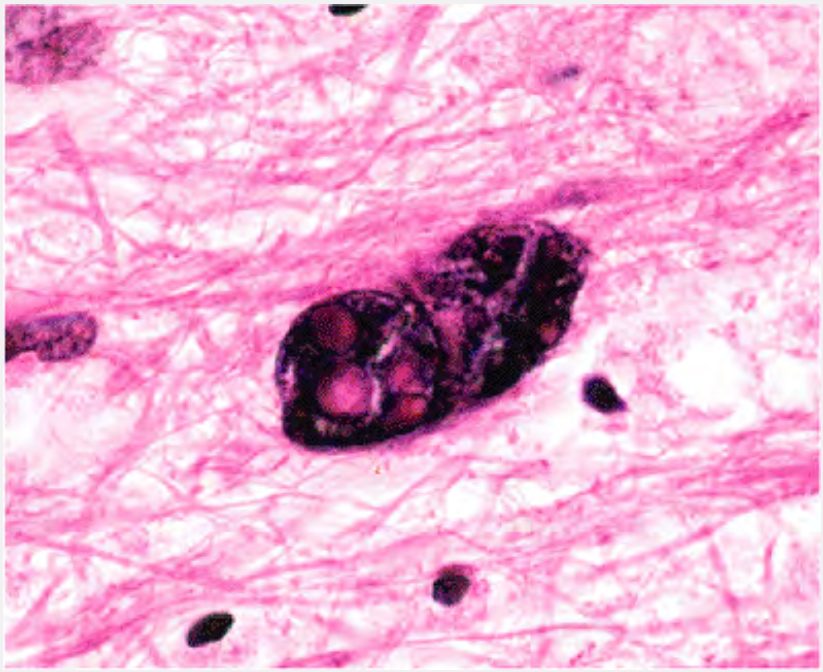

Figure 11.28 Bizarre reactive astrocytes of progressive multifocal leukoencephalopathy (PML). Atypical-appearing reactive astrocytes are sometimes the most striking finding in a PML biopsy and can be mistaken for neoplasia by the unprepared.

Among astrocytic reactions to injury, none is more striking than that observed in some cases of progressive multifocal leukoencephalopathy (PML). Not infrequently, the most eye-catching aspect of a PML biopsy is an alarming nuclear hyperchromatism and pleomorphism exhibited by scattered astrocytesâ€”a vignette that has on more than one occasion elicited a mental frisson from even the most experienced observer (Figure 11.28).

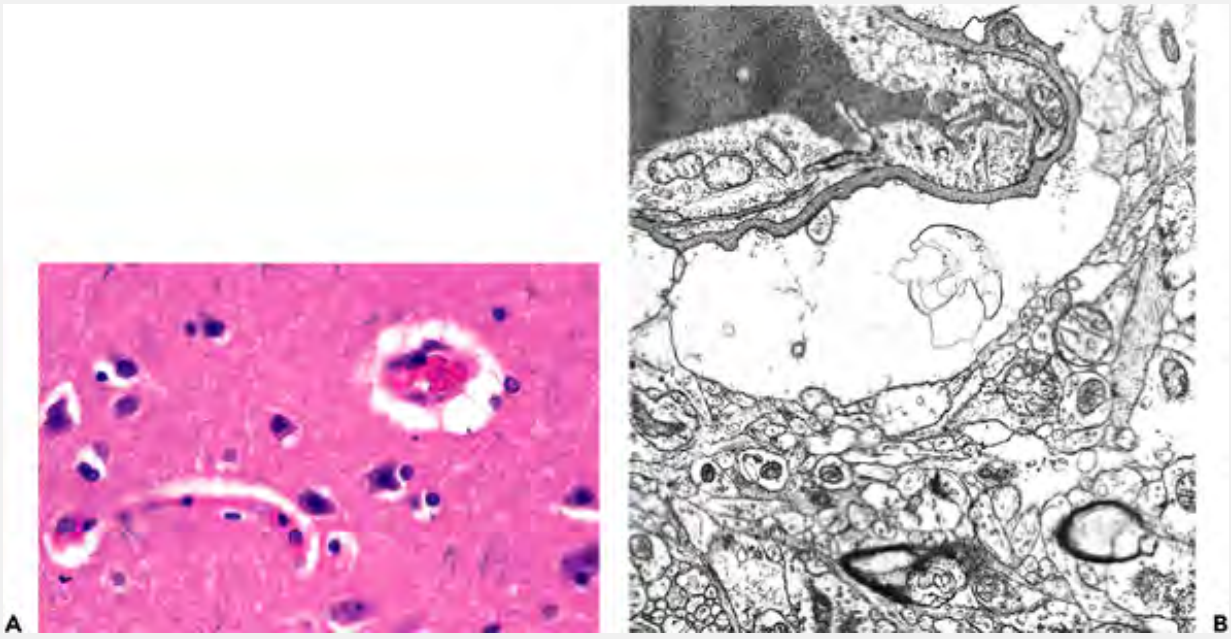

Figure 11.29 Perivascular astrocytic foot process swelling in autolysis. A. This common artifact of routine tissue processing is observed by light microscopy as apparent perivascular clearing of the neuropil. B. As seen by electron microscopy, the clearing is due to dilated astrocyte foot processes.

Perivascular clearing is a routinely observed artifact of autolysis (Figure 11.29). By electron microscopy, these clear spaces are revealed to be greatly dilated astrocytic perivascular foot processes. This phenomenon of water imbibition by astrocytes is seen both as an autolytic change in virtually all autopsy specimens and, when extreme, as a marker of antemortem hypoxic/ischemic injury.

Oligodendroglia

The oligodendroglia (â€œfew branchâ€• glia) are small cells that are active in the formation and maintenance of myelin and in the, as yet, poorly understood capacity of attending to neuronal cell bodies

(satellitosis). In white matter, the oligodendrocytes' obligatory orientation to fiber pathways is occasionally made apparent by a fortuitous plane of section wherein the fascicular distribution of these cells is seen (Figure 11.30). In gray matter, oligodendrocytes are encountered as two to three small, dark nuclei that are pressed against the cell membrane of larger neurons (Figure 11.31). In surgical specimens obtained from infiltrating gliomas, these normal satellite oligodendroglia must be distinguished from infiltrating neoplastic cells that, like their nontransformed counterparts, are attracted to the immediate perineuronal region. Both astrocytomas and oligodendrogliomas

may exhibit such satellitosis, but it is most prominent in the latter neoplasm. Generally, the nuclei of the neoplastic satellites are larger, more pleomorphic, and more coarsely constructed than the normal orbiting cortical oligodendrocytes.

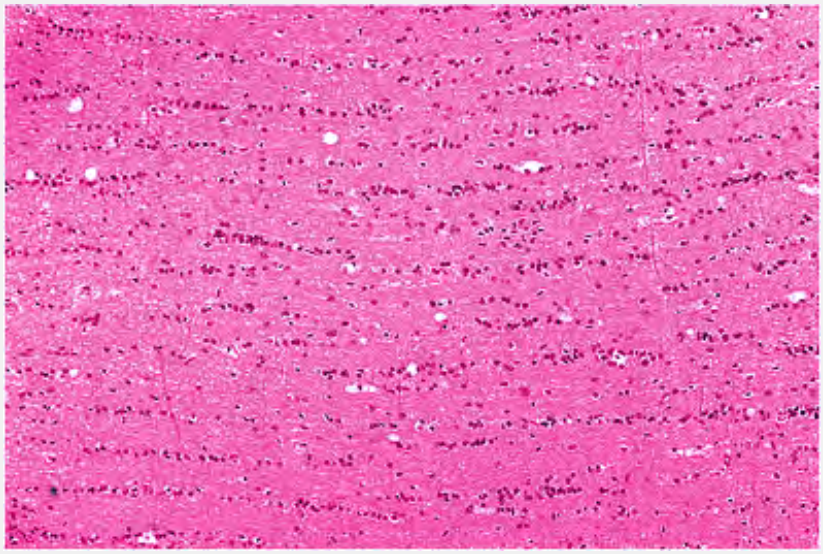

Figure 11.30 Oligodendroglia. As seen here in a white matter tract (the corpus callosum) cut in longitudinal section, these glia may be identified, even at low power, as rows of nuclei that queue up between fascicles of myelinated axons.

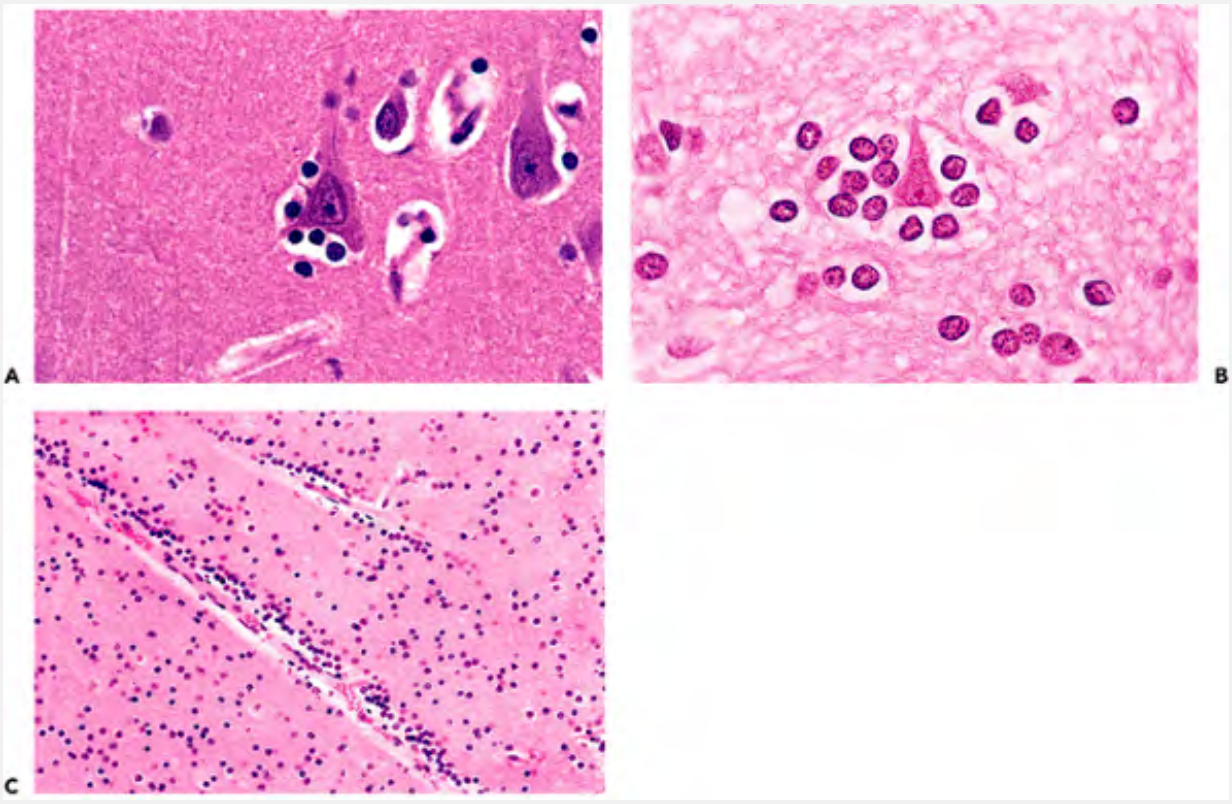

Figure 11.31 Perineuronal satellitosis. A. Normal perineuronal glia consist primarily of oligodendroglial satellite cells, together with occasional astrocytes and microglia. B. This affinity of normal oligodendroglia for neuronal perikarya is often retained by their neoplastic counterparts, oligodendrogliomas, in the form of neoplastic satellitosis. C. Nonneoplastic oligodendroglial hyperplasia can also be seen, as for example in some cases of longstanding epilepsy.

Identification of normal oligodendroglia in both gray and white matter is greatly facilitated by these cells' perinuclear halo (the so-called fried egg appearance), which results from swelling and vacuolation of the cytoplasm (Figure 11.32A). This is analogous to

the perivascular swelling and vacuolation of astrocytic foot processes. In oligodendroglial neoplasms (oligodendrogliomas), the perinuclear halo is a well-known, distinctive, and diagnostically useful feature (Figure 11.32B). Oligodendroglia and their neoplastic counterparts exhibit strong immunopositivity for S-100 protein (Figure 11.32C).

Ependyma

This cuboidal-to-columnar epithelium provides a lining for the CNS ventricular system (Figure 11.33) and specializes focally as a covering for the choroid plexus (Figure 11.47). The ciliated nature of the ependyma is readily appreciable in the child but is generally less so thereafter. Tanycytes (literally, stretched cells) are specialized constituents of the ependyma, the elongated abluminal processes of which reach the subependymal vasculature. Thus, these cells provide a physical link between the ventricular, vascular, and intraparenchymal compartments of the CNS. Tanycytes are

most numerous in the modified ependyma covering many of the circumventricular organs (discussed below). Visualization of these cells is best effected through use of the Golgi's stain.

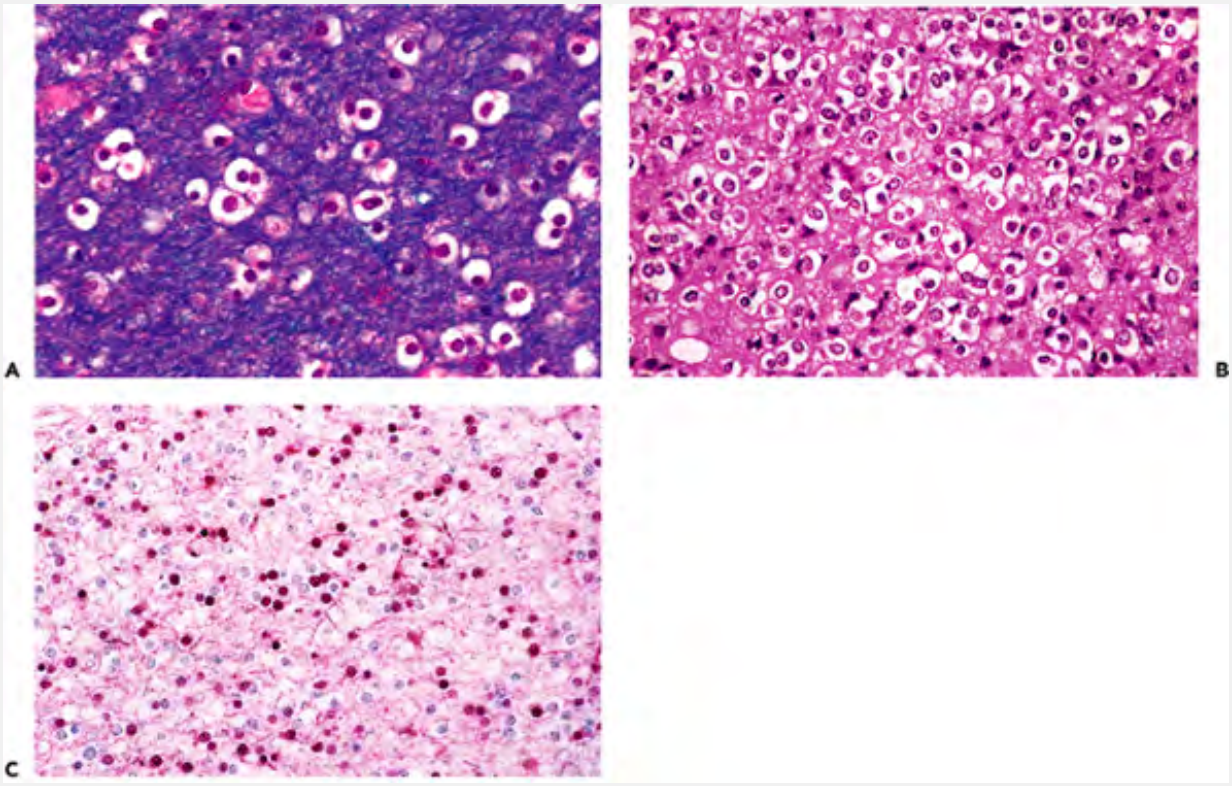

Figure 11.32 Oligodendroglia. In many specimens, oligodendroglia exhibit characteristic perinuclear halos (A). This â€œfried eggâ€• appearance is an artifact of hypoxia/ischemia and delayed fixation and is a useful diagnostic feature that is also exhibited by oligodendrogliomas (B). Oligodendroglia, both normal and neoplastic, typically show strong nuclear immunopositivity for S-100 protein (C).

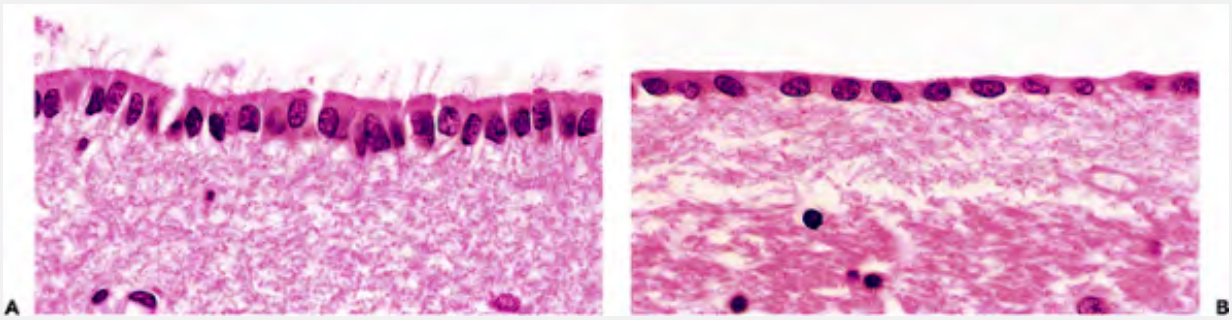

Figure 11.33 Ependyma and the subependymal plate. The lining of the ventricular system varies from a robust ciliated-columnar epithelium (A) to nearly squamous flattened cuboidal (B). The relative abundance of cilia and the height of the ependyma vary with anatomic location, and both decrease with age. The hypocellular fibrillary zone located immediately subjacent to the ependyma is known as the subependymal plate and contains scattered glia as single cells and in small clusters (Figure 11.36B). Glia of the subependymal plate respond to ependymal injury with a proliferative response termed granular ependymitis (Figure 11.36A). Subependymomas originate from the glia of the ependyma and subependymal plate.

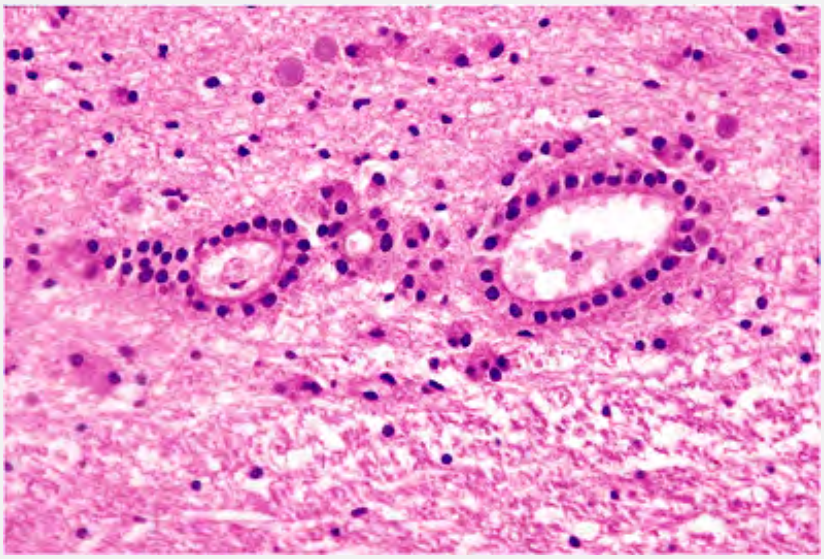

Figure 11.34 Ependymal rosettes. Clusters of ependymal rosettes may be found subjacent to the ependymal lining of the ventricular system throughout the neuraxis. They are particularly common in areas where opposed ventricular surfaces fuse during development, such as at the tips of the lateral ventriculur horns, especially the occipital horns (as illustrated here), and at the lateral angles of the fourth ventricle. These normal rosette clusters are occasionally sampled in surgical specimens and should not be misinterpreted as evidence of disease.

The closely apposed ependymal surfaces of the tips of the lateral ventriculur horns frequently fuse during development, resulting in cords of ependymal cell nests and rosettes. This is especially typical of the distal portions of the posterior horns in the occipital lobes (Figure 11.34). The white matter in such areas appears pale and can simulate the rarefaction seen after ischemic insult. Detached ependymal rosettes may be encountered subjacent to the ventricular lining at any location throughout the neuraxis.

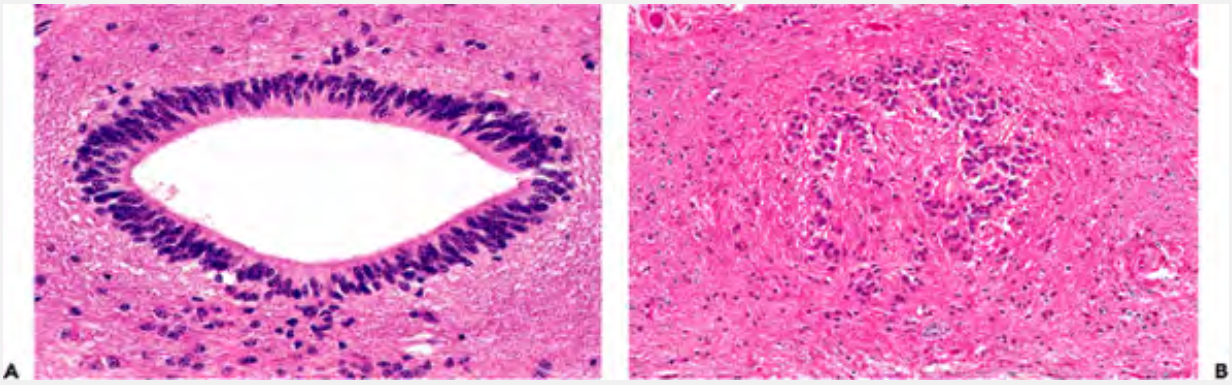

Figure 11.35 Central canal of the spinal cord. A. In the child, the central canal is widely patent and exhibits the ciliated columnar ependymal lining expected in a young individual. B. In contrast, the central canal of adults is typically obliterated over much of its length, with only residual small nests and occasional rosettes of ependymal cells.

The ependyma-lined central canal of the spinal cord is patent in the child (Figure 11.35) but generally becomes obliterated about the time of puberty unless obstructive hydrocephalus is present. In the latter case, the canal may remain patent and even become dilated (hydromyelia). In the normal adult, however, the spinal ependymal cells have completed their role as a generative epithelium and remain as scattered clumps and rosettes (Figure 11.35). Occasional sections of adult spinal cord may exhibit a focally patent central canal.

The primary ependymal response to injury is loss. The resultant focal denudation of the ventricular wall is often accompanied by a proliferation of local cells, the subependymal glia. This nonspecific reaction, termed *granular ependymitis* (Figure 11.36A), is the potential product of a broad range of disparate etiologies, from viral infection to hydrocephalus. It is seen frequently at autopsy as a very

focal, limited response and has, in this setting, little diagnostic significance. The normal ependyma is commonly thrown into folds, termed *plicae,* in many parts of the ventricular system (Figure 11.36B). These normal undulations should not be confused with granular ependymitis.

Microglia and the Monocyteâ€”Macrophage System

Normal Microscopic Anatomy

The small, dark, elongated nuclei of microglia are ubiquitous in the normal brain. They are so small and inconspicuous

in H&E-stained sections, however, that they are rarely noticed (Figure 11.37A). They must be distinguished from the commonly encountered tangential or *en face* sections of endothelial cells, which possess similarly elongated, albeit somewhat larger and plumper, nuclei. Special staining techniques such as the classic silver carbonate method, the more predictable lectin histochemistry (Figure 11.37B), and immunohistochemical markers such as HAM-56 uncloak the dendritic processes of microglia and permit unambiguous visualization. By these techniques, microglia are seen to be strikingly pervasive throughout the CNS parenchyma.

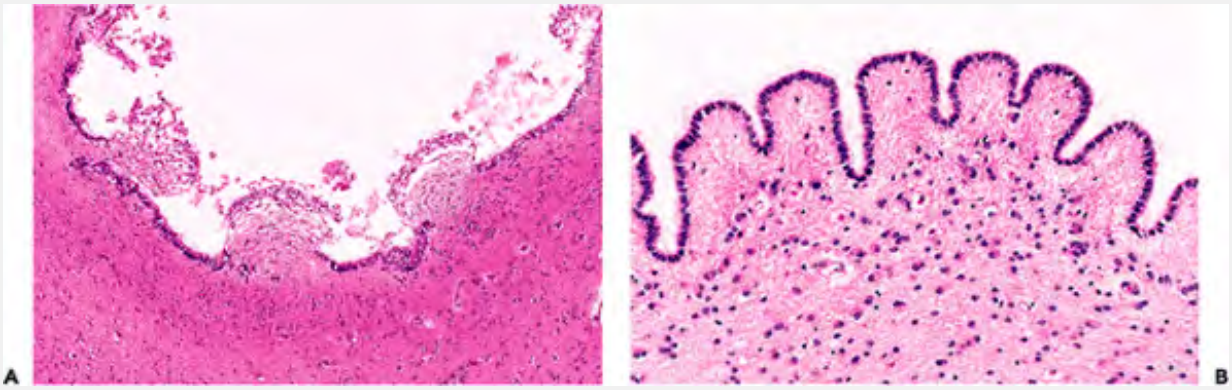

Figure 11.36 Granular ependymitis. A. The combination of focal denudation of the ependyma, coupled with an exophytic fusiform proliferation of the subependymal glia constitutes granular ependymitis. Despite the implication of an inflammatory etiology inherent in the name, this common alteration can result from many diverse insults, ranging from hydrocephalus to viral infections. B. Normal undulations of the ependyma, termed plicae, should not be confused with granular ependymitis.

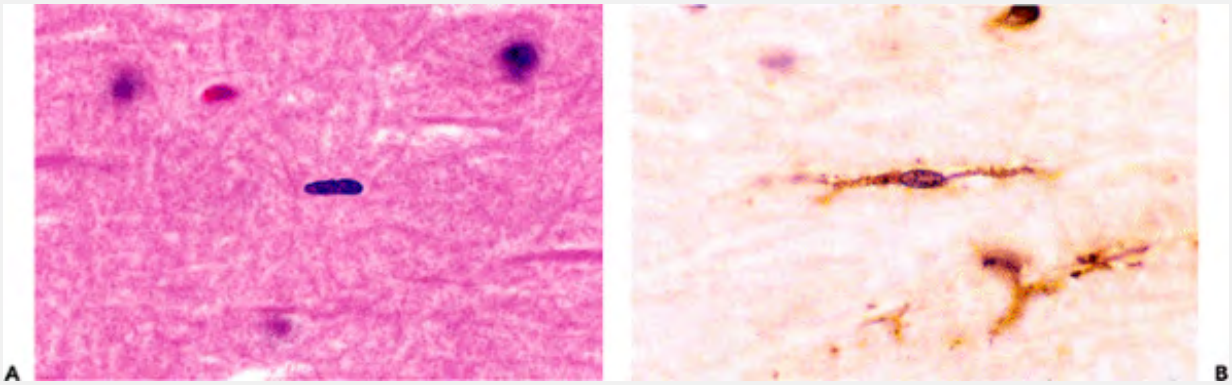

Figure 11.37 Microglia. A. These normally inconspicuous residents of the CNS parenchyma are identifiable by their

classical rod-shaped nuclei on routine H&E staining. B. Dendritic processes, often bipolar, are vividly demonstrated by lectin staining.

Response to Injury

In contrast to the relative passivity and anonymity of microglia in healthy nervous tissue, their activity is by no means subtle when called to action by parenchymal injury. Two variants are seen: microglial nodules and diffuse microgliosis. Microglial nodules (also called microglial stars) are frequent concomitants of viral or rickettsial infection, and they are generally acknowledged to consist of both astrocytes and microglia (Figure 11.38A). The microglia have an elongated shape and are known as rod cells. A form of glial nodule is also seen about degenerating neurons, as in amyotrophic

lateral sclerosis. Diffuse microgliosis is equally distinctive. In this context, the rod-shaped nuclei of microglia may be present in such numbers as to be easily identified (Figure 11.38B); however, the full extent of microgliosis is often best appreciated through immunohistochemistry for markers such as CD68 or HAM-56 (Figure 11.38C).

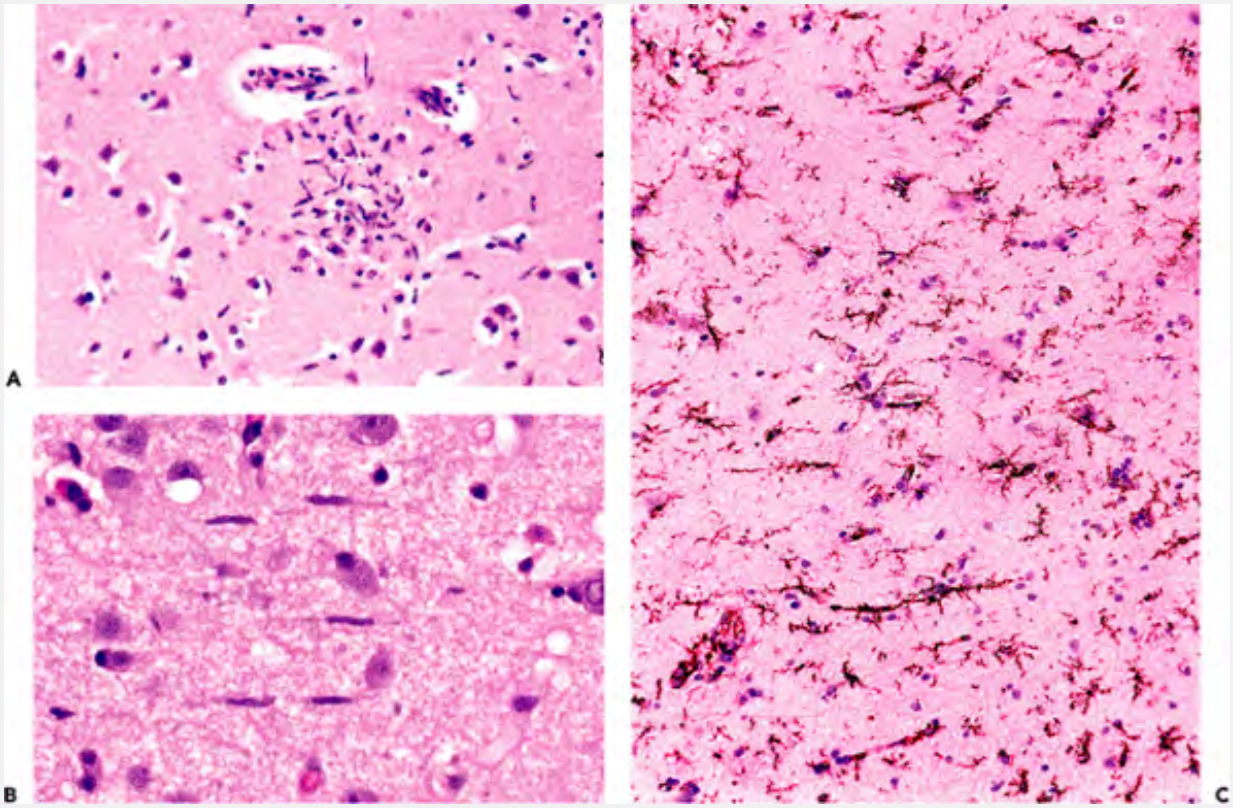

Figure 11.38 Microglia. Reactive microglia may assume several forms. Microglial nodules (A) are focal hypercellular collections of microglia together with reactive astrocytes that commonly form as a response to viral and rickettsial infections. In diffuse microgliosis (B), seen in a variety of conditions, including ischemia, the characteristic elongated rod-shaped nuclei can be identified on H&E-stained sections; however, the true extent of their presence is more accurately visualized through immunohistochemistry, as seen here with HAM-56 (C).

Destruction of nervous tissue, by whatever mechanism, generally elicits a macrophage response that serves to clear nonviable debris (Figure 11.39A). Both the activation of autochthonous tissue microglia and the diapedesis of blood monocytes are sources for these scavengers. The weight of evidence suggests that the

recruitment of blood monocytes plays a predominant role in large lesions such as infarcts but that the supply of indigenous cells is sufficient for lesser insults.

Macrophages are proliferative cells (Figure 11.39A, B). Mitotic figures will, therefore, usually be present in disease processes that elicit a macrophage response, such as infarction and demyelination. They should not be interpreted as suggestive of a neoplastic process. Macrophages often contribute substantially to the cellularity of tissue samples and, depending on preservation and fixation conditions, their identity may not always be obvious. For example, in some specimens, clearing of the macrophage cytoplasm lends an appearance similar to that of oligodendroglial cells, to the extent that, together with the attendant hypercellularity, an infiltrating glioma might be suspected. In such instances a number of antibodies, such as CD68 or HAM-56, can be used to identify the macrophage component (Figure 11.39C, D).

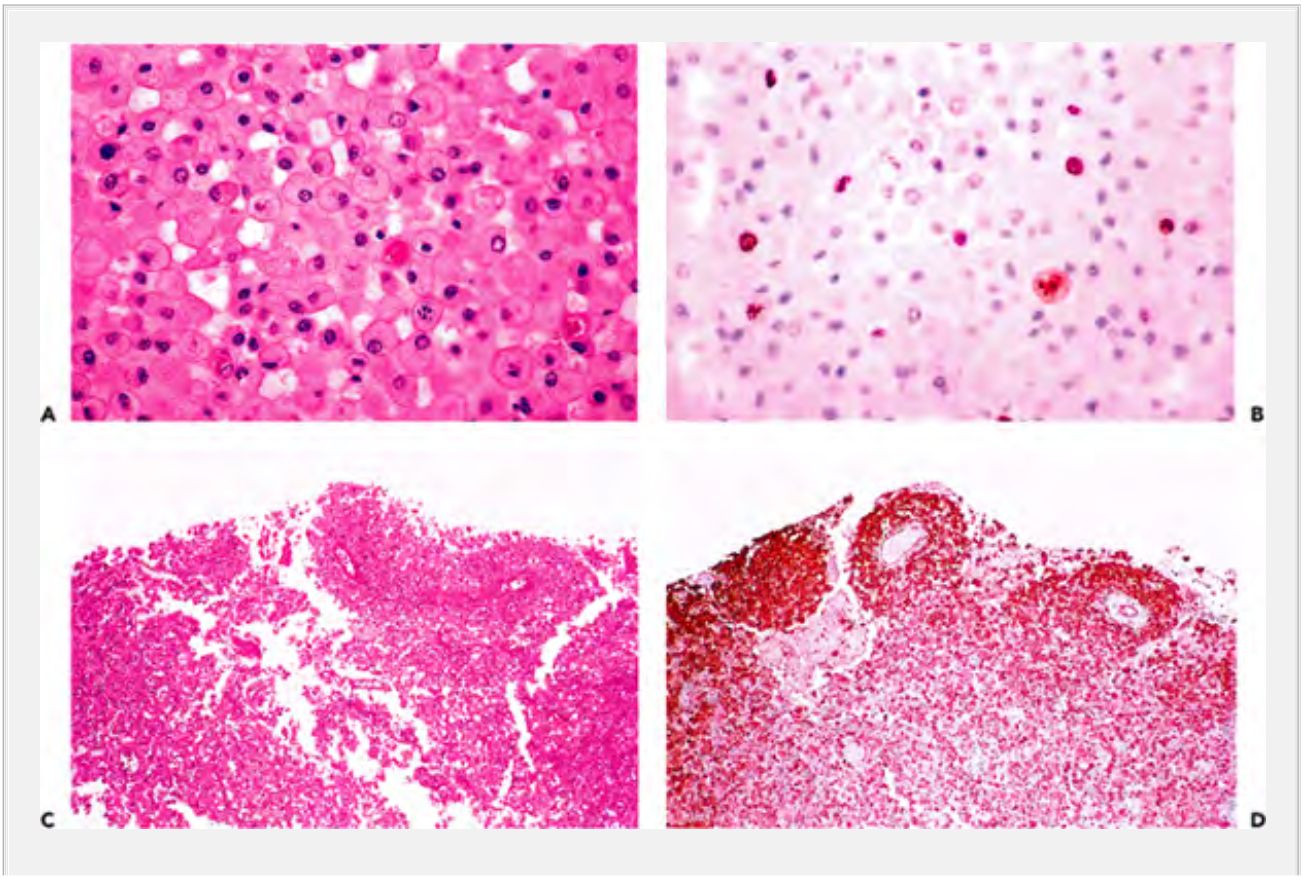

Figure 11.39 Macrophages. Discrete cell boundaries and vesicular cytoplasm serve to distinguish macrophages from other cellular constituents of the nervous system (A). Cognoscenti will be familiar with the colorful appellations given these cells in former times, including gitter cells (lattice cells) and compound granular corpuscles. Macrophages are mitotically active cells, and populations responding to CNS injury are readily labeled with proliferation markers such as the monoclonal antibody MIB-1 (B). Mitotic figures are, thus, to be expected in tissue samples from a wide range of nonneoplastic conditions that elicit a macrophage response, including infarcts and demyelinative diseases. In hypercellular biopsies (C), macrophages can be distinguished from other cellular constituents by a number of commercially available antibodies such as HAM-56 (D).

Specialized Organs of the Central Nervous System

Pineal Gland

The pineal body (epiphysis, or conarium) presents a singular histologic appearance among CNS tissues with a prominently lobulated architecture (Figures 11.40,11.41). This glandular appearance might be mistaken for carcinoma by the unwary, and it can be difficult to distinguish the normal pineal gland from a well-differentiated pineocytoma in small surgical specimens.

Generally present in the pineal gland after puberty are corpora arenacea (acervuli cerebri, or brain sand). These mineralized concretions accrue with age and confer the radiologic hyperdensity that, before the era of computerized tomography and magnetic

resonance imaging, made the normal midline position of the pineal gland a useful radiologic landmark (Figure 11.40).

The increase in corpora arenacea with senescence is accompanied by gradual gliosis and cystic change, with attendant effacement of the lush glandular appearance of the pineal gland seen in the earlier decades of life. The ubiquitous incidental pineal cysts typically have densely gliotic walls with scattered Rosenthal fiber formation (Figure 11.41C). The investing leptomeninges of the pineal contain arachnoid cell nests that occasionally give rise to meningiomas of the pineal region (Figure 11.41D).

Pineocytes express strong immunopositivity for the neuronal marker synaptophysin (Figure 11.42A). This useful phenotypic marker is retained by most pineal parenchymal neoplasms. In addition to pineocytes, the pineal gland also

contains an indigenous population of astrocytes whose distribution is revealed by immunostaining for GFAP (Figure 11.42B).

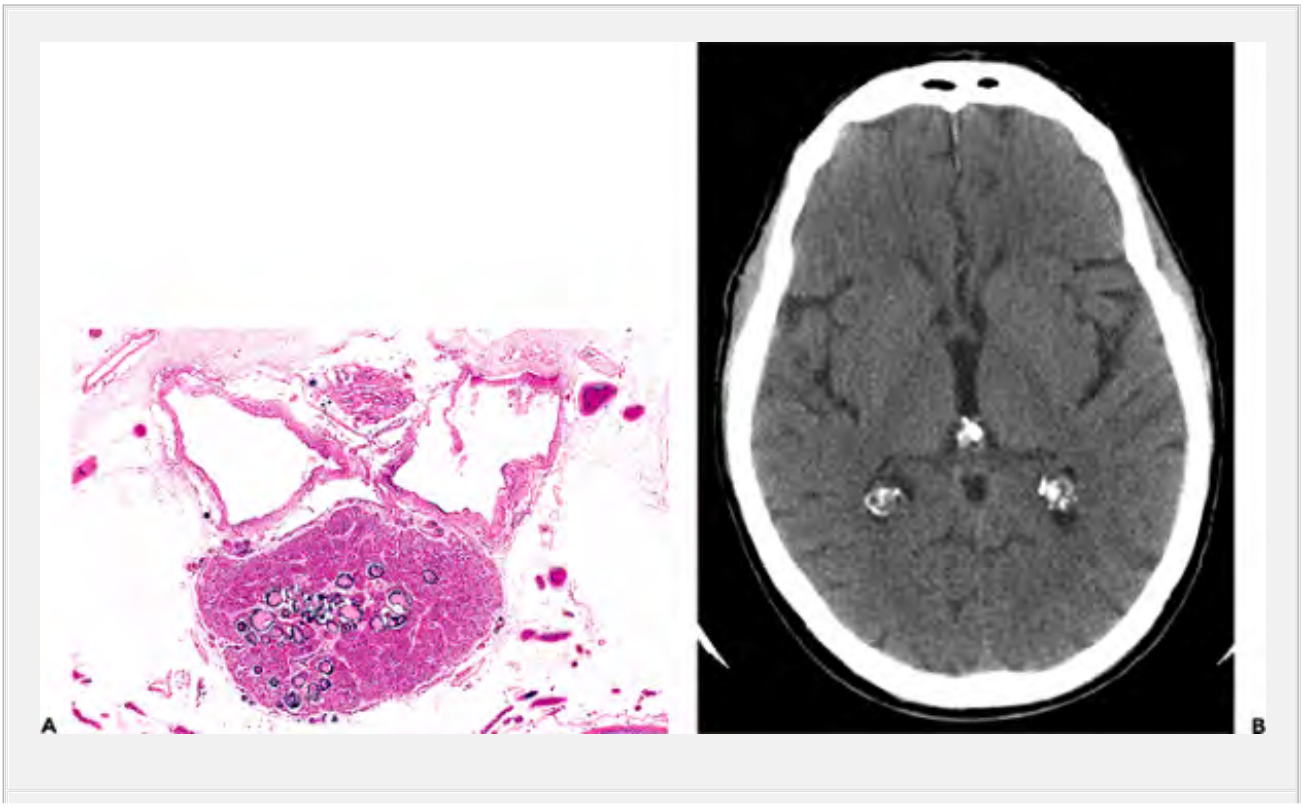

Figure 11.40 Pineal gland (epiphysis). A. Whole mount of a cross section of the pineal gland and its environs in situ reveals the typical mineralized concretions variously referred to as corpora arenacea (sand bodies), acervuli cerebri (little heaps), or simply brain sand. Superior to the pineal gland are the paired internal cerebral veins, and between them is the suprapineal recess of the third ventricle, which is lined with ependyma and often contains a tuft of choroid plexus. The loose connective tissue (redundant leptomeninges), in which all of these structures are located, is called the velum interpositum. B. The calcification of the pineal gland increases with age and was, thereby, quite useful as a radiographic midline marker prior to the advent of contemporary high resolution neuroimaging modalities. Also seen in this CT scan of a normal adult brain are prominently calcified tufts of choroid plexus (glomera choroidea; also Figure 11.47) in the atria of both lateral ventricles.

Median Eminence and Infundibulum

The median eminence, infundibulum, and neurohypophysis display a unique constellation of morphologic features that reflect their specialized neuroendocrine functions. The background stroma is highly spindled (Figure 11.43A) and contains nodular microvascular tangles termed gomitoli (Figure 11.43B), spherical granular bodies called Herring bodies (Figure 11.43C; Table 11.1), which are storage sites for oxytocin and vasopressin, and scattered cells bearing lipofuscin-like brown pigment (Figure 11.43D). The constellation of features comprising a highly spindled background, vascular tangles, and granular bodies gives this region of the CNS more than a passing resemblance to pilocytic astrocytoma. An additional incidental finding, particularly in tissue sections of the infundibulum, is the presence of small clusters of granular cells, termed granular cell tumorlets (Figure 11.43E).

Olfactory Bulbs and Tracts

The intracranial components of the olfactory apparatus (the olfactory bulbs and tracts) have a very distinctive histologic appearance. Familiarity with these structures is useful, not only for the neuropathologist, but also for the general surgical pathologist who may encounter them in resections performed as part of the surgical treatment for regionally invasive entities of the nasal and paranasal sinuses. In such situations, the surgical pathologist may be called upon to render an intraoperative frozen-section assessment of tissue resected superior to the cribriform plate. The ability to recognize the normal histologic features of olfactory bulb tissue is, thus, of more than pedantic importance.

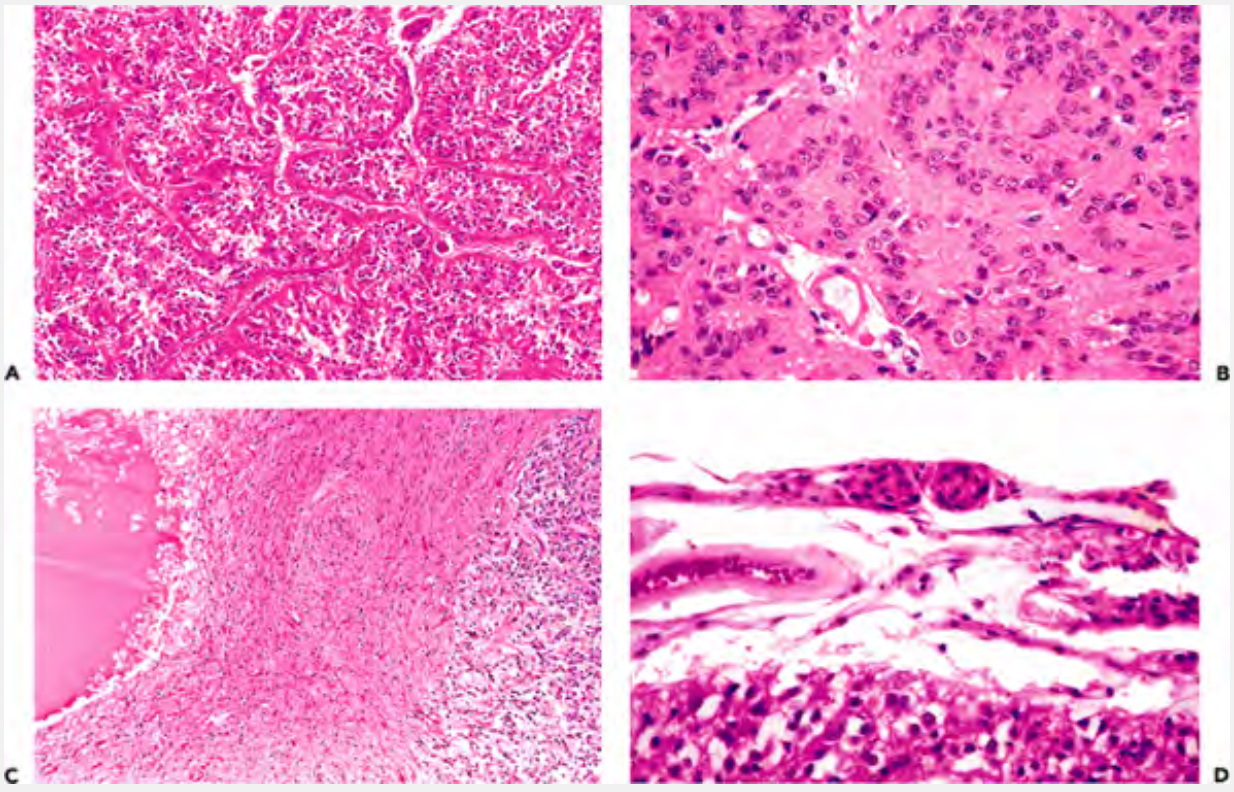

Figure 11.41 Pineal histology. The pineal gland has a richly

glandular architecture that is totally unlike any other region of the central nervous system. Salient features include a prominent lobular organization with connective tissue septa (A) and pineocytic rosettes (B). The latter impart a distinctly neuroendocrine character. Two additional histologic features of note are the ubiquitous incidental pineal cysts, whose walls (C) typically exhibit astrogliosis with scattered Rosenthal fibers, and arachnoid cell nests of the investing velum interpositum (D) that occasionally provide a source for meningiomas arising in this region.

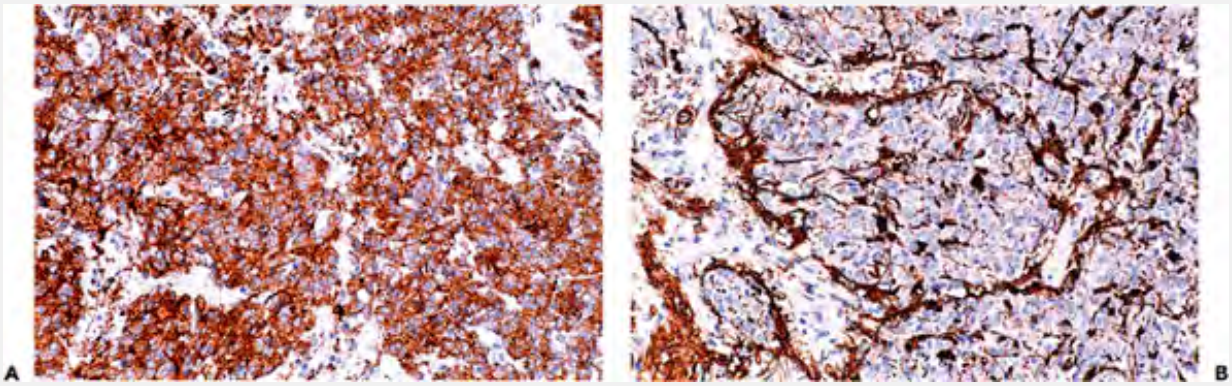

Figure 11.42 Pineal immunohistochemistry. A. Pineocytes (and their neoplastic progeny, the pineal parenchymal tumors) are strongly immunopositive for the neuronal marker synaptophysin.B. As expected, the indigenous population of pineal astrocytes are well visualized with antibodies directed against GFAP.

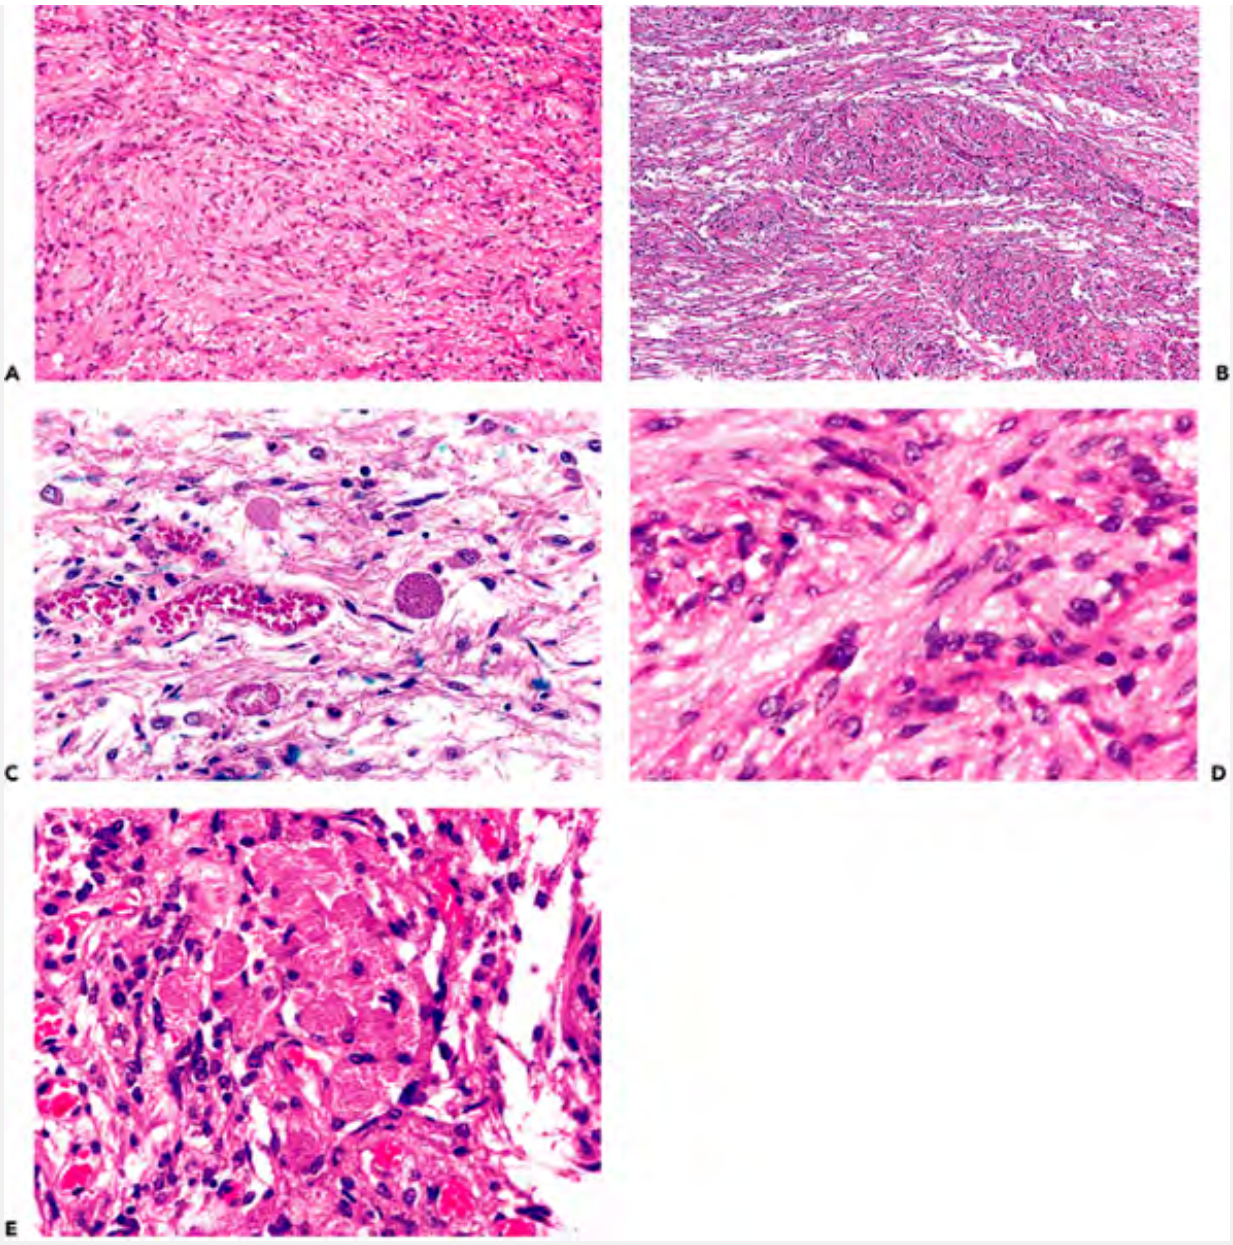

Figure 11.43 Median eminence, infundibulum, and neurohypophysis. This unique region of the CNS exhibits three distinguishing histologic features: A. a highly spindled stroma comprised of pituicytes; B. prominent capillary tangles of the hypothalamohypophyseal portal system called gomitoli; C. and spherical, eosinophilic axonal specializations for the storage of oxytocin and vasopressin called Herring bodies. This constellation of highly spindled stroma, vascular tangles, and granular bodies

bears a resemblance to pilocytic astrocytoma. D. The presence of lipofuscin-like pigment is also very characteristic. E. Small clusters of granular cells (granular cell tumorlet) may be seen, particularly in the infundibulum, as an incidental finding but occasionally reach a sufficient size to produce compression of the infundibulum and subsequent clinical presentation with mildly elevated serum prolactin (stalk effect).

Table 11.1 Granular Bodies in the CNS: Three Etiologic Classes

Normal

Reactive
Granular bodies adjacent to vascular malformations and conditions with iron deposition
Neoplastic
Pilocytic astrocytoma
Pleomorphic xanthoastrocytoma
Ganglioglioma

The olfactory bulb has a laminar organization (Figure 11.44). The outer layer is composed of spindled bundles of entering olfactory nerve fascicles intermixed with distinctive spherical, anuclear areas (termed glomeruli) that constitute specialized zones of synaptic contact between olfactory nerve collaterals and the dendrites of intrinsic olfactory bulb neurons. Mitral cells are large neurons, so-named for a resemblance of the perikaryon shape to a bishop's mitre. Their cell bodies are located in a lamina deep to that of the

glomeruli (Figure 11.44). The deepest layer consists of a thick lamina of granular cell neurons that are comparable in size to those of the cerebellum and dentate gyrus.

The olfactory tracts (sometimes incorrectly referred to as olfactory nerves) extend posteriorly from the olfactory bulbs. They are triangular in cross section and, in adults, are notable for their profuse numbers of corpora amylacea (Figure 11.45).

Choroid Plexus

The choroid plexus is a specialized organ of the CNS that is responsible for the production of cerebrospinal fluid. It is found in the body, atrium, and temporal horns of the lateral ventricles, in the interventricular foramina of Monro, in the roof of the third ventricle, and in the roof and lateral recesses of the fourth ventricle. The frontal and occipital horns of the lateral ventricles and the aqueduct of Sylvius

are devoid of choroid plexus. The plexus is most obvious in the atria of the lateral ventricles (Figures 11.40B, 11.47), where prominent bilateral tufts (glomera choroidea) are formed. Cystic xanthomatous change is a common incidental finding in these botryoid structures. The plexus is also a normal resident in the subarachnoid space of the cerebellopontine angle (CPA) cisterns, which it reaches from the lateral recesses of the fourth ventricle by protruding through the foramina of Luschka (Figure 11.46). The paired foramina of Luschka (lateral), which open laterally into the ventral basilar CPA cisterns, are to be distinguished from the single foramen of Magendie (median), which opens in the dorsal midline into the cisterna magna.

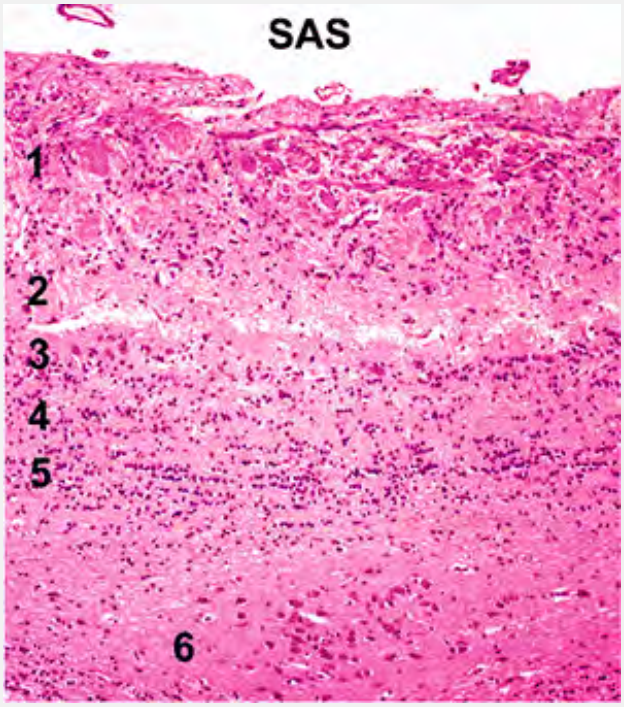

Figure 11.44 Olfactory bulb. The olfactory bulbs have a very distinctive laminar organization. The most superficial layer, termed the glomerular layer (*1*) is covered by the leptomeninges (pia-arachnoid) and the subarachnoid space (*SAS*). The glomerular layer displays a unique architecture, with spindled olfactory nerve fascicles intermixing with spherical hypocellular synaptic zones called glomeruli (*1*). Deeper layers include the external plexiform (*2*), mitral cell (*3*), internal plexiform (*4*), and granular cell layer (*5*). Deeper still is the anterior olfactory nucleus (*6*). A working familiarity with olfactory bulb histology is essential for the surgical pathologist because this structure is frequently seen in the frozen section laboratory during resection of superior nasal cavity tumors that may invade the cribriform plate and overlying olfactory bulbs.

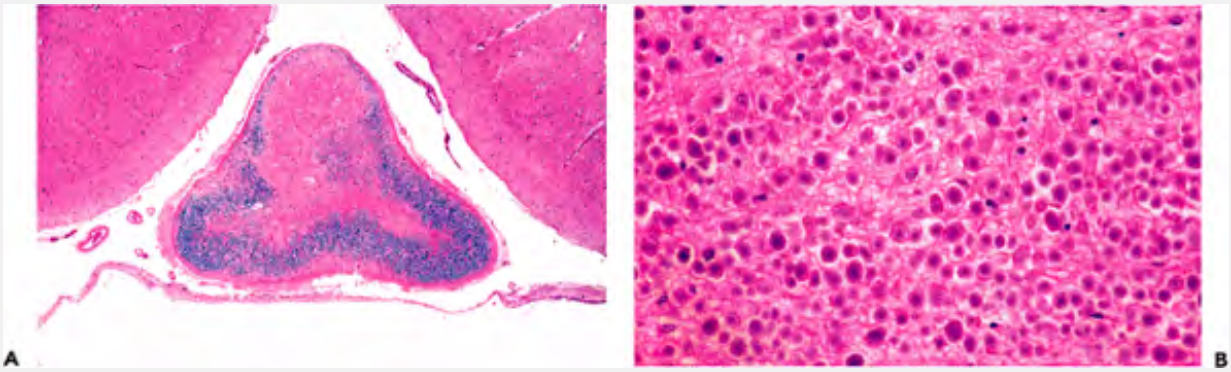

Figure 11.45 Olfactory tracts. A. The olfactory tracts contain myelinated fiber bundles and are roughly triangular in cross section. B. A distinctive feature of the tracts frequently observed in adults is their remarkable content of corpora amylacea.

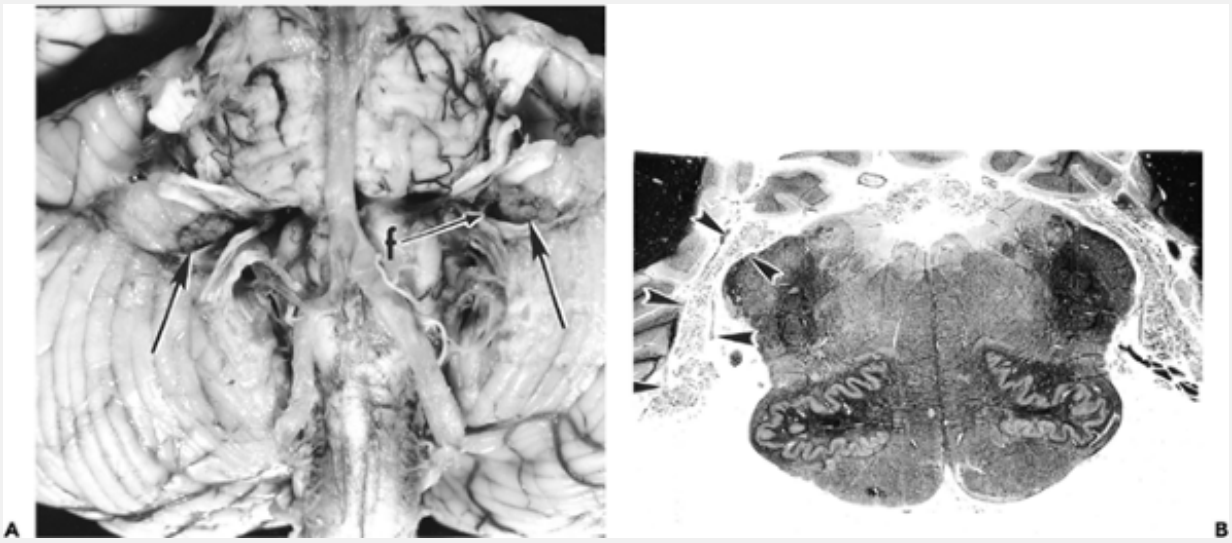

Figure 11.46 Choroid plexus. A. Small tufts of choroid plexus are normally visible on the basal surface of the brainstem in the cerebellopontine angle (*arrows*), and indicate the location of the

lateral foramina of Luschka (*f*) from which they protrude. The dusty discoloration of the inferior medulla is due to the presence of leptomeningeal melanocytes (Figure 11.57). B: The ependyma-lined sleeve of the lateral recess of the fourth ventricle (*arrowheads*), together with the protruding tuft of choroid plexus, is referred to in the older literature as the â€œflower basket of Bochdalekâ€• or â€œcornucopia.â€• Pieces of the ependymal cuff are often seen adherent to the lateral aspect of the medulla in autopsy brainstem sections and should be recognized as a normal finding.

Microscopically, choroid plexus consists of invaginated fronds of vascular leptomeninges covered by an ependyma that is modified to become a highly secretory epithelium (Figure 11.47). The cells are larger and more cobblestoned than those of the adjacent ependyma (Figure 11.33). In addition to collagen and blood vessels, small nests of meningothelial (arachnoid) cells are common normal habituÃ©s of the choroid plexus; whorls of these cells frequently give rise to psammoma bodies (Figure 11.47G). Nonspecific deposition of mineral salts also occurs commonly throughout the connective tissue core with increasing age and accounts for most of the plexuses' radiodensity. An additional aging change of no specific pathological significance is cytoplasmic vacuolization of the ependyma-derived lining cells (Figure 11.47E).

Circumventricular Organs

The circumventricular organs (CVOs) comprise a diverse group of specialized CNS centers that share two morphologic features: a periventricular location and vasculature that lacks the characteristic blood-brain barrier properties found throughout the rest of the brain and spinal cord. There are six CVOs: the pineal gland, subfornical organ, organum vasculosum of the lamina terminalis, area postrema, subcommissural organ, and the median eminence-infundibulum-

neurohypophysis (Figures 11.48,11.49). Of these, all except the subcommissural organ are fully developed in the adult human (Figure 11.49). The subcommissural organ, which is located on the ventral surface of the posterior commissure just caudal to the pineal gland, is a very prominent CVO in most vertebrates (Figure 11.49B); although it generally regresses near the end of gestation in humans, vestigial remnants may be present (Figure 11.49C).

Intradural Elements of the Peripheral Nervous System

The major intradural representatives of the peripheral nervous system are the cranial and spinal nerves and small autonomic fibers in the adventitia of blood vessels. In all of the cranial nerves except cranial nerve VIII, the transition from central to peripheral nervous system occurs within 2

mm of the pial surface. In the eighth cranial nerve, the central nervous system extends out along the nerve for a centimeter or so to the level of the internal auditory meatus. At this point, the transition occurs between the medial central nervous system segment and the lateral peripheral segment that emerges from the apparatus for hearing and balance (Figure 11.50). The myelin of the central nervous system is formed by oligodendrocytes, whereas that of the peripheral nervous system is formed by Schwann cells. Peripheral nerve is noted for its content of interstitial collagen and the elongated nuclei of Schwann cells.

E
F
G

Figure 11.47 Choroid plexus. Choroid plexus produces the cerebrospinal fluid and is found in the lateral ventricles, foramen of Monro, roof of the third ventricle, and fourth ventricle. The largest tufts are called the glomera choroidea and are located in the atria of the lateral ventricles (A). Choroid plexus consists of a botryoid, finely tufted tangle of epithelium-covered fibrovascular tissue (B) that is formed during embryonic development through an invagination of the vascular pia-arachnoid into the ventricular system, whereby it acquires its covering of modified ependyma. Two common incidental findings on MRI scans and in autopsy specimens are cystic change (C) and xanthogranulomas (D), both of which may be bilateral. Histologically, choroid plexus is seen to be covered by simple cuboidal epithelium (modified ependyma); in adults, each choroid epithelial cell bears a single prominent paranuclear cytoplasmic vacuole (E). An additional aging change seen in normal choroid plexus is calcification, which occurs in two forms: nonspecific deposition of calcium salts in the collagenous stroma (F) and as psammoma bodies (G). The latter arise from meningothelial cell nests that normally are present in the choroid plexus as a result of the stroma's embryologic derivation from the leptomeninges.

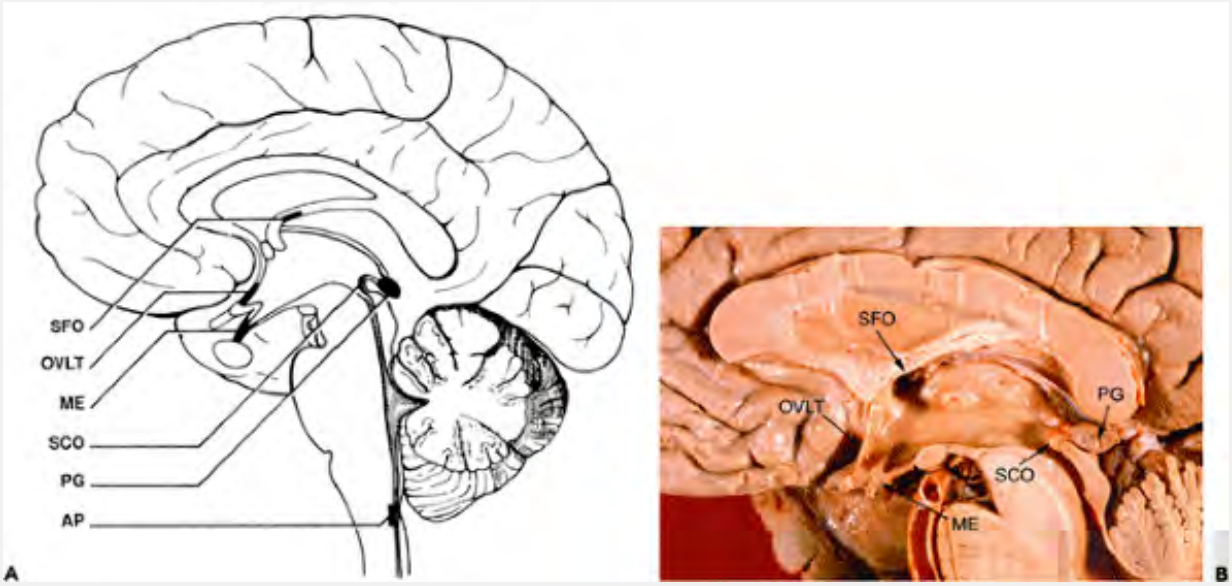

Figure 11.48 Circumventricular organs. The circumventricular organs share a midline or paramidline position, proximity to the ventricular system, and lack of the usual blood-brain barrier. The subcommissural organ is present in the developing fetus but is vestigial in the adult. (*AP,* area postrema; *ME,* median eminence and infundibulum; *OVLT,* organum vasculosum of the lamina terminalis; *PG,* pineal gland; *SCO,* subcommissural organ; *SFO,* subfornical organ)

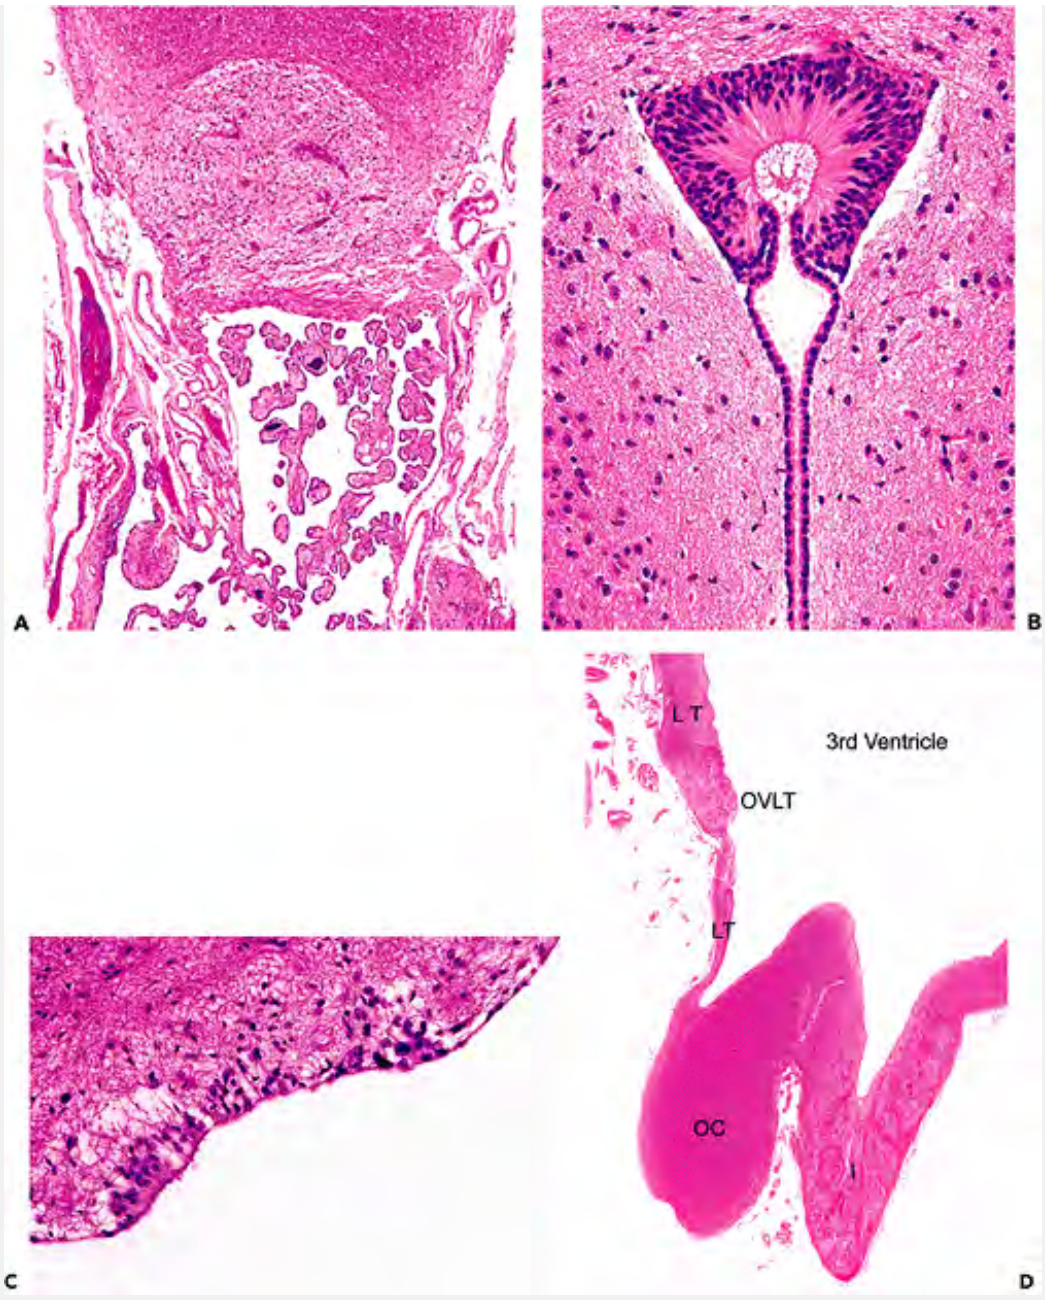

Figure 11.49 Circumventricular organs (CVOs). Histologically, all of the CVOs except for the subcommissural organ are very similar, with a loose neuropil that is highly vascular and lacks a blood-brain barrier as illustrated by the subfornical organ (A). The subcommissural organ is located in the region of the pineal gland just beneath the posterior commissure in the posterior

dorsal third ventricle and is highly developed in most mammalian species, as illustrated by the mouse (B). In humans, the subcommissural organ is vestigial, but remnants are occasionally encountered (C). The organum vasculosum of the lamina terminalis (*OVLT*) and the median eminence-infundibulum-neurohypophysis are two additional CVOs that are in contact with the third ventricle (D). (*I,* infundibulum; *LT,* lamina terminalis; *OC,* optic chiasm)

Two additional intrathecal components of the peripheral nervous system may pique interest on fortuitous encounter. The first is the so-called microneuroma, which is usually found in the parenchyma of the spinal cord or, more rarely, the medulla (Figure 11.51). These structures consist of a Gordian knot of unmyelinated axons that have been hypothesized to arise secondary to traumatic injury of peripheral nerve roots whose regenerating axons follow penetrating spinal or medullary arteries into the CNS parenchyma along the Virchow-Robin spaces. According to the hypothesis, the tapering perivascular spaces ultimately block further advance of the regenerating axons and, thereby, result in the observed neuroma.

An additional component of the peripheral nervous system that occasionally arouses interest is the unmyelinated terminal nerve (variously termed *nervus terminalis, cranial nerve zero,* and *terminal nerve*), which courses in the subarachnoid space covering the gyri recti of the orbital

surface of the frontal lobes (Figure 11.52). Although usually composed of multiple small anastomosing fascicles, it occurs as a single trunk in some specimens and can be quite striking. Rarely, intrafascicular ganglion cells may be observed.

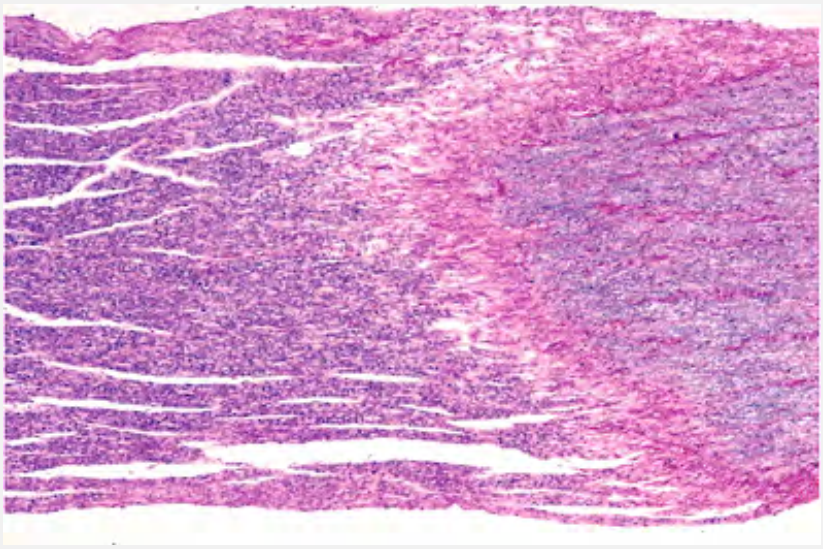

Figure 11.50 Transition zone from central to peripheral nervous system myelin. For cranial nerve VIII (vestibulocochlear), this transition occurs in the vicinity of the internal acoustic meatus.

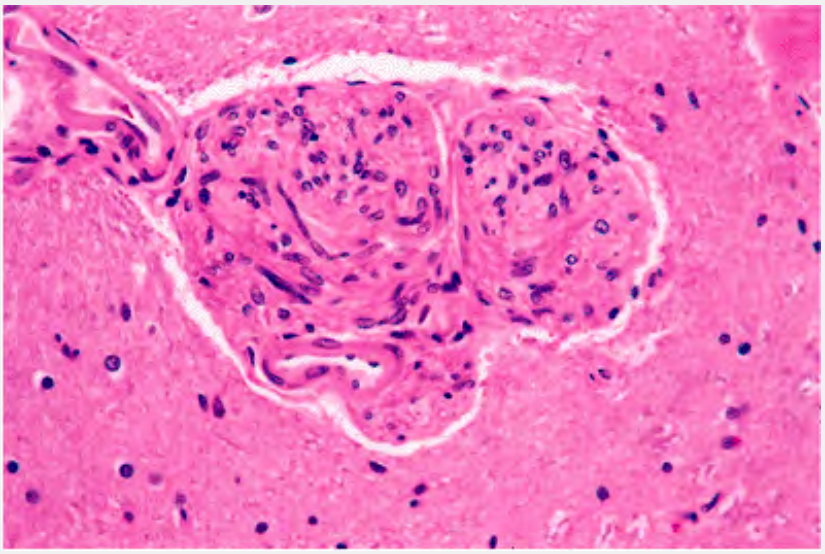

Figure 11.51 Microneuroma. These tangled balls of unmyelinated axons are most often encountered in the spinal

cord, less often in the medulla, as an incidental finding in an otherwise unremarkable specimen.

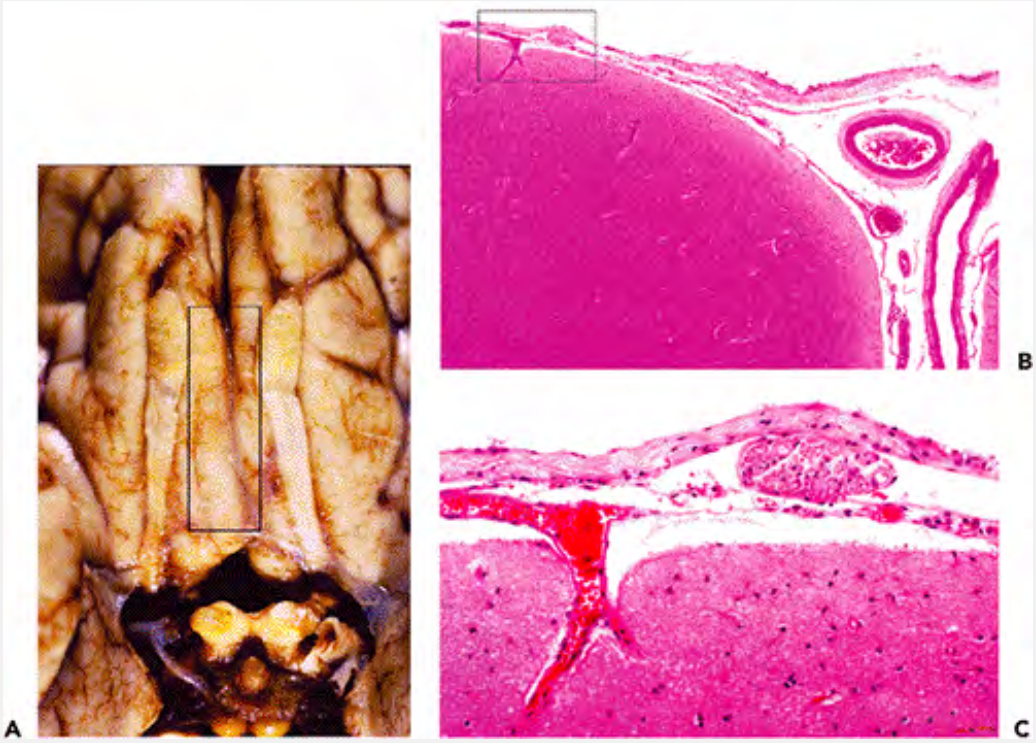

Figure 11.52 Cranial nerve zero. Cranial nerve zero (CN0), also known as the terminal nerve or nervus terminalis, is present in humans as a plexus of small peripheral nerve fascicles found in the subarachnoid space that covers the gyri recti that lie between the olfactory bulbs and tracts (A). Tissue sections taken through the gyri recti that include the overlying leptomeninges (B) will often include a terminal nerve fascicle cut in cross section (C). The small peripheral nerve fascicles of cranial nerve zero are one potential source of subfrontal schwannomas.

Meninges

Dura Mater (Pachymeninx)

The dura mater is composed of two tightly annealed layers of fibrous connective tissue. The outer layer functions as the periosteum of the cranium, whereas the inner meningeal layer is joined to the arachnoid membrane by weak intercellular junctions and focally forms the four dural reduplications that compartmentalize the cranial cavity: the falx cerebri, falx cerebelli, tentorium cerebelli, and diaphragma sellae. The two layers of the dura separate to accommodate the dural venous sinuses; the inner meningeal layer is pierced by draining veins and by arachnoid villi. The latter conduct cerebrospinal fluid back into the venous circulation and are obvious over the superior parasagittal convexities of the cerebral hemispheres, where they project into the superior sagittal sinus (Figure 11.53). They are present in all other major venous sinuses, as well. They are often observed along the posterior margin of the cerebellar hemispheres in relation to the sinus confluens and the transverse venous sinuses. Small villi are also present intraspinally.

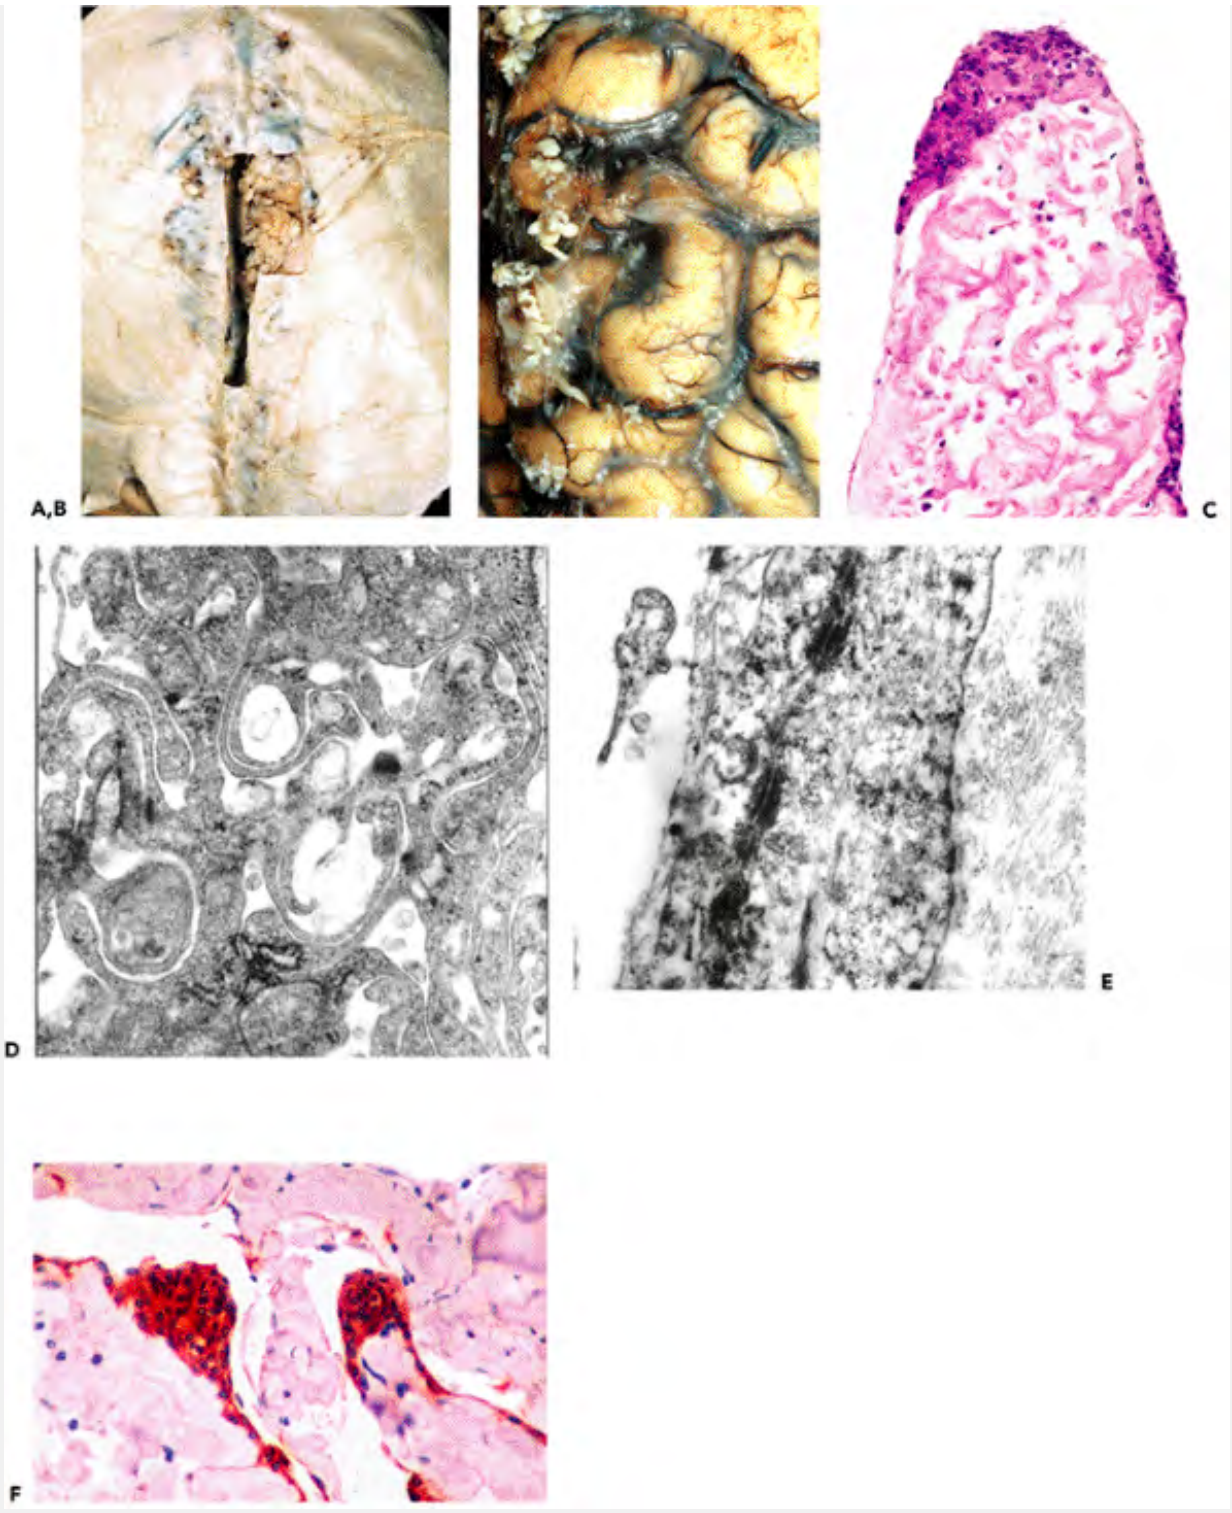

Figure 11.53 Arachnoid granulations (villi). Specialized structures of the arachnoid membrane serve to return

cerebrospinal fluid from the subarachnoid space to the venous circulation and are accordingly found in relation to all major dural venous sinuses. The villi are most prominent in the superior sagittal (A, B) and transverse sinuses. With advancing age, they undergo collagenous hypertrophy, as seen in these micrographs, and may then be referred to as pacchionian bodies. The enlarged villi remodel the overlying bone of the inner table of the calvarium to produce small pits termed pacchionian foveolae, or foveolae granulares. Nests of meningothelial cells may be seen anywhere along the arachnoid membrane but are especially prominent in the apical regions of arachnoid granulations, where they are termed arachnoid cap cells (C), and in the arachnoid covering the orbitofrontal cortex. Normal meningothelial cells are innately inclined to form whorls and psammoma bodies, two features that are often retained by their neoplastic counterparts, meningiomas. The meningothelial cells of the arachnoid membrane, including the cap cells, serve an epithelial function. Accordingly, they possess elongated, intertwined cell processes (D) that are tightly spot welded together by numerous desmosomes (E) and exhibit strong immunopositivity for epithelial membrane antigen (EMA) (F). Like the tendency to form whorls and psammoma bodies, these epithelial phenotypic traits are retained by neoplastically transformed meningothelial cells and serve as useful diagnostic features of the vast majority of meningiomas, which otherwise exhibit a very broad range of light microscopic morphologies.

The epithelial properties of arachnoid granulations are reflected ultrastructurally in elongated, interdigitating cell processes bonded together with desmosomes and immunohistochemically, by positivity for epithelial membrane antigen (Figure 11.53). These features are also characteristic of meningiomas.

With age, the deposition of collagen enlarges the arachnoid villi, which are then referred to as pacchionian bodies (Figure 11.53). Such large granulations frequently press through the overlying roof of the superior sagittal sinus and its lateral lacunae to produce small pits or depressions in the inner table of the calvarium. These are known as the *foveolae granulares* or *pacchionian foveolae.* Portions of the dura, particularly the falx cerebri and parasagittal dura associated with the superior sagittal sinus, often calcify nonspecifically with age. Calcification may also be seen in association with chronic renal failure. Focal ossification is sometimes encountered as an incidental finding.

Pia-Arachnoid (Leptomeninges)

The arachnoid forms a continuous sheet immediately subjacent to the dura. Based on descriptive and experimental ultrastructural observations, it is now generally accepted that the dura and arachnoid exist in vivo as a physically continuous tissue, with sparse but unequivocal intercellular junctions linking these two historically discrete membranes. The storied subdural space has, thus, taken its rightful place in the pantheon of neuromythology, alongside brain lymphatics and the syncytial theory of the neural net. It has been proposed that the term *spatium subdurale* be eliminated from the standardized nomenclature of Nomina Anatomica. Nevertheless, there is no disputing the fact that the interface between dura and arachnoid constitutes the weak link or path of least resistance for pathologic processes that tend to disrupt the meninges. It seems unlikely that such venerable terms as *subdural hematoma* will soon be cashiered.

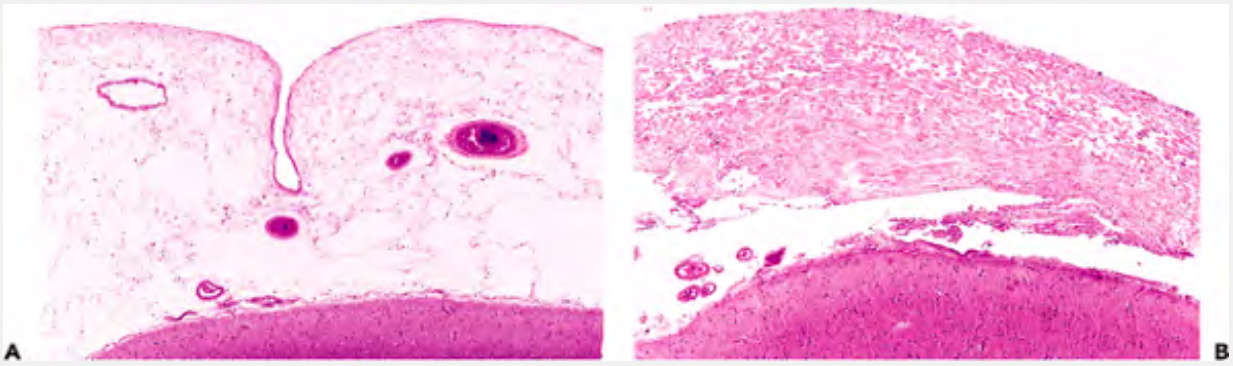

Figure 11.54 Subarachnoid space. A. The subarachnoid space is delimited by the arachnoid membrane externally and by the pia mater internally. Delicate arachnoid trabeculae course between these two membranes. B. In adults, gradual collagen deposition in the subarachnoid space results in grossly appreciable â€œcloudingâ€• of the leptomeninges. This aging fibrosis appears grossly as diffuse opacification with focal plaques and small punctate nodules. It is characteristically most prominent along the dorsal cerebral convexities adjacent to the superior sagittal sinus.

The pia mater and arachnoid are often considered as a single delicate covering of the brain and spinal cord (the pia-arachnoid, or leptomeninges). The arachnoid is connected to the pia by delicate strands termed *arachnoid trabeculae* (Figure 11.54A). In the young, the arachnoid is crystal clear, but with age it becomes gradually thickened. The extent of this change varies considerably. In some cases, it is severe enough to raise concern about a pathologic processâ€”meningitis and meningeal carcinomatosis being the two usual suspects. This normal age-related arachnoid thickening is typically most pronounced over the dorsal parasagittal cerebral convexities. Microscopically, it results from the deposition of dense

bundles of collagen (Figure 11.54B), analogous to the collagenous hypertrophy of arachnoid villi that occurs prominently in the same vicinity.

Focal nests of arachnoid cells (also called meningothelial cells) may be seen throughout the arachnoid membrane but are concentrated over the arachnoid villi (arachnoid cap cells) (Figure 11.53C). These distinctive elements become more obvious and more clustered with advancing age and, in the adult, often form whorls with centrally placed psammoma bodies. At this point, the resemblance of these nests to those of the meningioma is inescapable. As mentioned previously, small nests of arachnoid cells are also present intraventricularly in the vascular connective tissue core of the choroid plexus (Figure 11.47G). Both normal and neoplastic meningothelial cells are immunoreactive for epithelial membrane antigenâ€”an understandable property considering the epithelial phenotype of the desmosome-containing meningothelial cell (Figure 11.53).

The dorsal leptomeninges of the thoracic and lumbosacral spinal cord occasionally contain white waferlike

plaques (Figure 11.55), a finding that is often termed *arachnoiditis ossificans.* In fact, in the majority (but not all) of cases, these brittle lesions are roentgenographically and histologically devoid of bone or mineral. Rather, they most often consist of laminated, hyalinized fibrous tissue. True arachnoiditis ossificans generally occur in the context of prior symptomatic inflammation or trauma to the leptomeninges. Hyalin plaques, in contrast, are typically discovered as an incidental finding at autopsy in the absence of any relevant clinical history.

Figure 11.55 Hyaline plaques of the spinal leptomeninges. These plaques are common incidental findings at autopsy and occur most frequently in the dorsal spinal arachnoid, although they may occasionally be seen in the cerebral leptomeninges as well.

Like the dura, the pia is traditionally divided into two layers: the epipia, which covers the surface of the CNS parenchyma and surrounds the vasculature, and the intima pia, which extends into the CNS parenchyma as the posterior median and intermediate septa of the spinal cord. Classically, three specialized structures of the epipia are recognized: the denticulate ligaments on either side of the spinal cord, the linea splendens adjacent to the anterior spinal artery, and the filum terminale. All three structures are composed primarily of dense bundles of collagen.

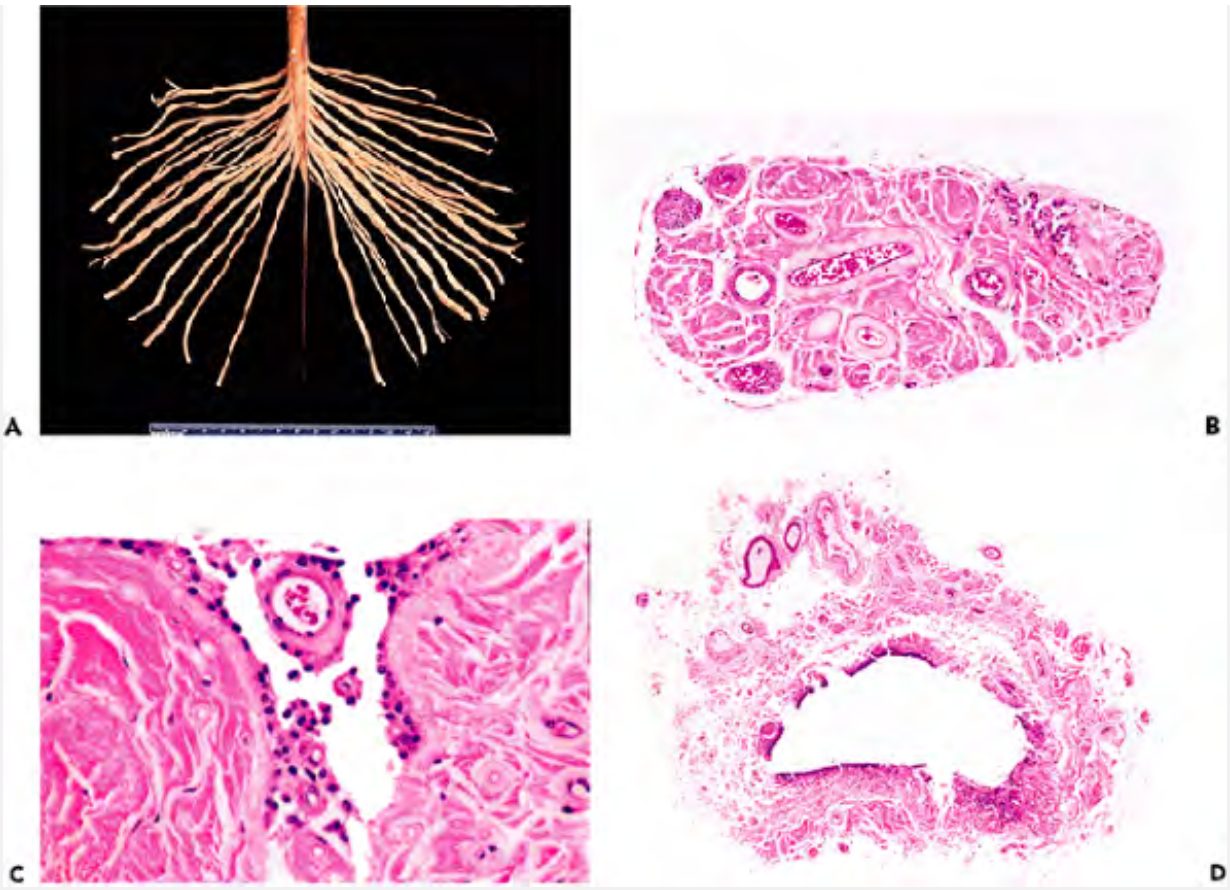

Figure 11.56 Filum terminale. A. The filum terminale is the terminus of the spinal cord and extends downward from the conus medullaris surrounded by the nerve roots of the cauda equina. B. As seen in cross section, the filum is composed primarily of dense collagenous tissue and contains blood vessels, small peripheral nerve fascicles, and, of significant clinical importance, a small, often eccentrically located, ependymal remnant of the central canal (*upper right*). The latter structure, shown at higher magnification in C, is the origin of myxopapillary ependymoma. D. A remnant of the embryonic terminal ventricle of Krause (ventriculus terminalis), which consists of a focal dilatation of the central canal located in the region of the junction of the conus medullaris with the filum, may be encountered in sections from this vicinity.

The filum terminale, which forms the terminus of the spinal cord, warrants additional brief description. As noted earlier, it is composed largely of leptomeningeal collagen but also contains small blood vessels and occasional small nerve fascicles; it may harbor focal collections of adiposites in a minority of normal individuals. Most importantly, however, is an ependymal remnant of the central canal (Figure 11.56). This structure is the source of origin for a unique neoplasm of the conus medullaris and filum terminale: the myxopapillary ependymoma.

Leptomeningeal Melanocytes

True melanocytes like those found in the skin are normal cellular constituents of the meninges. They are typically most concentrated in the leptomeninges of the ventral aspect of the upper cervical spinal cord and medulla oblongata (Figure 11.57). In individuals with an abundant melanocytic presence, the distribution territory extends upward through the pontine cistern and mesencephalic interpeduncular fossa, lateral to the inferior cerebellar hemispheres and mesial aspects of the temporal lobes, and as far rostrally as the gyri recti of the orbitofrontal cortex. It is not unusual for melanocytes to follow the investing leptomeninges of the perivascular Virchow-Robin spaces around large penetrating arteries for short distances into the CNS parenchyma.

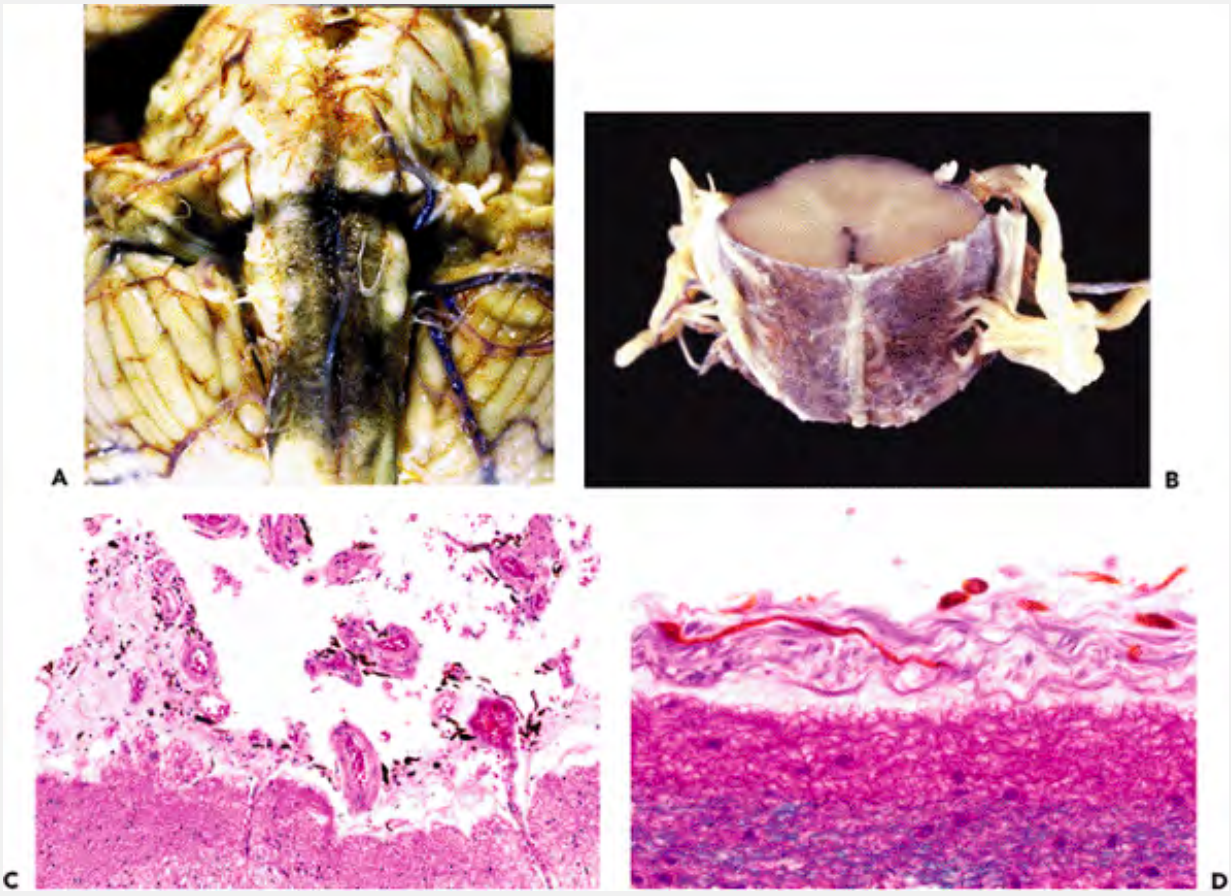

Figure 11.57 Leptomeningeal melanocytes. True melanocytes (not to be confused with neuromelanin-containing catecholaminergic neurons) are normal constituents of the pia-arachnoid and are often grossly visible as a dusky brown discoloration of the leptomeninges overlying the ventral aspect of the brainstem (A) and cervical spinal cord (B). On cross section their rounded profiles might be confused with hemosiderin-laden macrophages; but on longitudinal section their elongated, dendritic quality is evident (C, D).

â€œFormalin pigmentâ€•

Intrinsic melanocytes of the leptomeninges may be involved in a spectrum of proliferative conditions ranging from benign melanocytoma to primary CNS melanoma, with all of these entities being exceptionally rare. In contrast, the normal presence of melanocytes in the leptomeninges must always be borne in mind when examining surgical biopsies from CNS sites known to harbor these distinctive elements; one must avoid misinterpreting them as evidence of a melanocytic neoplasm or as hemosiderin-laden macrophages (Table 11.2). With regard to the latter, the long dendritic processes of the melanocytes are generally quite distinctive (Figure 11.57).

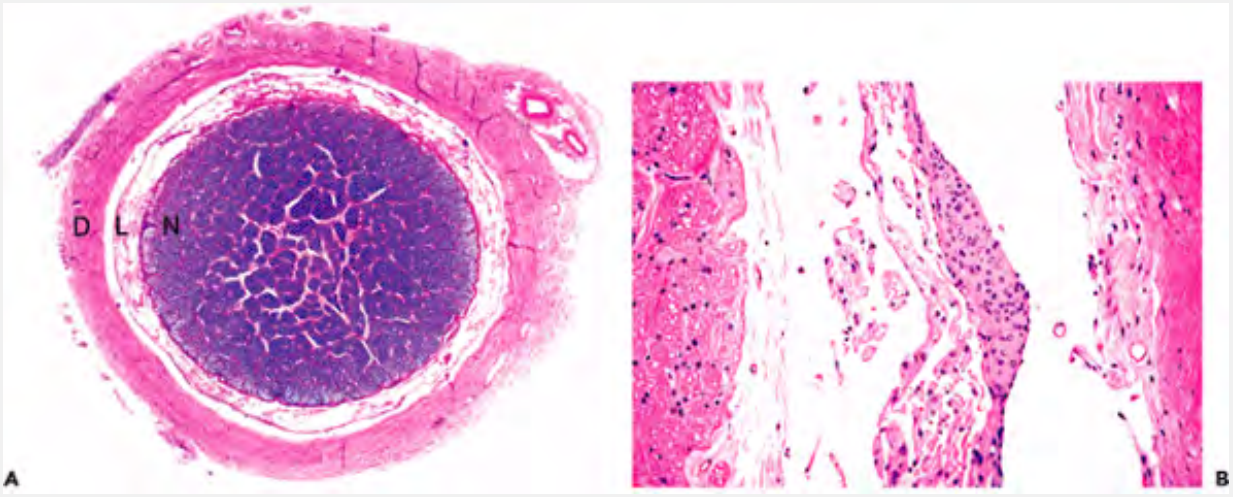

Figure 11.58 Optic nerve. A. A whole-mount cross section reveals that the optic nerve (*N*) is surrounded by leptomeninges (*L*), which include the pia mater and arachnoid together with the enclosed cerebrospinal fluid-containing subarachnoid space. The leptomeninges and subarachnoid space are in turn covered by the densely fibrous dura mater (*D*), which, in this location, is often referred to as the optic nerve sheath. B. At higher magnification, leptomeningeal arachnoid cell clusters are clearly seen. The presence of arachnoid cell nests around the optic nerve must be borne in mind when examining intraoperative frozen tissue sections from this neuroanatomic vicinity.

Optic Nerve

The optic nerves (as well as the optic tracts and optic chiasm) are direct extensions of the CNS and not peripheral nerves. The significance of this fact is that the myelin of the optic nerves is of the central type and is produced by oligodendroglia, not Schwann cells. Thus, the optic nerves are susceptible to diseases of CNS white matter, such as multiple sclerosis. Being extensions of the CNS, the

optic nerves are surrounded by the three meninges, pia mater, arachnoid, and dura mater, with the enclosed subarachnoid space (Figure 11.58). The presence of an arachnoid layer surrounding the optic nerve explains the occurrence of optic sheath meningiomas.

Fetal Brain

The two most distinctive histologic features of fetal brain compared to adult brain are active neurogenesis and paucity of myelin. The former is observed as a prominent, dense aggregation of neuroblasts and immature neurons in the periventricular and subpial zones. A similarly transient layer of migrating neurons in the fetal and infant

cerebellum (the external granular layer) has been discussed. These generative laminae begin involuting during the latter part of gestation; remnants are present during the first year of postnatal life (Figure 11.3C).

Artifacts

A variety of gross and macroscopic artifacts may complicate evaluation of the CNS. Many of these are seen frequently in surgical neuropathology practice, while a few are limited primarily to autopsy neuropathology (Table 11.3). Artifacts can be broadly separated into

those that hinder diagnostic evaluation versus those that mimic histopathologic lesions. Among the former are artifacts of the crush-burn-freeze-suck-soak group (Figure 11.59). The cavitron ultrasonic surgical aspirator (CUSA) is widely employed by neurosurgeons for the safe removal of diseased CNS tissue, particularly soft tumors, and a trap can be used to collect the aspirated tissue and saline irrigation solution for submission for histologic evaluation. Although microscopic examination of CUSA material can be very informative, the

pathologist must be aware of the artifacts that frequently accompany such specimens, including artificial distortion and smearing, and the introduction of extraneous material (bone dust, hemostatic agent); CUSA artifact is one cause of pseudonecrosis in CNS tissue samples (Table 11.4). Among artifacts that mimic lesions, the most common are perinuclear halo artifact, collapsed leptomeningeal vessels, and â€œbone dustâ€• (Figure 11.60).

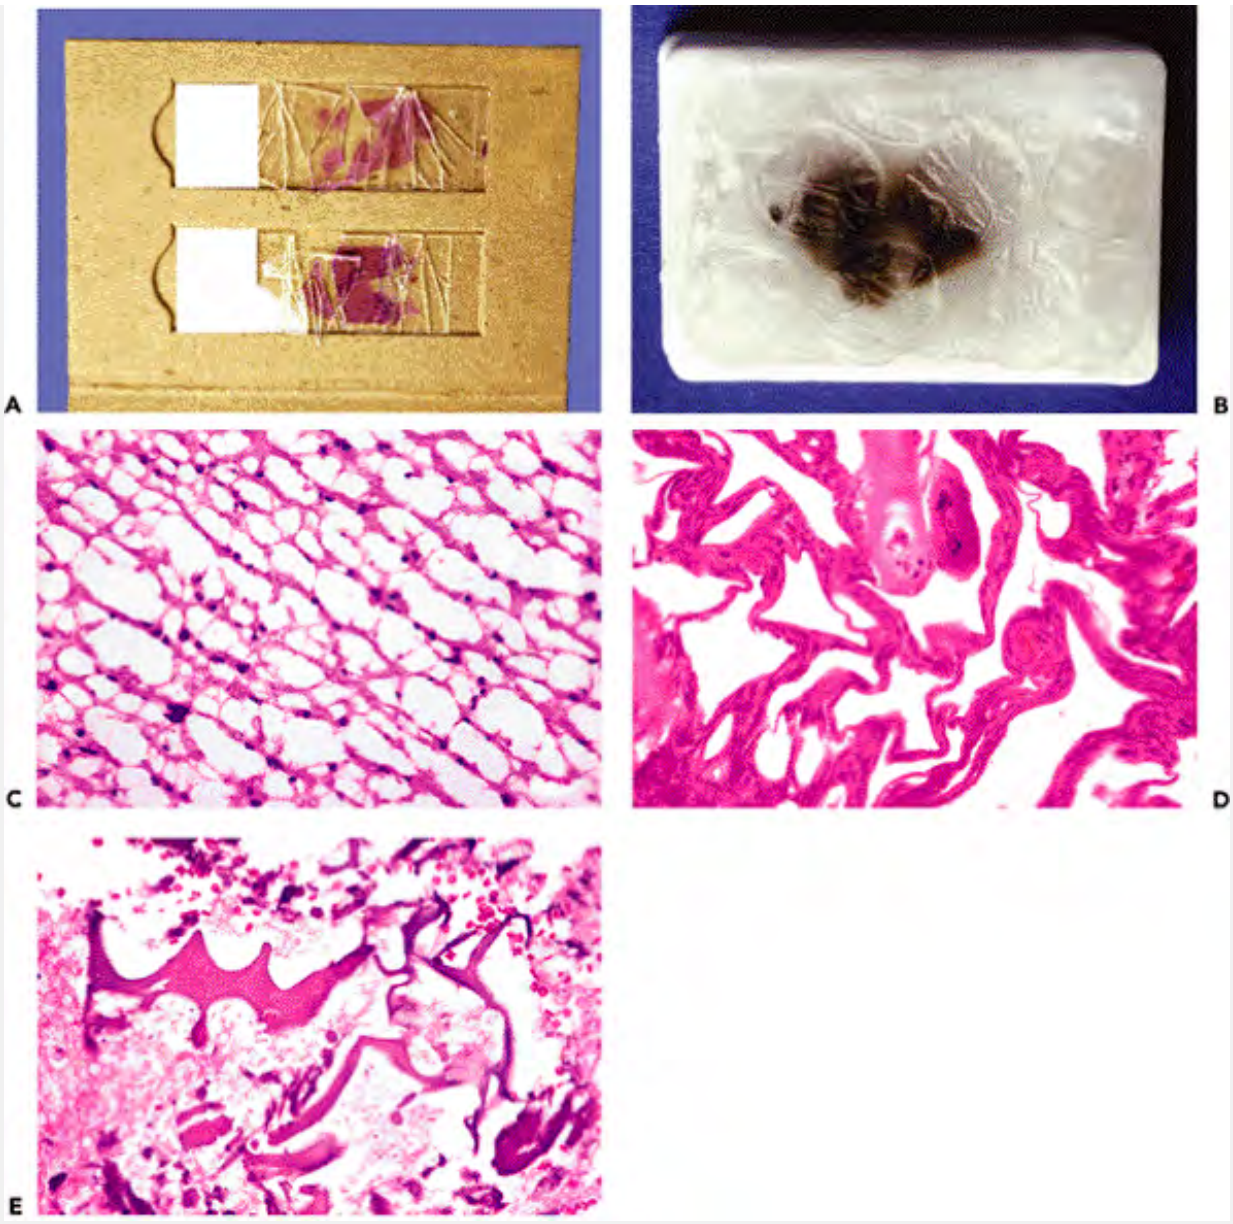

Figure 11.59 Artifacts. Many artifacts encountered in surgical pathology of the central nervous system prevent or severely hinder interpretation of the specimen. Among these, some are unique to the consultation service, such as postal service crush artifact (A) and hot weather bubble-wrap â€œparaffin poxâ€• (B), while others are secondary to surgical and laboratory tissue insults, such as severe freeze artifact (C), cautery artifact (D), and ultrasonic aspiration of brain tissue (E).

Iatrogenically introduced foreign material is also encountered with regularity by pathologists who examine CNS specimens and warrants brief mention (Table 11.5; Figure 11.61). A variety of foreign agents are used to control bleeding during surgery and may be introduced preoperatively by the interventional radiologist for embolization of vascular lesions or intraoperatively by the surgeon to control hemorrhage during and after surgery. All of these agents periodically appear in tissue sections. Because they are designed to be resorbable and can therefore be left in place, the morphologic appearance will vary depending on the time interval from placement at the initial surgery and subsequent resection during a second surgery (as, for example, resection of recurrent tumor). Resorbable hemostatic agents elicit a chronic inflammatory reaction of variable intensity, which occasionally may be severe enough to create mass effect and clinical symptoms (textiloma, gossypiboma).

Iatrogenic
Degenerating microfibrillar collagen (Avitene) textiloma (gossypiboma)

*Cavitron ultrasonic surgical aspirator (CUSA).

There are a few artifacts with which the pathologist who examines postmortem CNS specimens should be familiar (Figure 11.62), the most common being autolysis of the cerebellar granular cell layer (cerebellar conglutination), mechanical distortion of the spinal cord produced by forceps pressure during removal (â€œtoothpasteâ€• artifact), and the production of cystic cavities of varying size in the brain by the postmortem proliferation of gas-forming bacteria (â€œSwiss cheese brainâ€•).

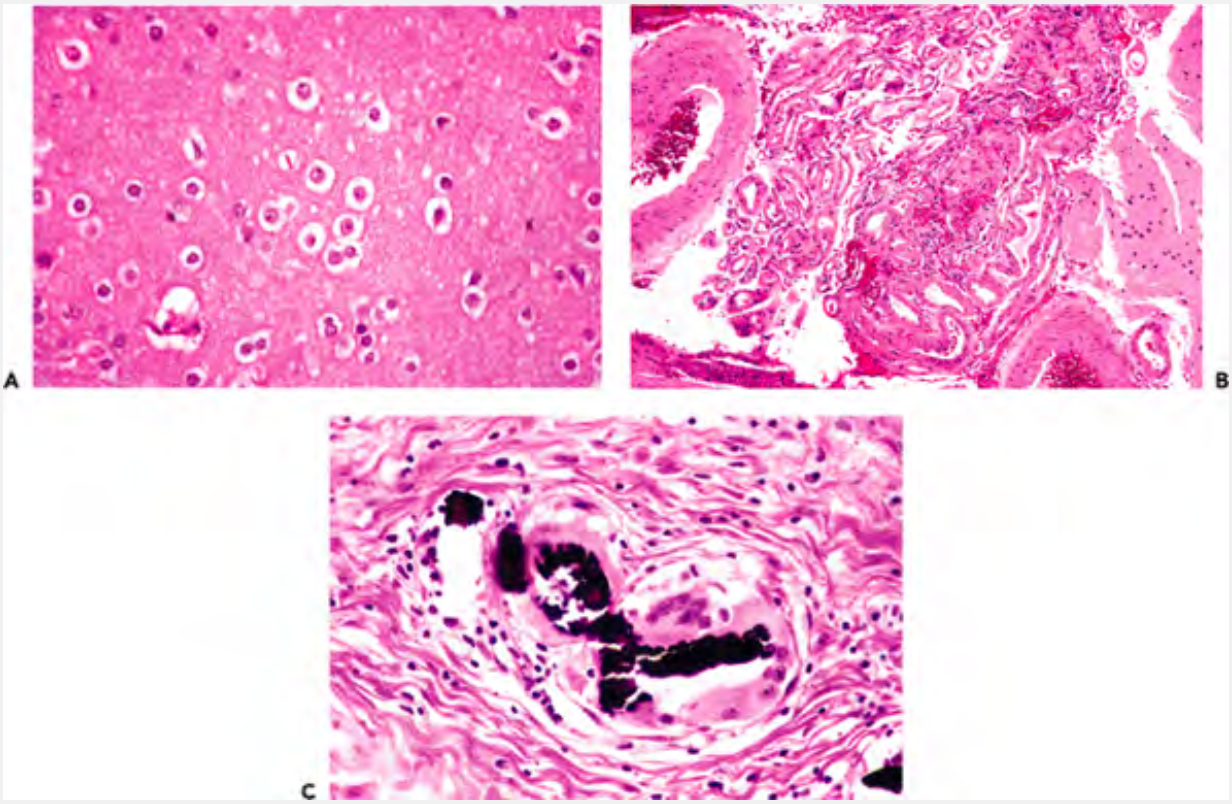

Figure 11.60 Artifacts. Several types of artifacts may not be recognized as artifactual in nature to the unaware and so may be particularly misleading. For example, one of the most characteristic morphologic features of normal oligodendrocytes and their derivative tumors, oligodendrogliomas, in formalin-fixed paraffin-embedded tissue sections is the presence of

perinuclear halos. However, depending on fixation conditions and other factors, prominent halos may sometimes be seen around other cell types, including neurons (A); care must be exercised in such situations to avoid misdiagnosis. Another example of misleading artifact is the tangle of normal blood vessels that results from collapsed vascular leptomeninges (B). The result can mimic vascular malformation. Before rendering a diagnosis of vascular abnormality in such circumstances, the adjacent brain or spinal cord tissue should be examined for evidence of associated features, such as gliosis, hemosiderin deposition, and granular bodies. Finally, also under the category of misleading artifact is â€œbone dust,â€• which consists of microscopic fragments of cranial bone produced by the surgeon's drill that become intermixed with the tissue sample and can mimic calcification or ossification. In repeat operations, such bone dust fragments left in situ at the previous operation can be seen accompanied by a foreign bodyâ€“type giant cell reaction (C).

Table 11.5 Iatrogenically-Introduced Foreign Material

Preoperative embolic agents
Gelatin foam (Gelfoam)
Polyvinyl alcohol particles
Acrylic microspheres (Embospheres)
Intraoperative hemostatic agents
Resorbable hemostatic agents
Gelatin foam (Gelfoam)
Oxidized cellulose (Surgicel, Oxycel)
Microfibrillar bovine collagen (Avitene)
Nonresorbable hemostatic agents
â€œRetainedâ€• cotton ball/pledgers

Cottonoids and kites (synthetic)
Surgically introduced therapeutic materials
Gliadel wafers (chemotherapy delivery)
Muslin (cotton) fabric (aneurysm wrapping)

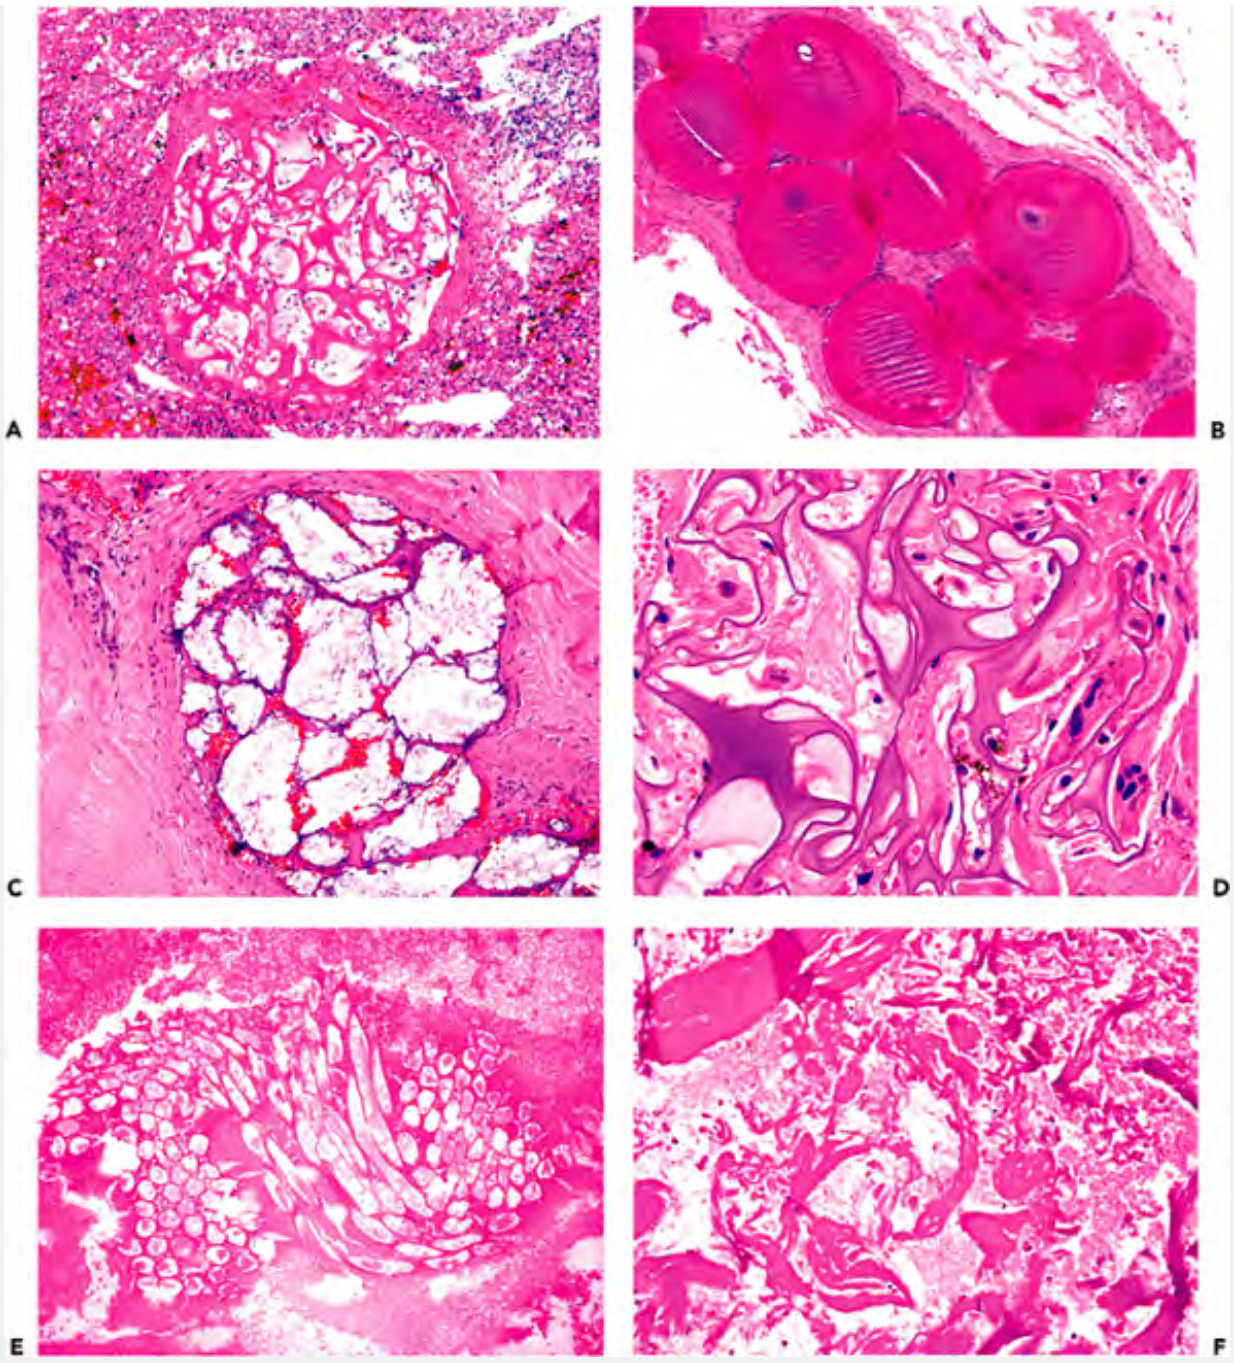

Figure 11.61 Artifacts. An additional category of artifacts seen in surgical neuropathology consists of foreign material placed by the interventional radiologist or neurosurgeon and subsequently encountered by the pathologist upon tissue resection. The most common examples of this are embolic and hemostatic agents.

Embolic materials are introduced by catheter prior to surgery for highly vascular lesions to reduce intraoperative bleeding; the most common are gelatin foam (A), acrylic resin spheres (B), and polyvinyl alcohol particles (C). Hemostatic agents, in contrast, are placed in the surgical site to stop bleeding during the operation and often are left in place after closing to prevent postoperative bleeding. The most commonly employed agents are gelatin foam (D), oxidized cellulose (E), and microfibrillar bovine collagen (F).

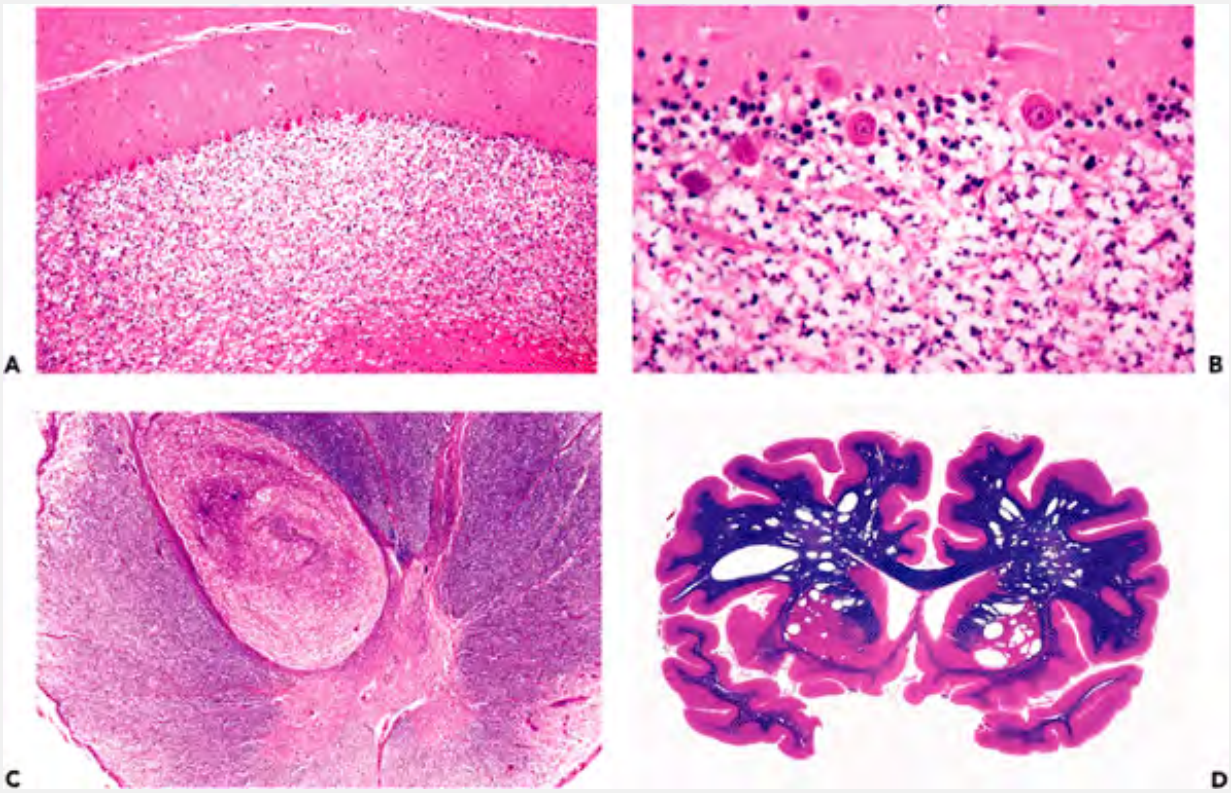

Figure 11.62 Artifacts. There are a number of gross and histologic artifacts that are usually encountered only in autopsy specimens of the central nervous system. The most common of

these are cerebellar conglutination (A, B), also known as â€œetat glace,â€• which consists of autolytic dissolution of the granular cell layer of the cerebellum; â€œtoothpasteâ€• or â€œsqueezeâ€• artifact of the spinal cord (C), which results from focal crushing of the cord by forceps during removal at autopsy and resultant internal herniation of the central gray matter, mimicking malformation or heterotopia; and â€œSwiss cheese brainâ€• (D), which is a striking macroscopic vacuolization of the brain resulting from postmortem proliferation of gas-forming bacteria.

Embryology

To fully appreciate the anatomy of the pituitary (hypophysis), an understa embryogenesis is essential. The gland consists of an anterior lobe (adeno posterior lobe (neurohypophysis), and an intermediate zone (Figure 12.1 of each differs significantly.

The adenohypophysis has its origin in a thickening of oral ectoderm (1 ,2 third week of gestation, this thickened plate invaginates in a cephalad dir Rathke's pouch, which retains its connection to the stomodeum via a narr sixth week, the stalk becomes so attenuated that the pouch loses its sto it comes into contact with the infundibulum. Cellular proliferation in the a Rathke's pouch gives rise to the pars distalis, the principal portion of the addition, a â€œtonguelike'' extension of the pars distalis, the pars tubera partially surround the anterior surface of the infundibulum. The posterior pouch gives rise to what in humans is a thin segment of pituitary, the pa intermediate lobe. In this zone, microcystic remnants of Rathke's pouch

material are commonly seen (Figure 12.1). Gross cystic dilatation of such common but infrequently produces clinically significant intermediate lobe cysts.

A remnant of the pharyngohypophysial stalk, demonstrable in fetuses and encountered in adults, comprises the pharyngeal pituitary (5 ,6). Located beneath the muco-periosteum of the nasopharynx, it extends from the pos vomer along the sphenoid bone. Although the full spectrum of anterior pi producing cells may be demonstrated in pharyngeal pituitaries, they are ra medical or surgical disease.

The neurohypophysis develops from a neuroectodermal bud first noticeable diencephalon at 4 weeks' gestation (1 ,3). Two weeks later, the outgrow abut the posterior portion of Rathke's pouch. This specialized portion of t comprises magnocellular nuclei, their axons within the median eminence stalk, and their terminations in the pars nervosa (posterior lobe). Oxytoc as well as their carrier proteins, the neurophysins,

are detectable in supraoptic and paraventricular nuclei at 19 weeks and in at 23 weeks (7).

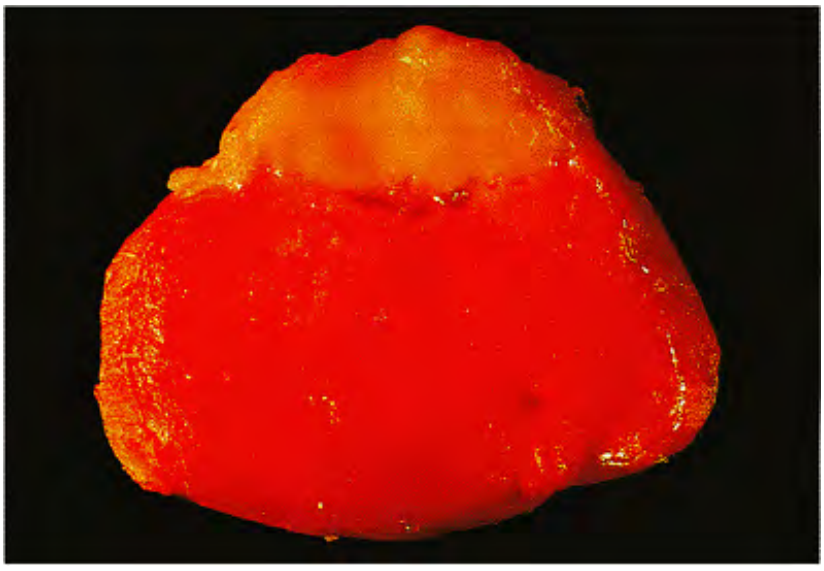

Figure 12.1 Normal unfixed adult pituitary gland cut in the horizontal pla lobe is located at the top of the field. A few intermediate lobe cysts are p color of the anterior lobe is a reflection of its extensive vascularity.

As early as 7 to 8 weeks' gestation, the portal system begins to develop. weeks both the median eminence and the anterior lobe are vascularized, hypothalamicâ€“pituitary portal system is not completed until 18 to 20 we

The hypothalamus develops from a swelling in the diencephalon. Althoug nuclei as well as the supraopticohypophysial tract are demonstrable at 8 unmyelinated axons, growing ventrally from the magnocellular (supraoptic paraventricular) nuclei, do not reach the posterior lobe until 6 months.

By 12 weeks, a number of cartilaginous plates have fused to form the ca neurocranium (1). The body of the sphenoid bone and the sella turcica r hypophysial cartilaginous plates located on either side of the developing p well formed by 7 weeks and matures through a process of enchondral os

Rare developmental malformations of the pituitary gland, including ectopic pituitary dystopia, have been reported (8 ,9).

The understanding of pituitary development has recently expanded as a re identification of molecular mechanisms that may specify cell determinatic Recent advances in pituitary development in mammals have suggested th organogenesis is controlled by a combination of sequential exogenous an (10 ,11 ,12). These signals induce the expression of interacting transcrip temporal and spatial patterns. Pituitary cell types appear to emerge from under the response of transcription regulators critical for determination a specific cell type. Briefly, the transcription factor pituitary homeobox 1 (*P* early development of the pituitary and cooperates with more functionally transcription factors. *Pit-1* is a transcription factor that regulates the fu of the somatotrophs, lactotrophs, and thyrotrophs. A family of basic heli transcription factors, *Neuro D1* , and a novel T box factor, *Tpit* , appear a role in the functional differentiation for pituitary pro-opiomelanocortin (and corticotroph cells. The nuclear receptor steroidogenic factor-1, *SF-1* differentiation of LH and FSH cells.

On the other hand, the time period of recognition of the various human p hormoneâ€“producing cells during embryonal development have been well immunohistochemical stains. Corticotrophs are the first cells to differentiat

fetal pituitary (at around 5 weeks gestational age). Somatotrophs appear a weeks, followed by thyrotrophs and gonadotrophs at 12 to 15 weeks. La seen in small numbers as early as 12 weeks, are only fully recognizable at ,14).

Gross Anatomy

Bony Sella

The pituitary gland is centrally situated at the base of the brain, where it the sella turcica, a saddle-shaped concavity within the sphenoid bone (Fig ,12.4). It is attached to the hypothalamus by both the pituitary stalk and network (Figures 12.5 ,12.6 ,12.7). By virtue of its location, the pituitary

gland has many important anatomic relations (15 ,16 ,17). Anterior to th bone forms a midline slope, the tuberculum sella, as well as a transverse chiasmal sulcus, so named for the overlying optic chiasm (see Figures 12 canals, which transmit the optic nerves, lie anterolateral to the sulcus, w tracts are posterolateral. In view of the pituitary's proximity to the optic lesions that extend superiorly may cause significant visual field deficits (F ,12.6 ,12.7 ,12.8 ,12.9 ,12.10 ,12.11). Specifically, compression of decus chiasm produces bitemporal hemianopsia, whereas compromise of an optic homonymous hemianopsia. Further suprasellar extension may cause hyp and hydrocephalus.

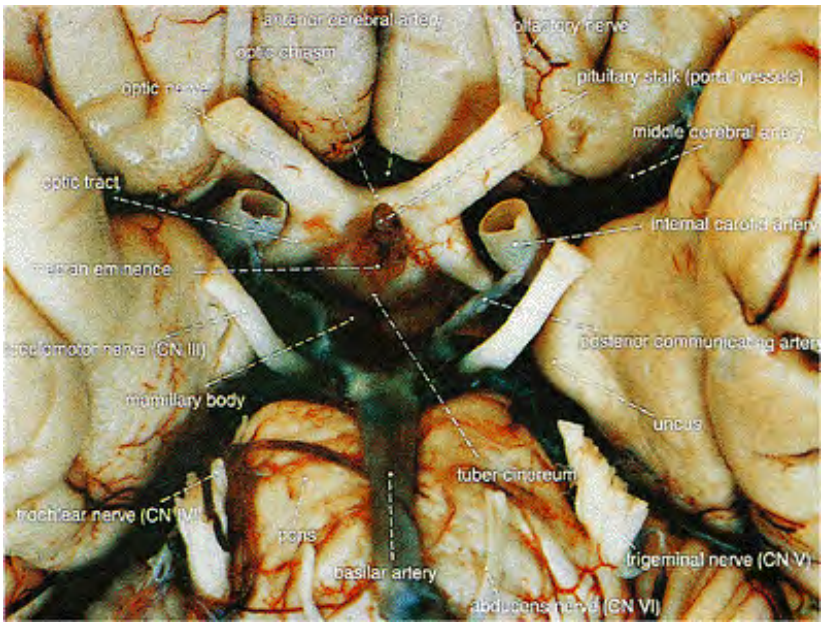

Figure 12.2 Ventral surface of normal brain showing the pituitary stalk a structures. The pituitary gland has been removed. The proximity of the op pituitary is the basis for the visual field deficits accompanying suprasellar pituitary adenomas. Visible along the posterior aspect of the stalk are trib system.

spinosum is not visible in this view. Yellow, sphenoid; pink, occipital; ligh green, parietal; white, frontal.

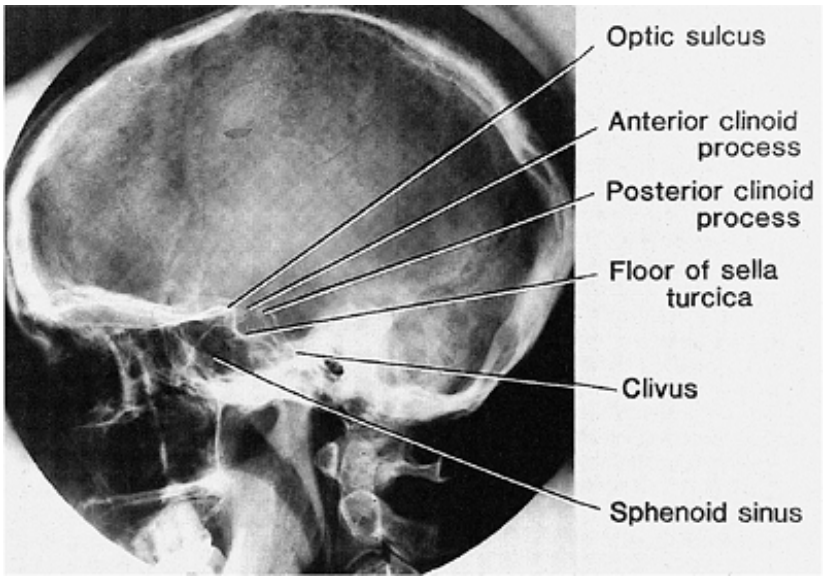

Figure 12.4 This normal lateral skull radiograph shows the central locatio turcica and surrounding bony anatomy.

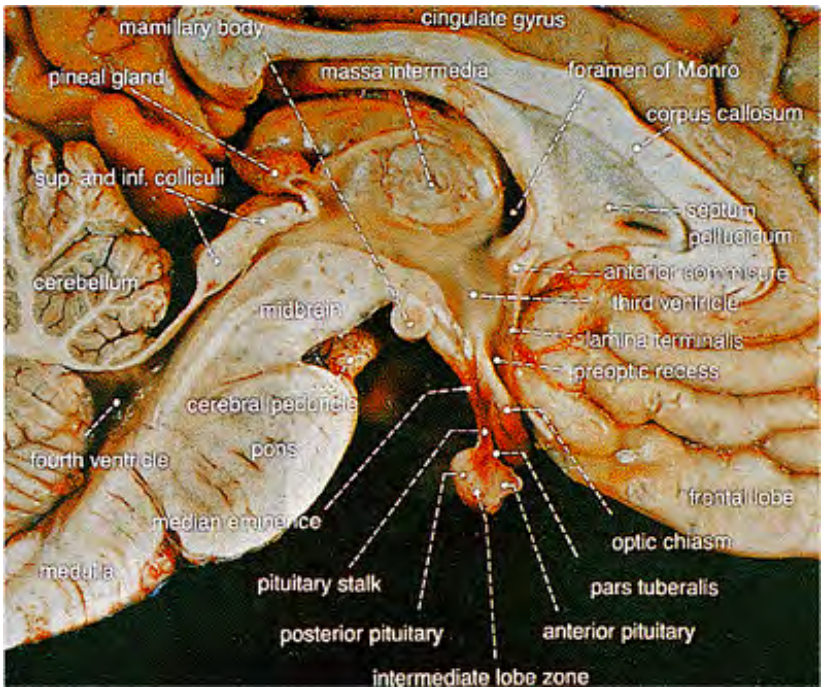

Figure 12.5 Midline sagittal section through the brain at the level of the pituitary gland, showing the pituitary gland with surrounding structures i hypothalamus, third ventricle, optic chiasm, and sphenoid sinus.

The floor of the sella forms a portion of the roof of the sphenoid air sinus relationship that permits ready surgical access (18) (Figures 12.4 , 12.6 ,12.10 ,12.11 ,12.12). Indeed, the transsphenoidal approach to the pitu mobilization of the nasal septal cartilage followed by resection of a portio plate. A sublabial incision is then made, and the sphenoid

speculum is placed in the septal space, permitting direct visualization of t the sphenoid sinus. Upon breaking through the anterior sphenoid wall, the bulging into the roof of the sinus. A septated sphenoid sinus may affect t orientation at surgery (Figures 12.8 ,12.9). The pituitary is then exposed bony sellar floor and incising the dural investment around the gland.

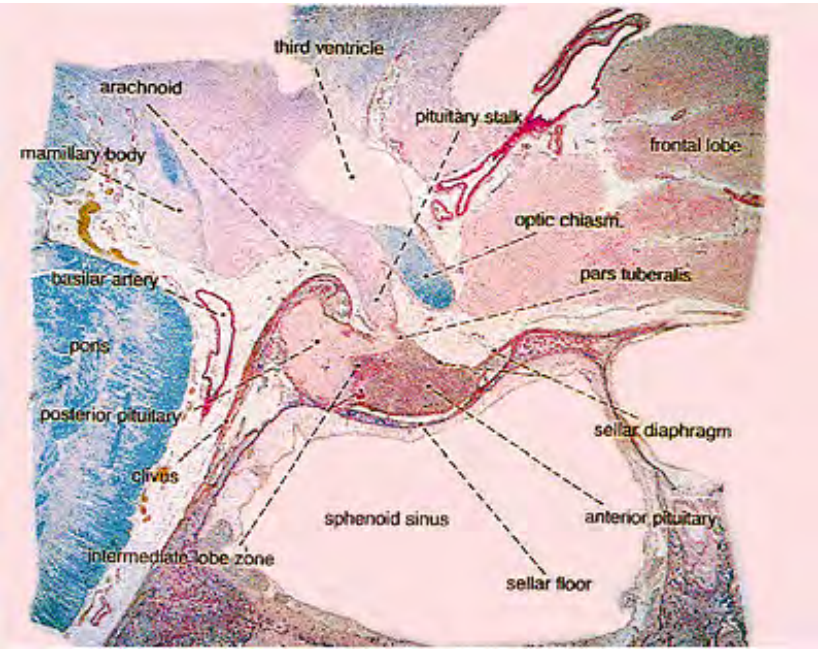

Figure 12.6 Sagittal whole-mount section of normal pituitary gland and structures. The anterior (*at right*) and posterior (*at left*) lobes are clear pars tuberalis is the thin tongue-shaped portion of anterior lobe that exte distance up the stalk. This diagram illustrates the proximity of the optic c pituitary. Superior extension of a pituitary tumor may compress the optic

resultant visual field deficits, whereas downward extension may fill the s Fast Blueâ€“PAS).

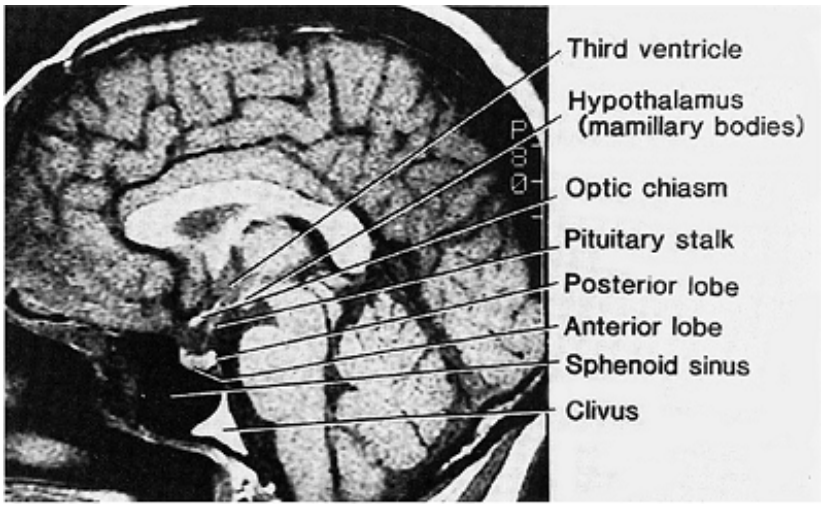

Figure 12.7 Magnetic resonance imaging (MRI): sagittal view of the brain pituitary stalk and gland. The clarity of the pituitary gland, stalk, hypotha chiasm is remarkable, making MRI an excellent imaging modality for the pituitary lesions. One advantage of MRI over computed tomography (CT) i bony artifact with MRI.

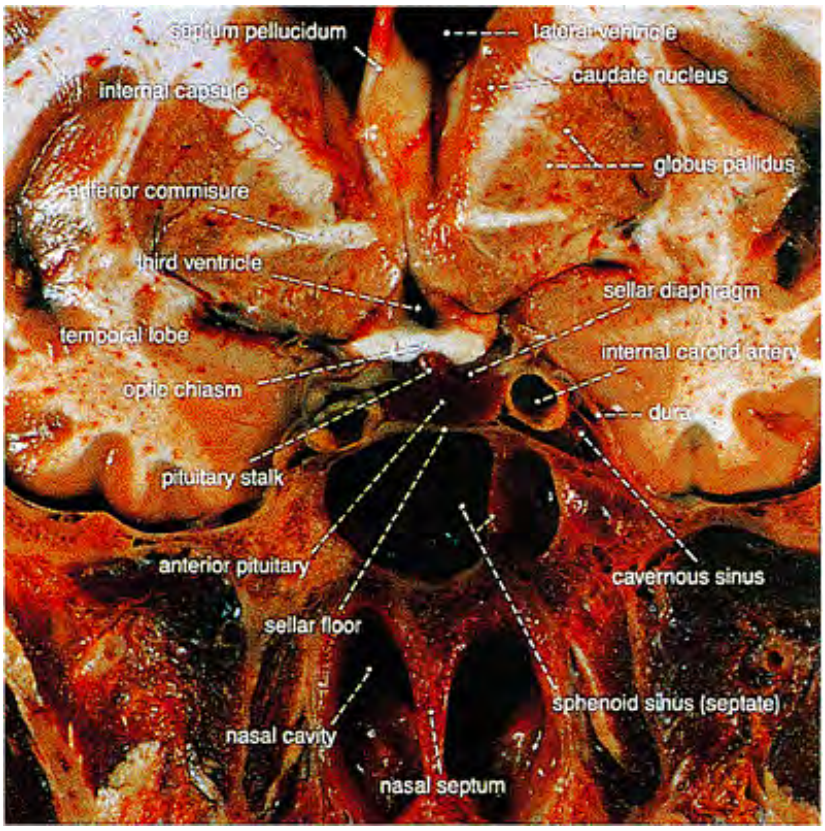

Figure 12.8 Coronal section of the head at the level of the pituitary stalk photograph clearly illustrates the intimate relationships between the cave sphenoid sinus, and the pituitary gland. Invasive adenomas may extend la both cavernous sinuses or inferiorly into the sphenoid sinus. Note the pro chiasm to the pituitary.

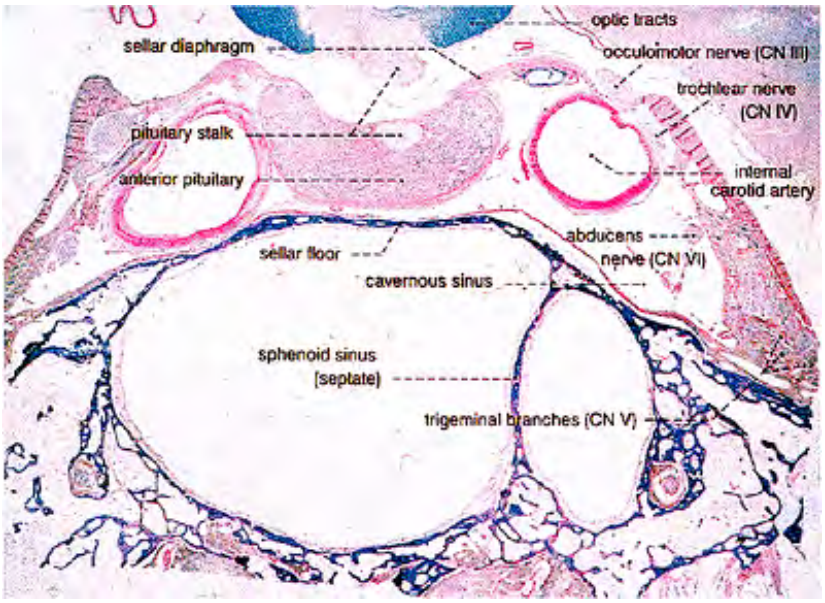

Figure 12.9 Coronal whole-mount view of the normal pituitary gland and structures. Note the location of cranial nerves III, IV, VI, and branches of within the cavernous sinuses, a relationship explaining the occurrence of in association with invasive pituitary adenomas. This section also illustrate the internal carotid arteries to the pituitary gland (Luxol-Fast Blueâ€“PAS

The sloping anterior sellar wall terminates in posterolateral projections, t processes (Figures 12.3 ,12.4). Posterior to the sella, the sphenoid bone dorsum sellae, anterolateral portions of which form the posterior clinoid Figures 12.3 ,12.4). Posterior to the dorsum sellae lies the downward-sl notorious as the site of predilection of chordomas (Figures 12.3 , 12.4 , 1 number of neurovascular foramina are situated in the sellar region; by na from anterior to posterior, they include the foramen rotundum (maxillary (mandibular nerves), spinosum (middle meningeal arteries), and lacerum arteries) (Figure 12.3).

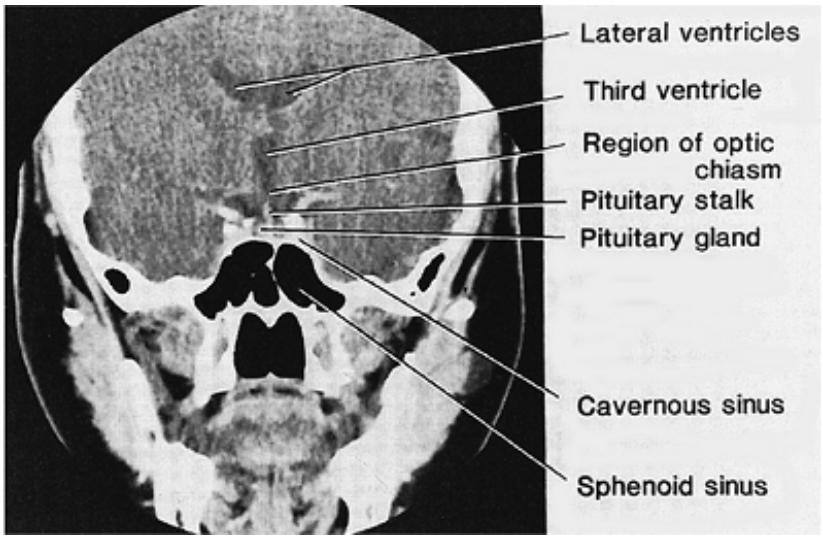

Figure 12.10 A computed tomographic (CT) coronal view of the normal s level of the pituitary stalk and gland. The CT scan is a good imaging moc the pituitary gland; however, radiologists often encounter problems with this reason, MRI is superior.

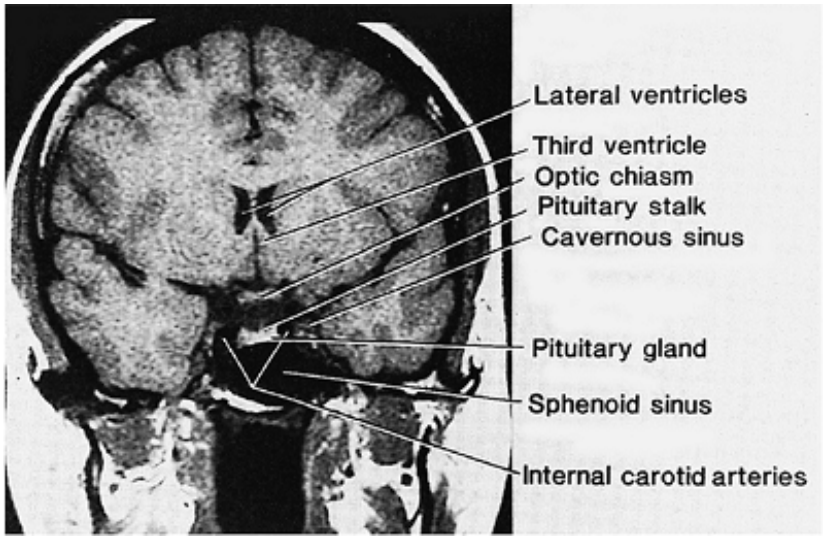

Figure 12.11 Coronal MRI of the skull and brain at the level of the pituit

Meninges

The physical relationship of the meninges to the pituitary and sella is unus pituitary lacks a leptomeningeal investment. Periosteal dura lines the sell the dura proper covers the lateral aspects of the cavernous sinuses and f diaphragm. The diaphragm is usually thin at the center and thick at its p possesses a variably sized central aperture through which the pituitary sta Leptomeninges do encircle the stalk; however, below the level of the sell reflect back upon themselves to form a circumferential channel, the infr hypophysial cistern. This arrangement explains the higher incidence of de meningiomas in the suprasellar surface of the diaphragm rather than in t compartment.

In some individuals, the leptomeninges exhibit an important anatomic var extension or herniation of the arachnoid through an inordinately large di In one study, the incidence of an intrasellar arachnoidocele was found to In such cases, transsphenoidal surgery may result in persistent cerebrosp rhinorrhea because of inadvertent violation of the subarachnoid space. W exertion of even normal CSF pressure, enlargement of such arachnoidocel sellar enlargement and pituitary compression, the gland being reduced to the posterior sellar floor (Figures 12.13). The so-called empty sella synd distinct predilection for obese, multiparous females (Figure 12.14). Its a manifestations are fully expressed in as many as 5.5% of autopsies (20 ,2 the gland

and traction deformation of the pituitary stalk may cause mild to modera and hyperprolactinemia, respectively.

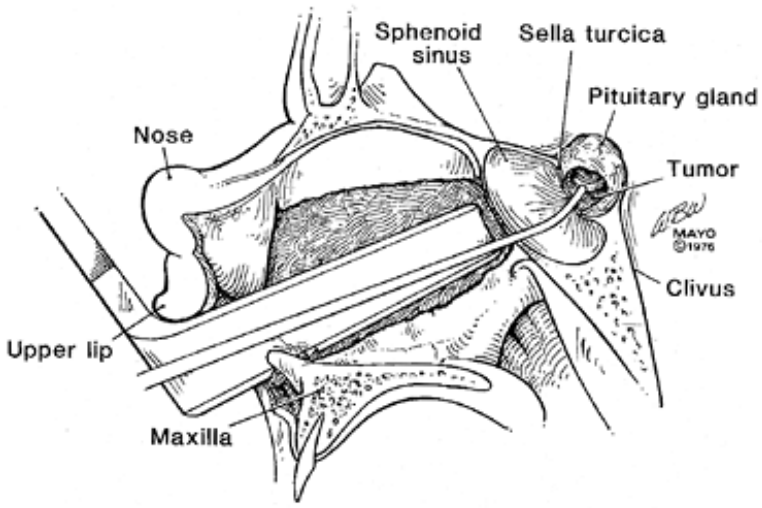

Figure 12.12 Transsphenoidal approach to the pituitary gland. After mob septal cartilage and resecting a portion of ethmoid plate, a sublabial incisi sphenoid speculum is placed. Next, the floor of the sphenoid sinus and the turcica are traversed. Finally, the dural investment of the pituitary gland gland is exposed. This diagram illustrates a curette in place for removal o adenoma.

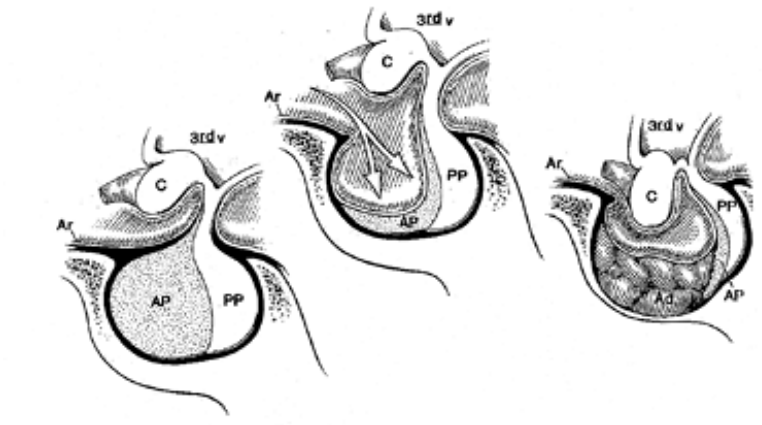

Figure 12.13 Illustration of normal as well as variants of the empty sella pituitary-sellar relationships. The leptomeninges cover the stalk and sellar not extend into the sella. B. In primary empty sella syndrome, an excess diaphragmatic orifice permits herniation of leptomeninges into the sella. pressure compresses the gland against the sellar floor. C. Secondary emp from infarction of a pituitary adenoma, infarction of the pituitary gland, a radioablation of the gland. (Ar, arachnoid; AP, anterior pituitary; PP, pos

optic chiasm; 3rd v, third ventricle)

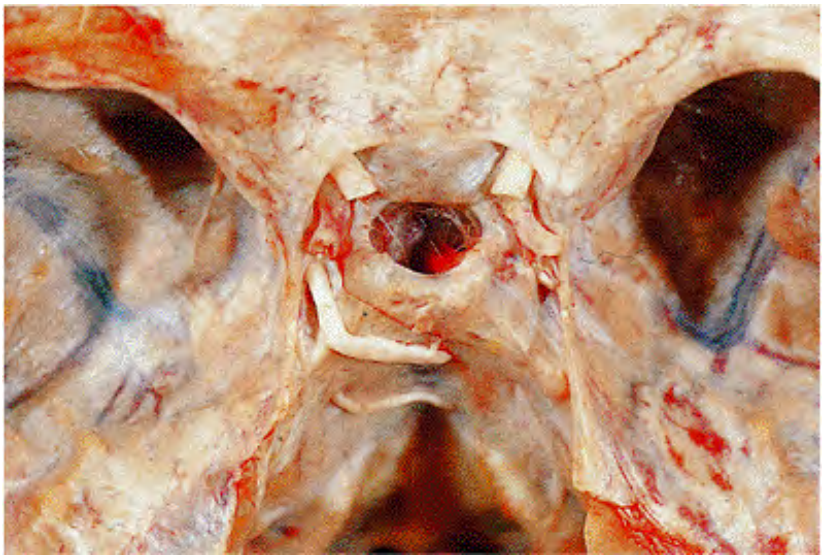

Figure 12.14 Superior view of the skull base, demonstrating an incident primary empty sella. Normally in this view the upper surface of the pituita visible through the diaphragmatic aperture, but here the sella appears em primary empty sella syndrome symptomatic. This specimen is from a 57- diabetic woman.

Vasculature

Vascular structures of major surgical significance abound in the sellar reg cavernous sinuses are situated on either side of the sella and, in part, lie to the sphenoid sinuses (Figures 12.8 ,12.9 ,12.10 ,12.11). Each cavern invested by dura of the middle fossa, as well as by thin bony walls of the Venous drainage to the sinuses comes from a number of sources, includin ophthalmic vein), brain (inferior and middle cerebral veins), and sphenop Communication between right and left cavernous sinuses takes place thr sinuses bordering the anterior and posterior aspects of the sella (22). Tl forms a venous ring around the sella and its contents. Additional interca located along the ventral surface of the pituitary. The cavernous sinuses addition to their content of venous sinuses, a number of vital neurovascu

). These include the cavernous segments of the internal carotid arteries a cranial nerves III (oculomotor), IV (trochlear), V (trigeminal), and VI (ab 12.8 ,12.9). Delicate areolar tissue fills the interstices between venous and nerves. The location of the horizontal portions of the internal carotid cavernous sinuses varies, not only from person to person but from left to the carotids may lie immediately adjacent to the sella, in which case they surgical risk (19) (Figures 12.8 ,12.9). Furthermore, the anterior portion may indent the sphenoid bone and thus be separated from the cavity itself mm of bone (15). Several branches of the internal carotid artery arise w sinus, including the meningohypophysial trunk (the largest intracavernous of the inferior cavernous sinus, and small capsular branches (23 ,24). Th meningohypophysial trunk gives rise to several vessels, one of which, th artery, supplies the posterior or neural lobe and the pituitary capsule.

Given their location, the cavernous sinuses may be directly involved by p example, extension of an invasive adenoma into the cavernous sinuses m neuropathies of cranial nerves III through VI (Figure 12.9), including pto diplopia.

The principal arterial supply of the pituitary originates in two branches of carotids: the superior and inferior hypophysial arteries (25 ,26) (Figure superior hypophysial artery springs from each carotid shortly after its ent cavity and promptly divides into posterior and anterior branches, each of with the corresponding branch from the opposite side to form an arterial upper pituitary stalk. The anterior branches give rise to trabecular or lora descend on the upper surface of the anterior lobe, course toward the pitu terminate in long stalk arteries along the pars tuberalis. In their brief cou anterior lobe, trabecular arteries each give rise to a small artery of the fi posterior and anterior branches of the superior hypophysial arteries are al short stalk arteries, which penetrate the superior aspect of the pituitary s or downward within it. In contrast to the superior hypophysial arteries, t originate from the meningohypophysial trunks within the cavernous sinuse inferolateral portions of the gland and bifurcate into medial and lateral br anastomose with their opposite counterparts to form an

arterial circle about the posterior lobe. Thus, branches of the inferior hy

supply primarily the posterior lobe and lower portion of the stalk, contrib capsular branches to the periphery of the anterior lobe (27). Although m branches in the pituitary stalk and infundibulum form arterioles and capill to unique vascular complexes termed gomitoli (Figures 12.15 ,12.16). T threadâ€• consist of a central artery surrounded by a glomeruloid tangle transition from central arteries to the capillaries is via short specialized with thick smooth muscle sphincters that serve to regulate blood flow. Th periarteriolar capillaries drains into an extensive pampiniform network, th which envelopes the stalk (Figures 12.2 , 12.15).

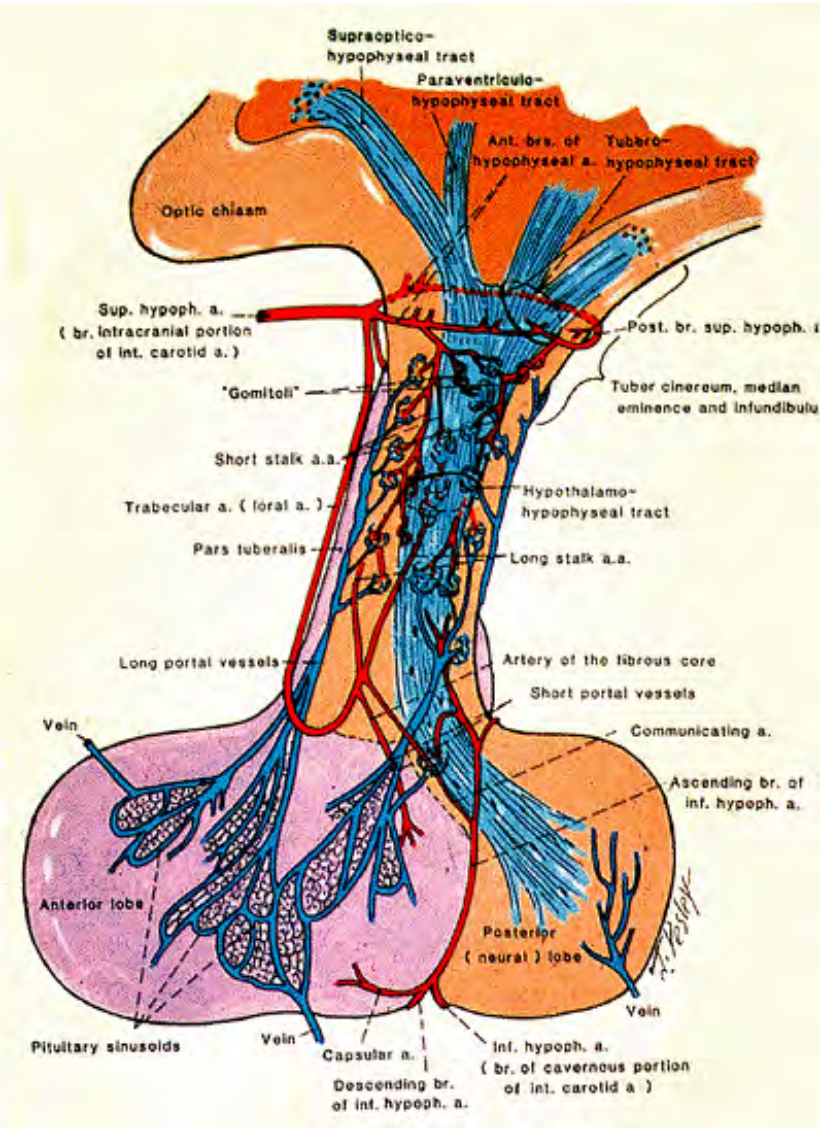

Figure 12.15 Diagrammatic representation of the vasculature of the pitu

superior and inferior hypophysial arteries and branches of the internal ca comprise the major blood supply of the gland. Small terminal branches of inferior hypophysial arteries give rise to tangled capillary loops termed g into portal vessels. The latter traverse the length of the stalk and termina in the anteior lobe. The anterior pituitary thus receives the majority of its from arteries but from the portal system. The portal system forms a vital hypothalamus and the pituitary gland.

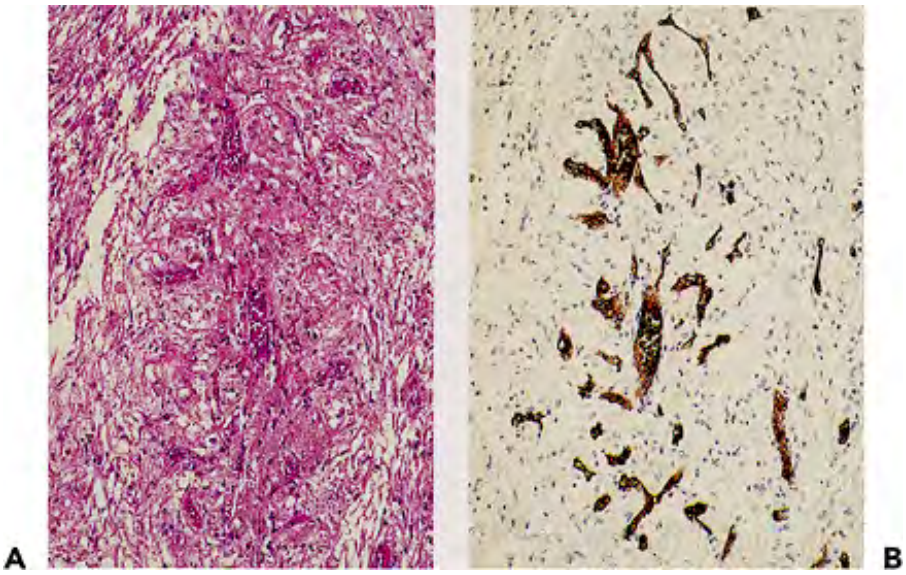

Figure 12.16 Gomitoli, tortuous capillary loops surrounding a central arte portion of the pituitary stalk (A) (H&E, original magnification Ã—100). Th vascularity of the gomitoli is highlighted by staining with *Ulex europeus* le (immunostain, original magnification Ã—100).

The hypophysial portal system, the critical link between hypothalamus an origin from the capillary plexus of the median eminence and stalk, which terminal ramifications of the superior and inferior hypophysial arteries (2 plexus in the median eminence and superior stalk, the site of uptake of factors, drains into the long portal vessels that course along the surface o the majority (90%) of the anterior lobe, whereas the smaller capillary ple stalk gives rise to the short portal vessels that descend into its central p bordering the posterior lobe (27 ,28). Distally, the portal system commu

delicate capillary network in the anterior lobe, which carries hypophysiotr the pituitary and conveys anterior lobe hormones to the general circulatio

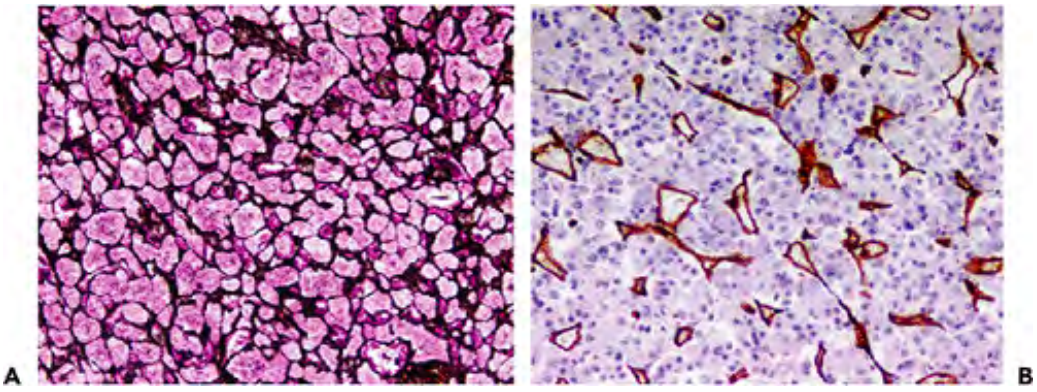

Figure 12.17 Adenohypophysis. A. The intricate capillary and connective outlined in reticulin stain. The reticulin stain is invaluable in the evaluatio adenomas, which are largely devoid of reticulin, whereas the surrounding it (Wilder reticulin, original magnification Ã—40). B. The capillary endothe lobe capillary network stains strongly for CD31 (immunostain Ã—100).

Venous outflow of the pituitary is via collecting vessels that drain into th sinus, cavernous sinus, and superior circular sinus (26).

There is considerable variability in the vascular anatomy of the pituitary. direct arterial supply via capsular branches of the inferior hypophysial ar of the anterior lobe's circulation is venous, originating from the portal ves contrast to that of the anterior lobe, the blood supply of the posterior lob arterial, a characteristic that explains the predilection of metastatic carcin lobe.

Physiology and Histology

Hypothalamus

The pituitary is known to be under significant hypothalamic control. In fac the hypothalamus form a complex neurohormonal circuit, a vital element a normal endocrine status. Weighing approximately 5 g and forming the w

inferior third ventricle, the hypothalamus lies above the

pituitary to which it is connected by the pituitary stalk (Figures 12.5 12.6). As the name suggests, the hypothalamus lies inferior to the thalamus. glance it appears poorly demarcated, the hypothalamus is bordered anteri commissure, lamina terminalis, and optic chiasm; posteriorly and superior tegmentum and mamillary bodies; dorsally by the hypothalamic sulcus; ar subthalamic nuclei (29 ,30). The region consists of several ill-defined bu neuronal nuclei (Figures 12.18 ,12.19 ,12.20 ,12.21). Afferent and effer these nuclei into contact with nearby as well as remote portions of the c system, including other diencephalic structures, the cerebrum, brain stem Two major and distinct hypothalamohypophysial secretory systems are re consists of the supraoptic and paraventricular nuclei and their projections lobe (supraopticohypophysial and paraventriculohypophysial tracts); the o mainly of nuclei of the tuberal region, the funnel-shaped floor of the third processes terminating in the median eminence (tuberohypophysial tract)

Table 12.2 Major Hypothalamic Hormones: Their Compositio Localization

In H&E-stained sections, three principal cell types are identified in the no acidophils (40%), basophils (10%), and chromophobes (50%) (Figures 12 designations reflect their staining affinities for acidic and basic dyes, with cells lacking affinity for either. These reactivities form the basis of an ou of pituitary adenomas that offers little in specifying their hormone conten function. On the other hand, advances in immunohistochemistry permit m functional correlation (Figure 12.26). Numerous cells in the central or m basophilic and stain strongly via the PAS method. Such cells produce ad (ACTH) and glycoprotein hormones (LH, FSH, TSH). In contrast, most cells are acidophilic and are engaged either in growth hormone (GH) or, less f prolactin (PRL) production. The essential morphologic features of the five and the biochemical characteristics of the six hormones of the anterior pi summarized in Table 12.3 . Their ultrastructural features are presented in

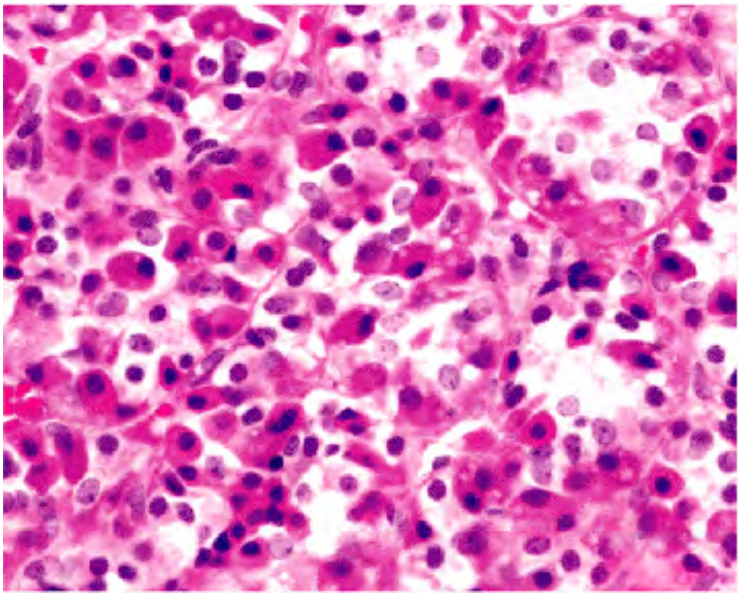

Figure 12.23 Anterior lobe. An H&E-stained section shows chromophobic basophilic cells. Acidophils are most numerous in the lateral wings, where found in greatest number in the central or mucoid wedge. Table 12.4 The Normal Pituitary: Ultrastructural Features

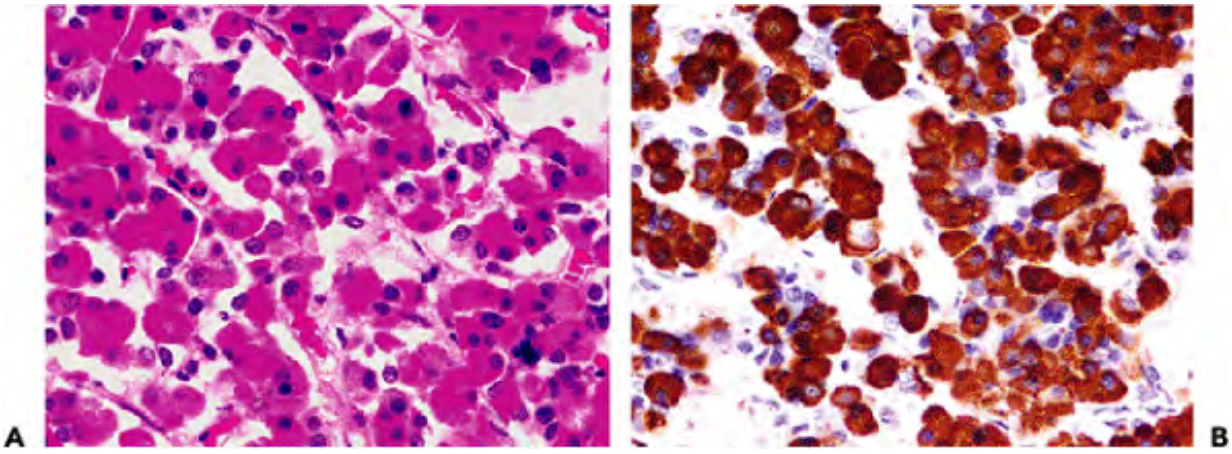

Figure 12.27 Somatotrophs. A. By H&E stain, somatotrophs are medium abundant, eosinophilic and granular cytoplasm GH. Somatotrophs comprise lobe cells (original magnification Ã—200). B. The strong staining reaction numerous secretory granules present at the ultrastructural level (see Figu (immunostain, original magnification Ã—200).

Somatotroph cells.

Somatotrophs, or GH cells, occur in greatest density in the lateral wings approximately 50% of all adenohypophysial cells. A minority of somatotro scattered throughout the median portion of the gland. They are medium- with round, centrally located nuclei, relatively prominent nucleoli, and wi acidophilic granules (Figure 12.27). Immunohistochemical stains for GH diffuse cytoplasm staining, consistent with the numerous secretory granul ultrastructural level (Figures 12.27 ,12.28). Somatotroph cells are rathe and their number, morphology, and immunoreactivity are unchanged by a

The product of GH cells has extensive effects by direct action of GH and mediators of hepatic origin called somatomedins (insulin-like growth facto Growth hormone functions as the major promotor of growth but also in s metabolic pathways, including glucose, insulin, and fatty acid. The pulsatil from the anterior lobe is under the control of the two hypothalamic regu growth hormone releasing hormone (GHRH) and somatostatin (growth h inhibiting hormone). The GHRH controls GH synthesis by regulating transc via control of cAMP levels. Somatostatin appears to determine the timing pulses but has no effect on GH synthesis. Hypersecretion of GH in childre whereas its overproduction in adults leads to acromegaly.

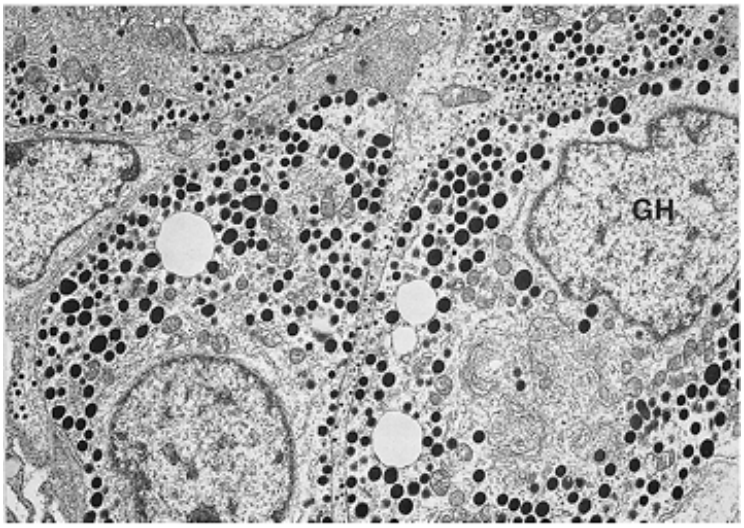

Figure 12.28 Densely granulated somatotrophs (GH cells) showing promi numerous 200- to 500-nm secretory granules (original magnification Ã—

Lactotroph cells.

Lactotrophs, or PRL cells, comprise approximately 20% of anterior pituitar concentrated in the posterior portions of the lateral wings. Histologically, acidophilic (densely granulated) or chromophobic (sparsely granulated). are more numerous, are located predominantly in the posterior lateral wi elongate processes, and, despite an abundance of endoplasmic reticulum Golgi complexes, contain relatively few cytoplasmic granules (Figures 12. Table 12.4). Densely granulated lactotrophs are thought to represent a whereas sparsely granulated cells are engaged in active secretion. A cha PRL staining of lactotrophs by immunohistochemistry, the so-called â€œG the presence of paranuclear staining corresponding to PRL in the Golgi ap 12.29).

With the exception of pregnancy and lactation, there is no significant diffe number between males and females. The doubling in volume of the pituit is due to striking hyperplasia as well as hypertrophy of chromophobic lac pregnancy cells. They persist until shortly after delivery or the terminatio). Prolactin cell hyperplasia also may accompany estrogen administration (32). The existence of mammosomatotrophs, cells engaged in PRL and G possessing unique ultrastructural features, attests to the existence of a relationship between PRL and GH cells (38).

Prolactin secretion is unique among the anterior pituitary hormones in tha hypothalamic

inhibition by dopamine (hypothalamic PRL-inhibitory factor, or PIF) produc tuberoinfundibular dopamine neurons. Several prolactin-releasing factors secretion, including TRH and vasoactive intestinal peptide (VIP). A fragmer been shown to inhibit PRL release. Prolactin synthesis is also regulated by on PRL gene expression. Disruption of the hypothalamus or the hypotha stalk may impede dopamine delivery to the anterior lobe, causing hyperp phenomenon termed â€œstalk effect.â€• Common situtations are any s or parasellar mass (e.g., pituitary macroadenoma, Rathke's cleft cyst, cr glioma) that compresses the pituitary stalk. The most striking example of

hyperprolactinemia that follows surgical transection of the stalk, a practic once used in the past for the treatment of metastatic breast cancer (39).

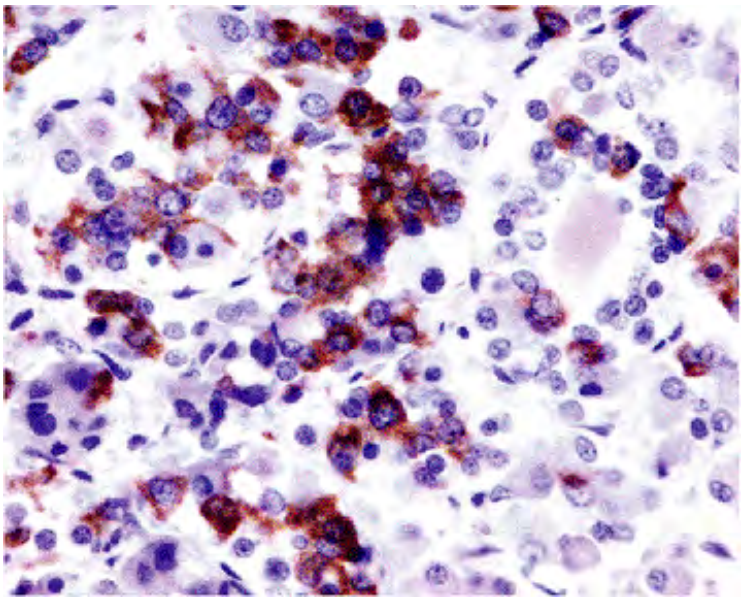

Figure 12.29 Lactotrophs. Lactotrophs comprise 15% to 20% of anterior majority are sparsely granulated, angular cells with processes that may v cells. Many lactotrophs in this field show paranuclear staining, a pattern in the Golgi apparatus (PRL immunostain, original magnification Ã—100).

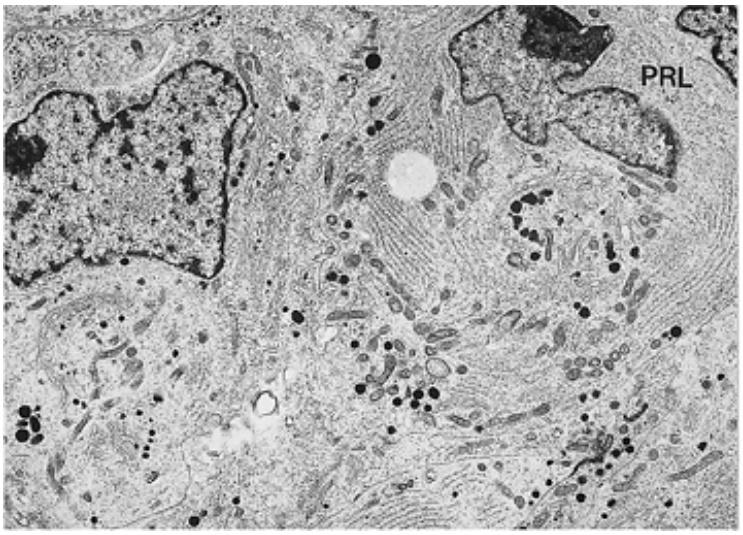

Figure 12.30 Sparsely granulated PRL cell. Note the abundant cisternae endoplasmic reticulum and the prominent Golgi complex containing pleor

granules. Mature PRL granules range in size from 200 to 350 nm (origina
Ã—8,700).

Prolactin acts through specific prolactin receptors in multiple tissues, incl
ovary, testis, and prostate. The main site of PRL action is in the breast,
the formation of casein, lactalbumin, lipids, and carbohydrates, all essent
breast milk. During pregnancy, high levels of estrogen, progesterone, pla
PRL induce acinar development and promote milk formation. As previously
secretion is under the control of oxytocin, a potent stimulator of myoepit
in breast tissue.

Corticotroph cells.

Corticotrophs, or ACTH cells, comprise 15% to 20% of adenohypophysial
numerous in the mid- and posterior portions of the mucoid wedge (Figure
Histologically, corticotroph cells are polygonal, medium- to large-sized, ar

Thyrotroph cells.

Thyrotrophs, or TSH cells, are located primarily in the anterior part of the comprise only 5% of adenohypophysial cells (41). They are medium sized elongate (Figures 12.35 ,12.36). Like corticotrophs, normal TSH cells are PAS positive (see Table 12.4 for ultrastructural features).

Thyroid-stimulating hormone (TSH, a glycoprotein hormone) binds to thyr RNA and protein synthesis and thereby the production of thyroglobulin ar Like the other two glycoprotein hormones of the pituitary [luteinizing horr follicle-stimulating hormone (FSH)], TSH consists of two noncovalently bo (Î±) and beta (Î²). The Î±-subunit is common to all three glycoprotein ho subunit is specific for each hormone and confers biological specificity. Sec

regulated by both hypothalamic hormones and circulating thyroid hormor releasing hormone (TRH) stimulates TSH release, while somatostatin and TSH secretion. In the setting of primary hypothyroidism, thyrotrophs unc and hyperplasia. When excessive, the response may produce sufficient hy pituitary gland to mimic adenoma. Pituitary adenomas that elaborate TSH occur in the setting of hypothyroidism (36), although a minority result i

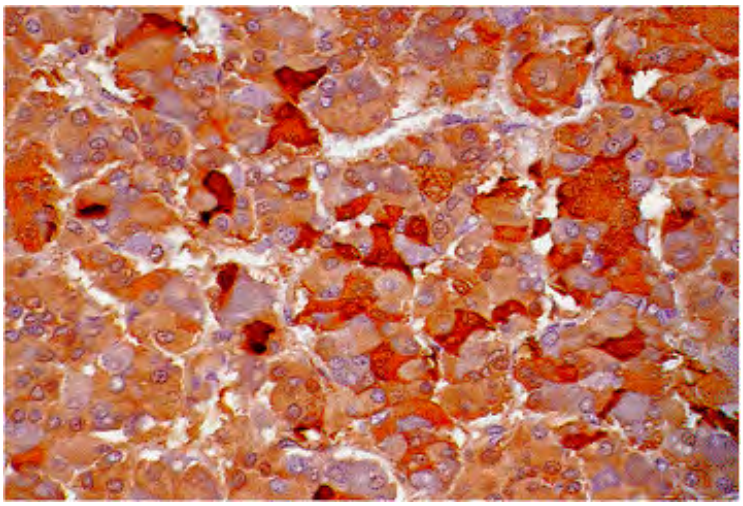

Figure 12.35 Thyrotroph (TSH cell). Thyrotrophs are medium-sized angu demonstrating elongate processes. They comprise only about 5% of ante cells and show strong TSH immunoreactivity (TSH immunostain, original Ã—100).

Gonadotroph cells.

Gonadotrophs, or FSH and LH cells, comprise 10% of the adenohypophysis affinity for both basic and PAS stains, and generally are evenly distribute anterior lobe. Immunohistochemical and ultrastructural studies have shown may be produced in isolation or by the same cell (42) (Figures 12.37 ,12 for ultrastructural features). In the daily practice of surgical pathology, against the specific Î²-subunits of LH and FSH are universally applied. In

against the Î±-subunit of the glycoprotein pituitary hormones (LH, FSH, ar determination of abnormal production and/or secretion of this subunit ho

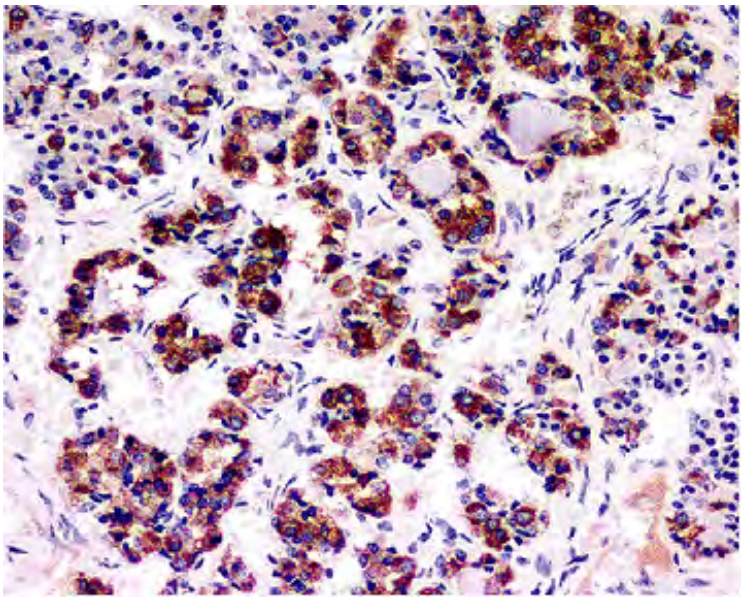

Figure 12.37 Gonadotroph (FSH/LH cell). Gonadotroph cells manufacture The paucity of strongly staining cells in this field reflects the fact that onl lobe secretory cells are gonadotrophs (FSH immunostain, original magnif

Both LH and FSH play distinct but essential roles in the reproductive phys

females. Secretion of these hormones from the gonadotroph cells is regu of the GnRH (LHRH) signal and feedback effects of gonadal steroids and follistatin and activin (43). GnRH (LHRH) interacts with a membrane rece LH and FSH release and synthesis, and it is necessary for gonadotroph c steroids and peptides are ineffective alone in stimulating release. In the f required for ovulation and follicular luteinization. In males, it stimulates cells to produce testosterone. Follicle-stimulating hormone promotes follic the female, whereas in the male it induces Sertoli cells to produce an ar protein.

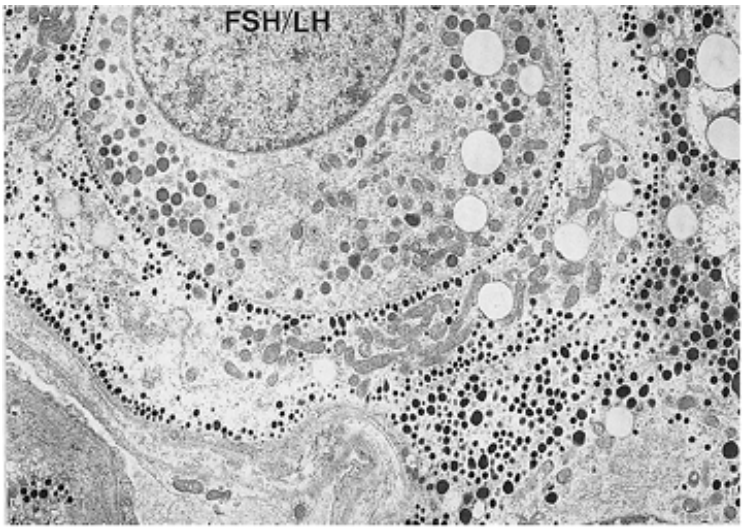

Figure 12.38 Gonadotroph (FSH/LH cell). The dull, low-contrast appearan typical of gonadotrophs. Their spherical and slightly irregular secretory g characteristic; they have variable electron density and measure 250 to 40 process surrounding the gonadotroph likely belongs to a thyrotroph (orig Ã—8,250).

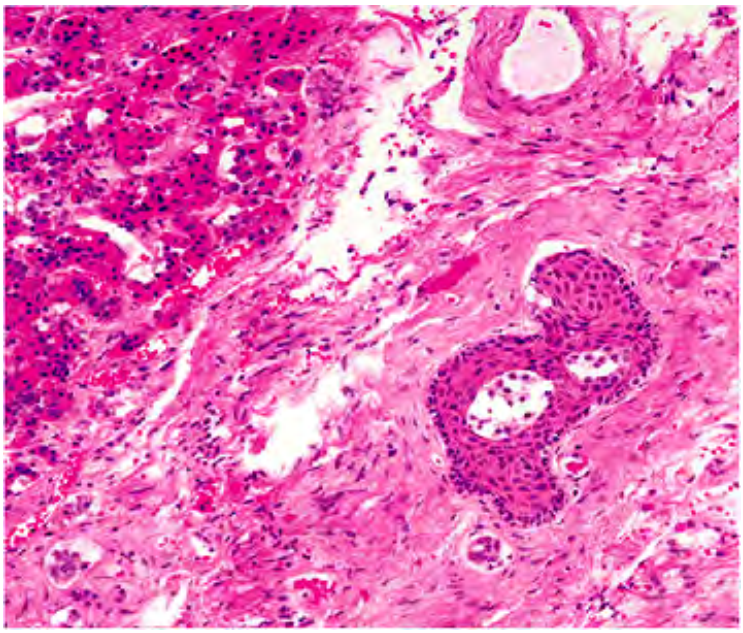

Figure 12.39 Anterior pituitary, pars tuberalis. Squamous metaplasia of common feature of this portion of the gland.

Par Tuberalis.

The pars tuberalis, an upward extension of the anterior lobe along the pi composed of normal acini of pituitary cells scattered among surface porta often show immunoreactivity for ACTH, FSH, LH, and Î±-subunit. Althoug they may or may not differ from similar cells in the pars distalis, these ce tendency to undergo squamous metaplasia (Figure 12.39) (44).

Follicles are not an uncommon feature of the normal anterior pituitary. T constituent cells, termed follicular cells, appear to be derived in large par secretory cells (Figure 12.40). Ultrastructurally, they are

often poorly granulated or agranular and linked by apical junctional comp follicular lumina, one often finds cellular debris (Figure 12.41). The stim formation is therefore thought to be damage or rupture of anterior lobe s

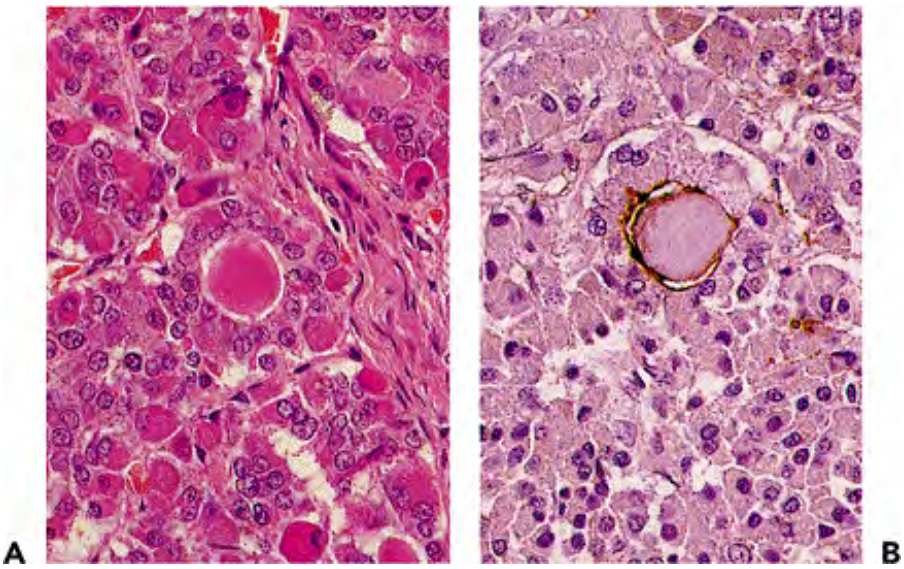

Figure 12.40 Anterior pituitary, follicle formation. A. Follicles, some con quantity of colloid-like material, are commonly found in the anterior lobe magnification Ã—100). B. Follicles show prominent apical staining for ep antigen (EMA) (EMA immunostain, original magnification Ã—100).

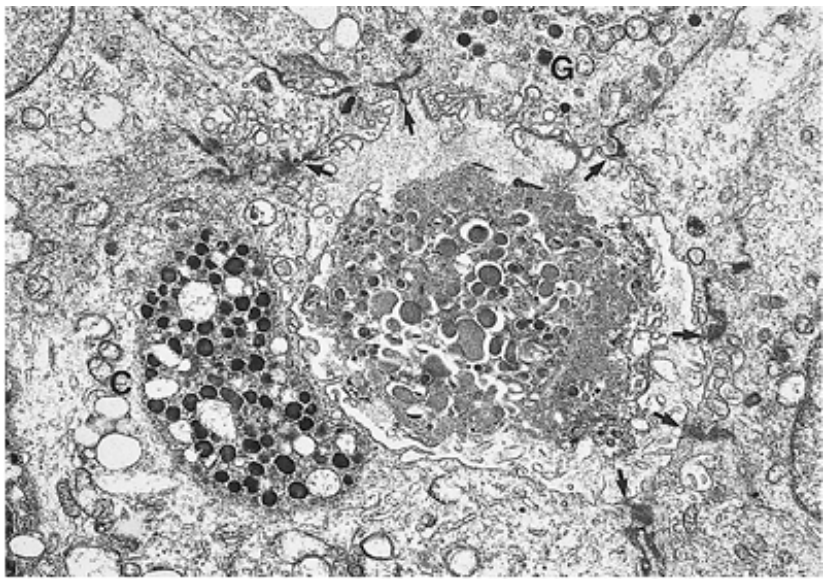

Figure 12.41 Electron micrograph of a pituitary follicle. This young follic debris within its lumen. The gonadotroph (G), but not the corticotroph (C) follicle. Follicles are composed of granulated adenohypophysial cells that, formation of junctional complexes (*arrows*), surround damaged adenohy (original magnification Ã—12,600).

Folliculostellate cells.

The folliculostellate cell is the sixth cellular element of the adenophypoph sustentacular-like cell that appears to have multiple functions related to secretion of growth factors (46 ,48). They comprise less than 5% of the are scattered about the anterior lobe, and contribute to the formation of and cysts of the intermediate lobe. They are readily identified by their re protein (Figure 12.42), and can also be identified by glial fibrillary acidic vimentin. They participate in regulating the activity of anterior pituitary through the production of cytokines (such as interleukin-6, and leukemia and growth factors (including basic fibroblast growth factor and vascular factor) (48). Additionally, ultrastructural and immunohistochemical studie adenomatous and nonneoplastic pituitary folliculostellate cells suggest tha represent an adult stem cell progenitor population (47 ,48).

Variation in Normal Morphology of the Adeno

A number of normal histologic variations in the pituitary gland may mimi lesions. Examples include squamous cell nests in the pars tuberalis, baso posterior lobe, granular cell clusters and tumorlets of the stalk and neur salivary gland rests.

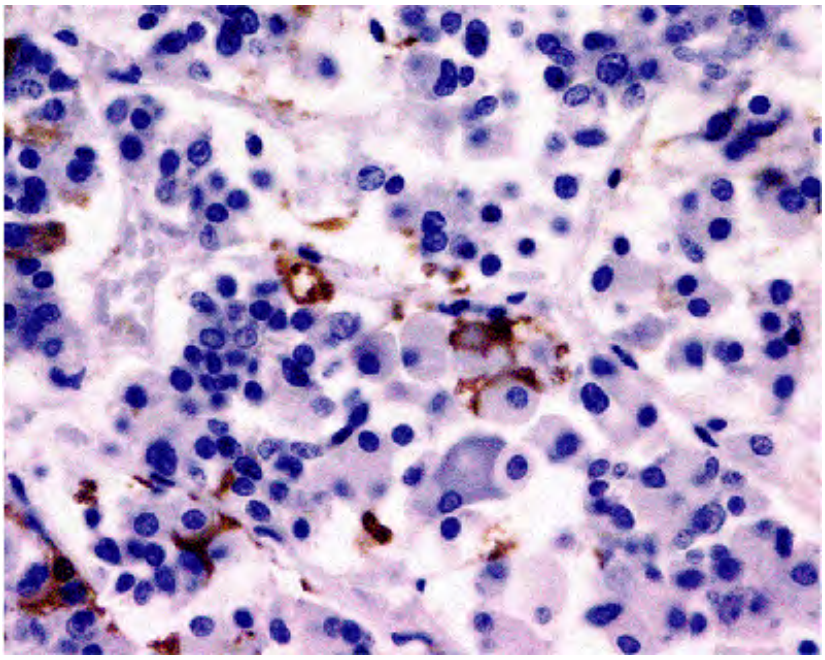

Figure 12.42 Anterior lobe folliculostellate cells. Folliculostellate cells cor of anterior lobe cells and are scattered throughout the pituitary, including lobe zone. Folliculostellate cells staining for S-100 protein, GFAP, and vir immunostain, original magnification Ã—100).

Squamous cell nests show a definite predilection for the pars tuberalis; th in up to 24% of autopsy cases, occur more commonly in elderly patients, predilection (49). They arise through a process of metaplastic transforma adenohypophysial cells, as evidenced by simultaneous expression of kerat hormones, most often FSH, LH, or ACTH (44) (Figure 12.39). Because s also may accompany foci of ischemic infarction in the anterior lobe, it app inherent property of pituitary secretory cells.

Basophil invasion, a finding more common in males and the elderly, may an adenoma. It consists of corticotrophic basophils extending from the pa the neurohypophysis (Figures 12.43 ,12.44). Similar to ordinary corticot basophilic cells are immunoreactive for ACTH, Î²-LPH, endorphins, and ot derivatives; however, they contain few cytokeratin filaments and are less Crooke's hyalinization in response to hypercortisolism (36).

Salivary gland rests appear as tubular glands upon the surface or in the s neurohypophysis, often just posterior to the pars intermedia (Figure 12.4

composed of a single layer of cuboidal to columnar epithelium with basall finely granular, strongly PAS-positive cytoplasm. Salivary gland rests are Their ultrastructural features include well-developed rough endoplasmic droplets, microvilli, and desmosomes, all of which support the contention salivary glands (50).

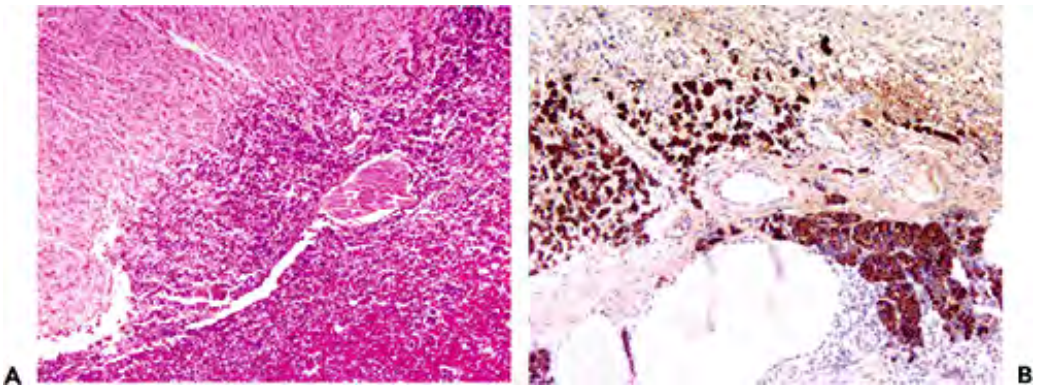

Figure 12.43 Basophil invasion. A. This subpopulation of corticotroph cel infiltrate the substance of the posterior lobe (H&E, original magnification invading cells are strongly immunoreactive for ACTH and other POMC der (ACTH immunostain, original magnification Ã—40).]

Age-Related Changes of the Adenohypophysis

The cytology of the anterior pituitary varies with age. For instance, the la pituitary gland shows PRL cell hyperplasia, a reflection of high maternal when compared with the adult pituitary, the prepubertal gland shows gor be poorly developed. In adults the pituitary undergoes several changes w (51 ,52).

With few exceptions, the main one being pregnancy, the gland weight rer throughout life, decreasing only slightly in the elderly due to anterior lob results in a doubling of the size of the pituitary due to gradual increase i PRL cells (â€œpregnancy cellsâ€•) (53 ,54) (Figure 12.46). The increa cells during pregnancy appears to result not only from proliferation of PRL recruitment of GH cells to PRL production (55). This increase in PRL-proc

part a hyperplasia, gradually disappears within months after delivery or a
is often incomplete; hence, the pituitaries of multiparas are larger than th
were never pregnant. Pregnancy also results in a significant decrease of
immunoreactivity, a reflection of the production of gonadotropic hormones

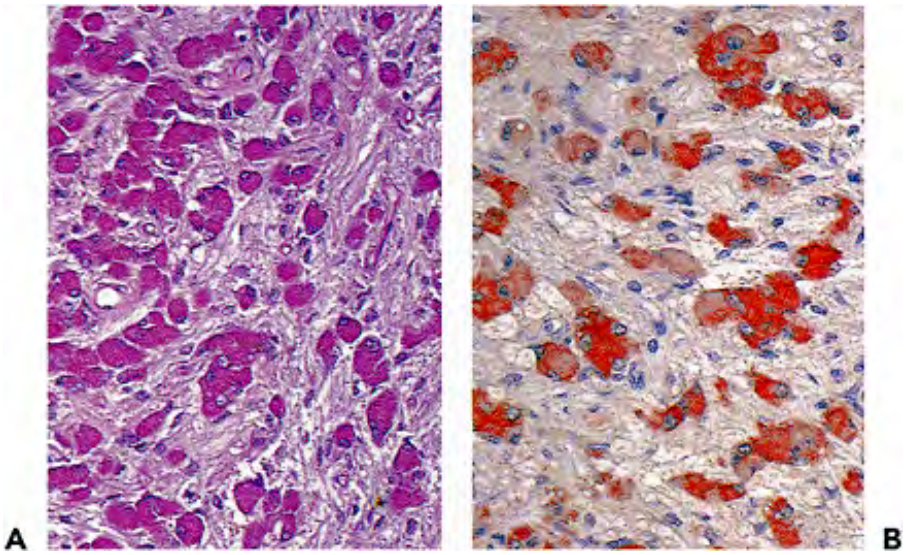

Figure 12.44 Basophil invasion. A. PAS staining (original magnification A
immunostain (original magnification Ã—63).

The effects of age on the cellular contents of several pituitary hormones
Specifically, GH and PRL cells have been shown to undergo no significant
granularity, distribution, or immunoreactivity with increasing age (56 ,57
TSH cells also appear to be unaffected by age, but no data are available
of senescence on FSH and LH cells. Small foci of lymphocytes, usually in
lobe, are present in about 40% of adult pituitaries but are conspicuously
and very young children (51).

Fibrosis is the most frequent age-related change in elderly patients. It is
perivascular in distribution (Figure 12.47)

but is on occasion patchy, suggesting a remote microinfarct. Interstitial
deposits of amyloid have been demonstrated in the majority of autopsy-
pituitaries (58). Immunohistochemically, these reacted for antiamyloid la
chain and amyloid P component. The mean volume percentage of such de

approximately 0.5% of the anterior lobe. The occurrence of amyloid and i deposition was related not only to patient age but also to the prevalence obstructive pulmonary disease and to nonâ€“insulin-dependent diabetes

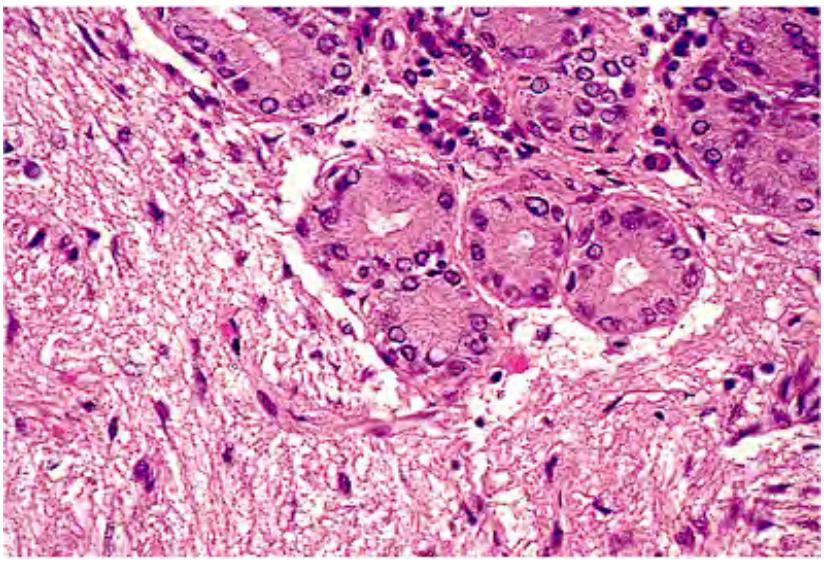

Figure 12.45 Salivary gland rest in the posterior lobe. The glands are co layer of cuboidal to columnar epithelium with basally oriented nuclei and positive cytoplasm. Salivary gland rests are encountered both on the surfa posterior lobe, where it abuts the intermediate lobe zone (H&E, original

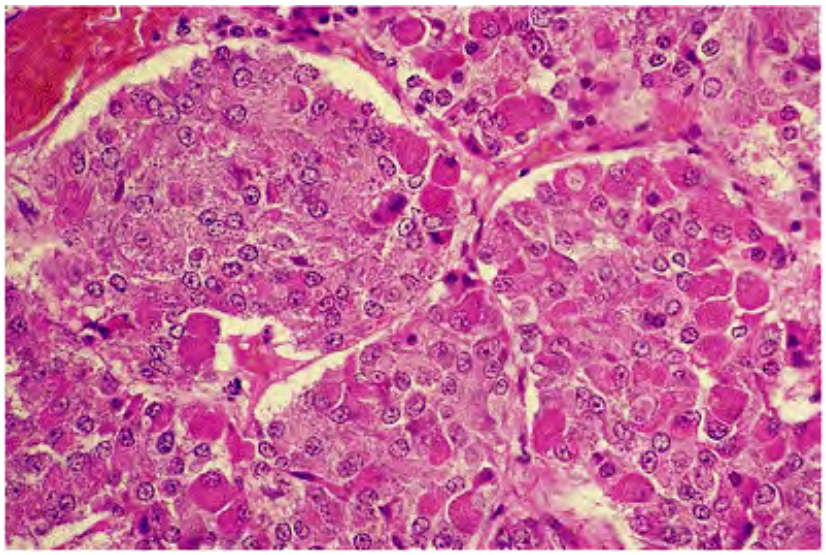

Figure 12.46 The pituitary in pregnancy features abundant pale chromop

(pregnancy cells) (H&E, original magnification Ã—100).

Neurohypophysis

As a functional unit, the neurohypophysis consists of the infundibulum, p posterior lobe. The posterior lobe, a ventral extension of the central nervo site of release of the hypothalamic hormones oxytocin and vasopressin. I consist of unmyelinated axons originating from the supraoptic and parave to a lesser extent, from cholinergic neurons of the hypothalamus, an ext network, and specialized glial cells termed pituicytes (Figure 12.48).

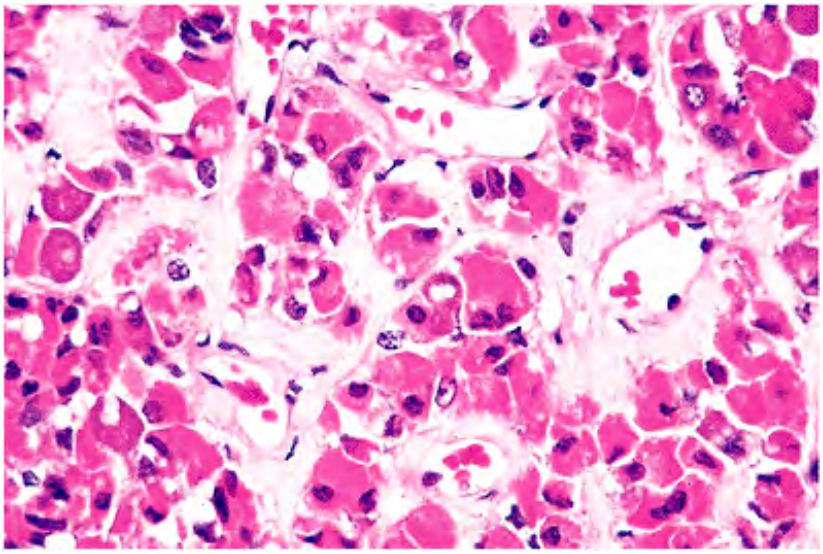

Figure 12.47 Perivascular fibrosis is a common feature of the aging pitu magnification Ã—100).

Pituicytes, the most numerous cells of the neurohypophysis, are morpho uni- or bipolar cells that display the prolongation of the cytoplasm into on processes. Pituicytes are strongly positive for glial fibrillary acidic protein 12.48), as well as S-100 protein and vimentin. Similar to glial cells of ot central nervous system, pituicytes expand processes to adjacent connectiv blood vessel wall. Pituicytes appear to exist in five principal forms: majo oncocytic, and granular (59). Their morphologic diversity, ranging from ependymal, is thought to be a reflection of their physiologic role, which as

).

Histologically, the axons of the posterior lobe are readily identified using immunostains for

neuronal markers. Focal axonal dilatations, known as Herring bodies, rep accumulations of posterior lobe hormones (Figure 12.22). At the ultrastr unmyelinated axons appear as delicate fibers, measuring 0.05 to 1.0 Âµ contain longitudinal arrays of microtubules and neurofilaments. Two types axon, A and B, have been described based on the morphology of their n granules. Type A fibers, far more numerous than type B, contain 100- to vasopressin granules, whereas type B fibers, likely aminergic in nature, ranging from 50 to 100 nm (61). Neurosecretory fibers are closely assoc their axons often being ensheathed by them (Figure 12.49).

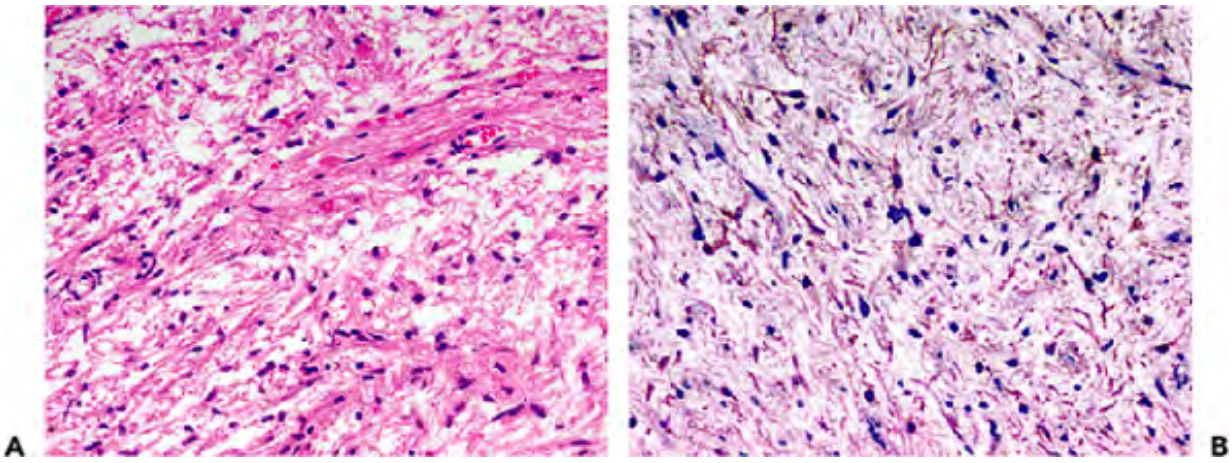

Figure 12.48 Posterior lobe. A. Pituicytes have elongated nuclei disperse of the neurohypophysis (H&E, original magnification Ã—100). B. These c for glial fibrillary acid protein (GFAP) (GFAP immunostain, original magni

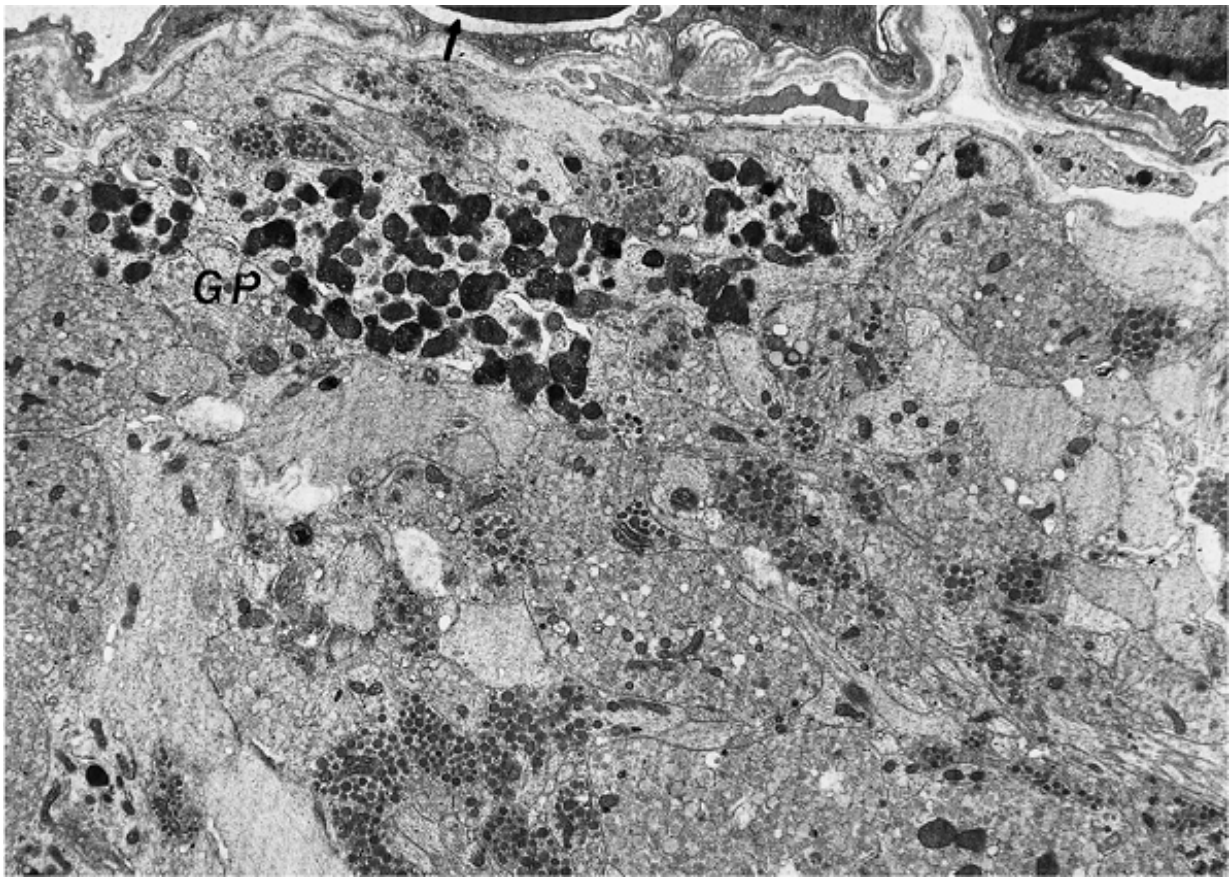

Figure 12.49 Pituitary, posterior lobe. This electron micrograph shows a containing neurosecretory granules of varying electron density. A granula containing numerous prominent lysosomes lies in close proximity to the (*arrow*). The intravascular space is bounded by fenestrated endothelial c Outside the endothelium lies the perivascular space, a region containing a (not shown here), including pericytes, histiocytes, fibroblasts, and mast magnification Ã—6,200).

The most important function of the neurohypophysis is the transfer of ho from neurosecretory granules to the intravascular space. The complex ana neuronal, vascular, and perivascular compartments forms the basis for th Beginning at the neuronal side, neurohormonal factors appear to be relea channels that traverse the outermost, or abluminal, basement membrane communicate with the perivascular space. They then traverse the inner, membrane and endothelium in order to gain access to the vascular space).

Variation in Normal Morphology of the Neuro

Granular cell nests or tumorlets, most located in the stalk or posterior lob about 6% of autopsy pituitaries and are more common among the elderly scattered cells to compact tumorlike nodules, they are composed of plum acidophilic and strongly PAS-positive cytoplasm and relatively small nuclei Only rarely do granular cells form clinically significant tumors (64). The tumorlets and tumors of the neurohypophysis is uncertain. In rare cases, immunoreactivity has been shown, providing some evidence of the hypoth granular cell nests may originate from pituicytes (65).

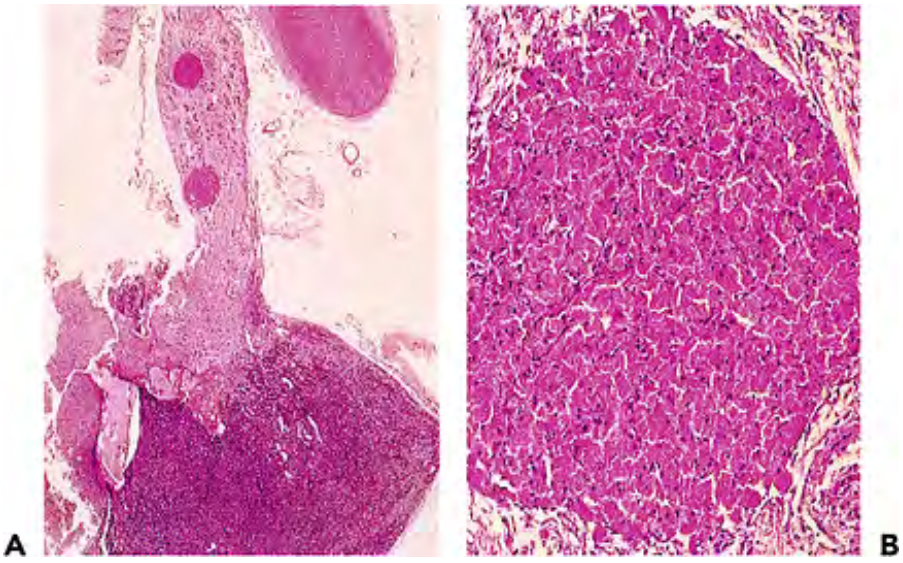

Figure 12.50 Pituitary stalk, granular cell tumorlets. A. Low-power view two tumorlets. The optic chiasm is at the upper portion of the field; the a lower portion of the field (H&E, original magnification Ã—20). B. High-pov granular cell tumorlet. Such nodules are composed of pituicytes, modified abundant lysosome-rich eosinophilic cytoplasm. Tumorlets, as well as ind are of no clinical significance (H&E, original magnification Ã—100).

Differential Diagnosis

The principal consideration in differential diagnosis of pituitary lesions is

normal pituitary tissue from adenoma. The most conspicuous architectural adenohypophysis is the arrangement of its cells in acini that, depending c section, vary from round to oval or somewhat elongate. The acini are sur reticulin- or PAS-positive capillary network (Figure 12.17). In contrast, lack this uniform acinar architecture, showing only scant reticulin that is vessels (Figure 12.51). Although most normal pituitary acini are heterog cellular content, thus permitting the distinction of normal from adenomato sections alone, some parts of the pituitary contain largely a single cell typ monomorphous. For instance, eosinophilic GH cells are present in large nu wings. On the other hand, occasional adenomas composed of mixed cell ones associated with acromegaly) superficially resemble normal adenohypo the distinction of normal from adenomatous tissue may be more easily ac reticulin staining than by immunohistochemistry alone. Small biopsies of may include the so-called basophilic infiltration normally seen in the post (Figures 12.43 ,12.44). Since these basophilic cells are arranged diffusely lack the typical acinar formation seen in the anterior pituitary, they may ACTH-microadenomas.

A limited biopsy of the pituitary may occasionally include intermediate zon normal derivatives of Rathke's cleft. Correlation with radiologic and opera obviates confusion with Rathke's cleft cyst. Clinically significant cysts are neuroimaging and are identified as sizable cysts by the experienced surg

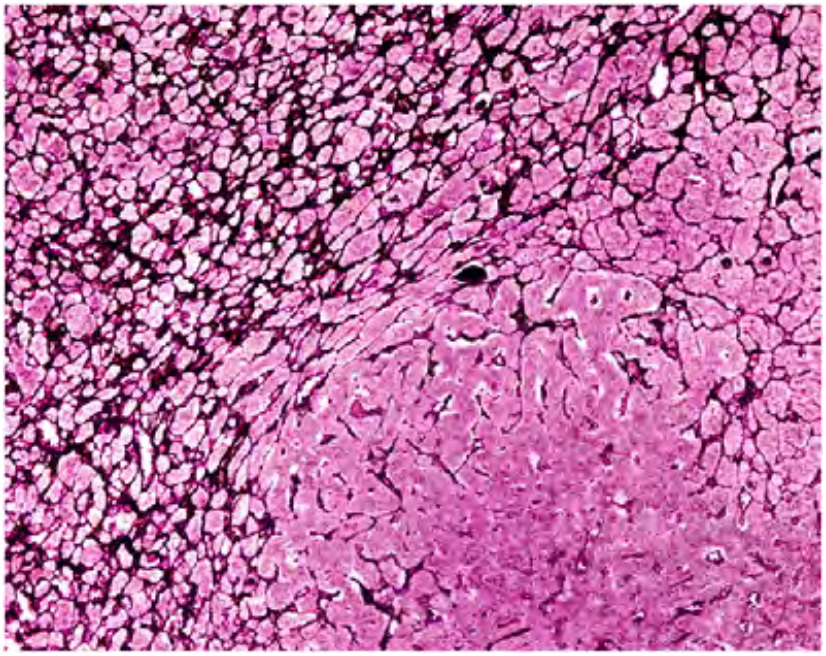

Figure 12.51 Disruption of the reticulin network in a pituitary adenoma. pattern of the normal adenophypophysis (*upper left*) with the adenoma ((wilder reticulin, original magnification Ã—100).

As previously noted above, adenohypophysial cells may undergo squamou particularly in the pars tuberalis. This location is only occasionally sample specimens. Scant in extent, intimately associated with adenohypophysial cytologically benign, they are unlikely to be confused with either cysts (e cysts) or with neoplasms (craniopharyngiomas). In very small numbers, lymphocytes are seen in the intermediate zone of the normal pituitary in subjects (66). Unassociated with endocrine disease, such cells are readil the far more widespread and dense infiltrates of lymphocytic hypophysitis

A limited biopsy of the neurohypophysis can readily be mistaken for glioma majority of its nucleated cells are specialized astrocytes (pituicytes). Unli astrocytomas, the tumor most closely mimicked by posterior pituitary tiss neurohypophysis contains large numbers of axons terminating on vessels. some possess PAS-positive swellings (Herring bodies). Secondary involvem by more ordinary diffuse astrocytomas is exceedingly rare.

Normal Eye and Ocular Adnexa

Gordon K. Klintworth

Thomas J. Cummings

Introduction

The eye and surrounding tissues are subject to a wide variety of primary ocular and systemic disease processes. An understanding of ocular anatomy will enable the general surgical pathologist to appreciate morphologic abnormalities and will facilitate the diagnosis of many of the pathologic conditions affecting those structures. Similar to other specimens received by the surgical pathologist, in some cases a discussion with the ophthalmologist who is submitting the tissue is important for proper handling, sectioning, and processing of the tissue. Proper handling of the tissue is required so as to not artifactually mask the diagnostic histologic features, such as the common age-related arcus lipoides.

This chapter presents an overview of the normal histology of the eye and ocular adnexa. Several excellent texts are available for more detailed information on ocular anatomy and development (1,2,3,4,5).

The eye is roughly spherical in shape and external measurements are routinely obtained in three dimensions. In the adult, the anterioposterior plane of the eye measures approximately 24 mm,

whereas the vertical and the horizontal dimensions are both about 23 to 23.5 mm. Located midway between the anterior and posterior poles of the eye is the equator of the globe.

Several external landmarks allow the pathologist to orient the globe and to determine whether an eye is from the right or the left side (Figure 13.1). By establishing the nasal (medial) and temporal (lateral) sides of the globe and the superior surface of the eye, the side of the eye can easily be deduced. The six extraocular muscles (four rectus and two oblique muscles) that arise in the posterior orbit and run forward to insert upon the sclera are important in this regard. The rectus muscles arise from a fibrous ring at the apex of the orbit, the annulus of Zinn, and are enveloped by a fascial membrane that creates a cone-shaped structure posterior to

the globe. The levator palpebrae superioris also arises at the orbital apex and extends anteriorly to the eyelids. Of the extraocular muscles, only the inferior oblique has a muscular insertion upon the sclera; the other muscles have tendinous insertions. The extraocular muscle insertions are usually removed by the surgeon when the globe is excised (enucleated), but they are frequently present on eyes obtained postmortem. The superior and inferior oblique muscles are most useful in orientating the globe. The tendinous insertion of the superior oblique muscle behind the superior rectus muscle insertion indicates the top of the eye. The inferior oblique muscle inserts on the sclera temporally in the horizontal meridian, and its fibers run inferiorly toward the back of the orbit. The optic nerve is also useful in assessing orientation because it exits the globe slightly nasal to the posterior pole of the eye. Adjacent to the optic nerve, the prominent long posterior ciliary arteries course through the superficial sclera in opposite directions in a horizontal plane. Anteriorly, the dimensions of the cornea may be helpful in topographic orientation. In the adult, the cornea is elliptical in shape with its horizontal diameter being slightly greater than its vertical breadth. In young children, this difference is less apparent.

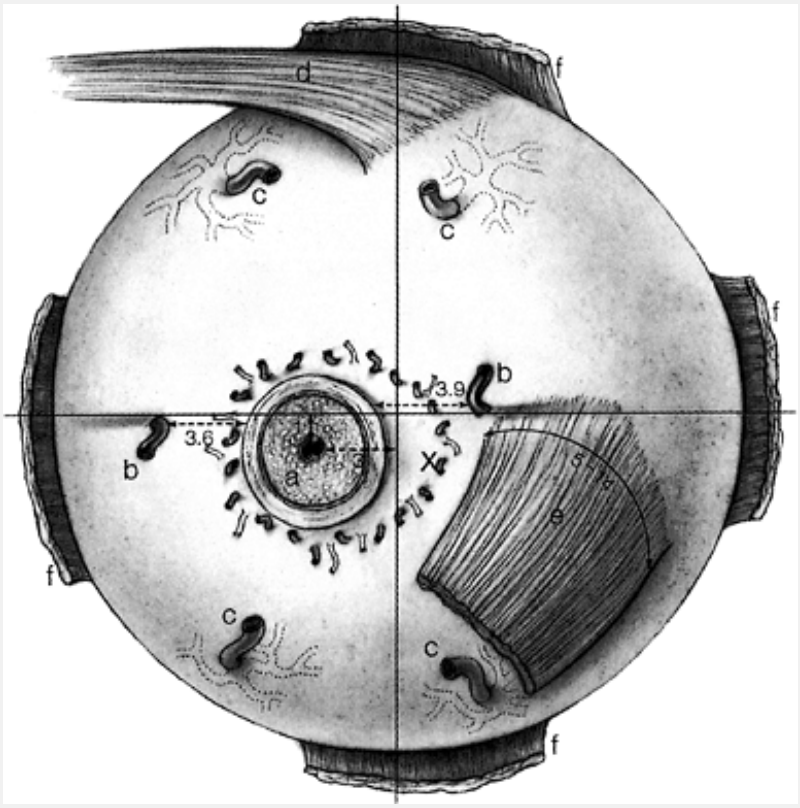

Figure 13.1 This drawing depicts the right eye as seen from behind. Several external landmarks are useful in determining orientation of the globe. The optic nerve (*a*) is located approximately 1 mm inferior to and 3 mm nasal to the posterior pole of the eye. The long posterior ciliary arteries (*b*) are located in the horizontal plane, and four vortex veins (*c*) exit the sclera posteriorly. The superior oblique muscle (*d*) inserts on the top of the globe, whereas the inferior oblique muscle (*e*) inserts temporally, and its fibers run posteriorly and nasally. The rectus muscles (*f*) insert horizontally, inferiorly, and superiorly. The approximate location of the macula (*x*), the part of the retina responsible for the most distinct vision, is slightly temporal to the optic nerve. (Reproduced with permission from: Hogan MJ, Alvarado JA, Weddell JE. *Histology of the Human Eye: An Atlas and Text.* Philadelphia: WB Saunders; 1971.

)

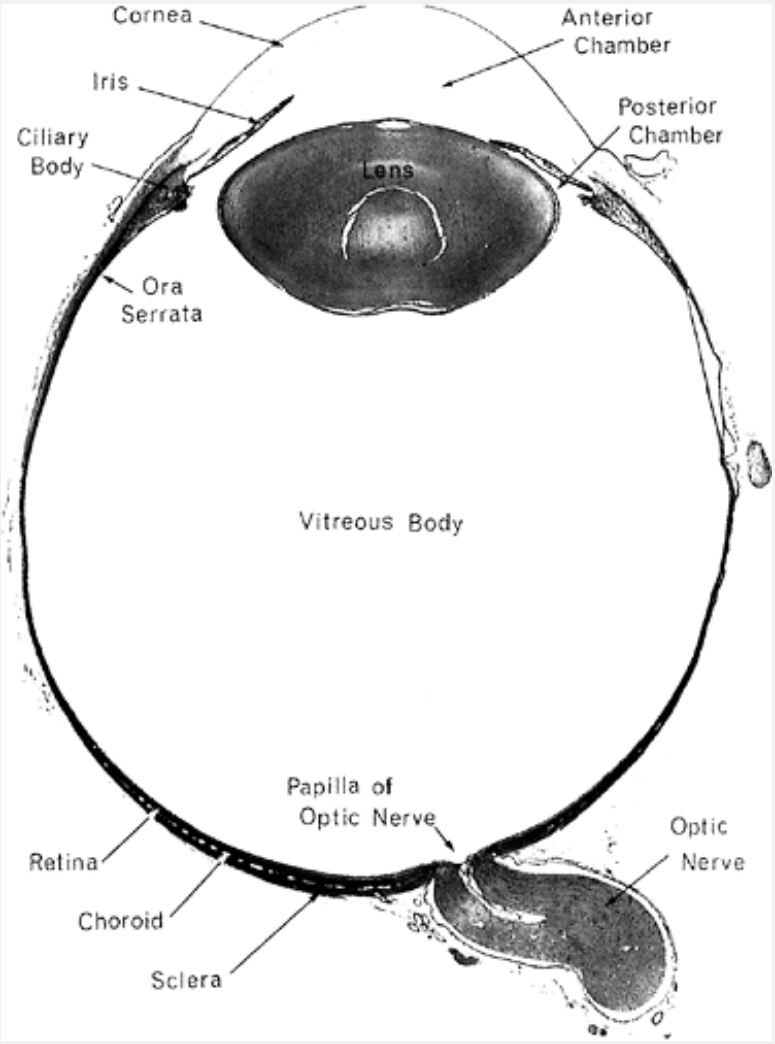

Figure 13.2 This photomicrograph of a histologic section of an eye from a rhesus monkey illustrates the major tissue layers of the eye, the lens, the vitreous humor body, and the spaces of the anterior and posterior chambers. (Reproduced with permission from:
Bloom W, Fawcett DW. *A Textbook of Histology.* 12th ed. New York: Chapman and Hall; 1994.

)

The eye is traditionally described as having three tissue layers that surround the vitreous humor, the lens, and the spaces of the anterior and posterior chambers (Figure 13.2). The outermost part of the eye is composed of the transparent cornea and the opaque sclera. The ocular middle layer is made up of the iris, ciliary body, and the choroid. The innermost retina is in direct contact with the vitreous humor body.

Cornea

The transparent cornea occupies one-sixth of the anterior surface of the globe and refracts the entering light. Although individual variation is common, the cornea measures approximately 11.7 mm in the horizontal plane and 10.6 mm in the vertical plane. Centrally, the cornea is about 0.5 mm thick, but peripherally it thickens to about 0.67 mm. Histologically, the cornea consists of six distinct layers: (a) the epithelium; (b) the basal lamina of the epithelium; (c) Bowman's layer; (d) the stroma; (e) Descemet's membrane; and (f) the endothelium (Figure 13.3).

Figure 13.3 The stratified squamous epithelium of the cornea (*arrow*) overlies the basal lamina and Bowman's layer. The clefts within the collagenous stroma (*double arrows*) represent artifacts of tissue processing. No blood vessels or lymphatics are normally present within the cornea. Descemet's membrane and the corneal endothelium are located just posterior to the stroma. (H&E, Ã—33.)

The corneal epithelium, which is composed of stratified nonkeratinized squamous cells, is about five cell layers thick centrally. The peripheral cornea is often twice as thick. The basilar epithelial cells are polygonal in shape; and, as they become displaced to the corneal surface during differentiation, a more flattened appearance is acquired. In the normal cornea, even the most superficial epithelial cells retain their nuclei. Mitotic figures are uncommon in the epithelium but are observed in the basal cells

occasionally. Some Langerhans cells are present within the corneal epithelium, especially peripherally (6). Apoptosis is also uncommonly seen in the epithelium of the normal cornea. Langerhans cells are most readily identified by special histochemical and immunohistochemical methods and are not normally recognizable in routinely stained tissue sections.

The corneal epithelium rests upon a basal lamina, which is difficult to see in hematoxylin and eosin (H&E)â€“stained tissue sections. Staining with the periodic acid-Schiff (PAS) reaction makes this layer apparent (Figure 13.4). In certain pathologic conditions, the epithelial basal lamina assumes an intraepithelial location.

Bowman's layer is an acellular structure located just posterior to the epithelial basal lamina (Figure 13.4). It is approximately 8 to 14 Âµm thick. As shown by transmission electron microscopy, Bowman's layer is not a true basement membrane but is composed of randomly oriented delicate collagen fibers. The anterior face of Bowman's layer ends distinctly at its junction with the epithelial basal lamina. Posteriorly, Bowman's layer merges inconspicuously with the underlying corneal stroma. Unmyelinated sensory nerves reach the epithelium from the stroma after crossing Bowman's layer. However, nerve processes are difficult to detect in the cornea in standard tissue sections, even with the use of special histologic techniques.

The stroma accounts for approximately 90% of the cornea's thickness. It is composed of numerous layers of collagen fibers embedded in a proteoglycan-rich extracellular matrix, and the anterior and posterior portions of the cornea have several differences. The stroma contains keratan sulfate proteoglycans (lumican, keratocan, mimecan), as well as a galactosaminoglycan-rich proteoglycan (decorin). Transmission electron microscopy has disclosed that the corneal collagen fibers are regularly spaced and of a uniform diameter; this arrangement contributes to the transparency of the cornea. The corneal fibroblasts (keratocytes) are surrounded by the stromal collagen lamellae. Other cell types are

seldom identified in tissue sections of the normal corneal stroma, but rarely an occasional mononuclear leukocyte or granulocyte may be present. The normal cornea lacks blood vessels, and its nutrition is obtained from an arterial plexus at the junction of the cornea and sclera and from direct contact with the aqueous humor of the anterior chamber. In tissue sections of routinely processed formalin-fixed corneas, clefts are almost invariably present between the collagen lamellae. Initially interpreted as lymphatic channels by early histologists, these clefts are artifacts of tissue processing. Lymphatic vessels are not present in the normal cornea.

Descemet's membrane, a true basal lamina elaborated by the underlying corneal endothelial cells, begins to form

during fetal life. At birth, it is approximately 3 to 4 Âµm thick (Figure 13.5). Basal laminar material is continuously added to the posterior part of Descemet's membrane throughout life so that by adulthood, this structure attains a thickness of approximately 10 to 12 *Âµ*m. The fetal and postnatal regions of Descemet's membrane differ ultrastructurally. This difference is occasionally discernible by light microscopy.

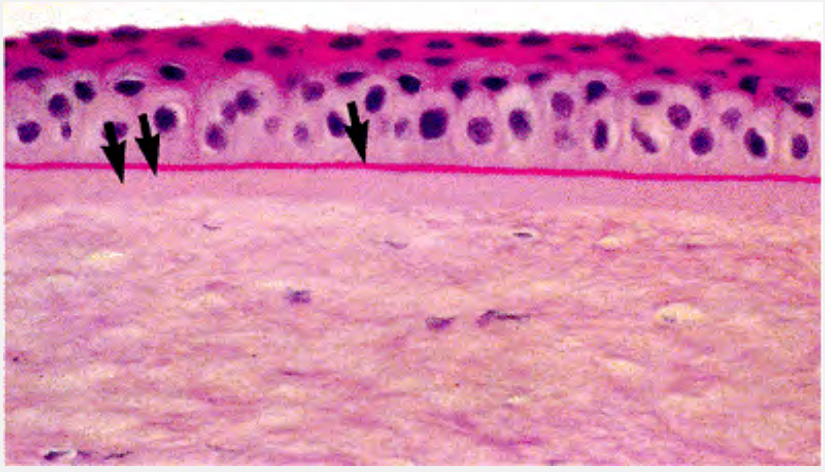

Figure 13.4 The corneal epithelium rests upon a thin basal

lamina (*arrow*), which is prominent in this section following periodic acid-Schiff staining. The acellular band directly underneath the basal lamina is Bowman's layer (*double arrows*) (PAS,Ã—132).

The corneal endothelium (Figure 13.5) is directly exposed to the aqueous humor in the anterior chamber. Although this cell layer does not line blood vessels or lymphatic spaces, the term *endothelium* is firmly entrenched in the literature. These cells function as an osmotic pump to regulate a necessary state of stromal dehydration that preserves corneal clarity. Endothelial decompensation results in corneal edema and diminished optical transparency. The corneal endothelium has been shown by immunohistochemistry to be S-100 proteinâ€“positive, a finding supportive of other evidence suggesting a neural crest origin (7). They react with the monoclonal antibody 2B4.14.1, which recognizes the renal Tamm-Horsfall glycoprotein (THGP) antigen, raising the possibility that the cornea expresses a molecule with homeostatic properties similar to that ascribed to THGP (8). The endothelial cells of the cornea normally form a single flattened layer and, virtually, never regenerate by mitosis in human eyes. Under pathologic conditions (epithelial ingrowth and posterior polymorphous corneal dystrophy), cytokeratin-containing squamous cells replace the endothelium and form a layer that is more than one cell thick.

After the second decade of life, age-related focal excrescences (Hassall-Henle warts) commonly form on the peripheral part of Descemet's membrane (Figure 13.6). Virtually identical focal thickenings occur on the central part of Descemet's membrane (corneal guttae) under pathologic circumstances and most notably in Fuchs's corneal dystrophy. The presence of excrescences on Descemet's membrane in tissue sections of corneal buttons removed at penetrating keratoplasty (full-thickness corneal transplant) is always abnormal. Hassall-Henle warts are too peripheral in location

to be present in a surgically excised corneal button.

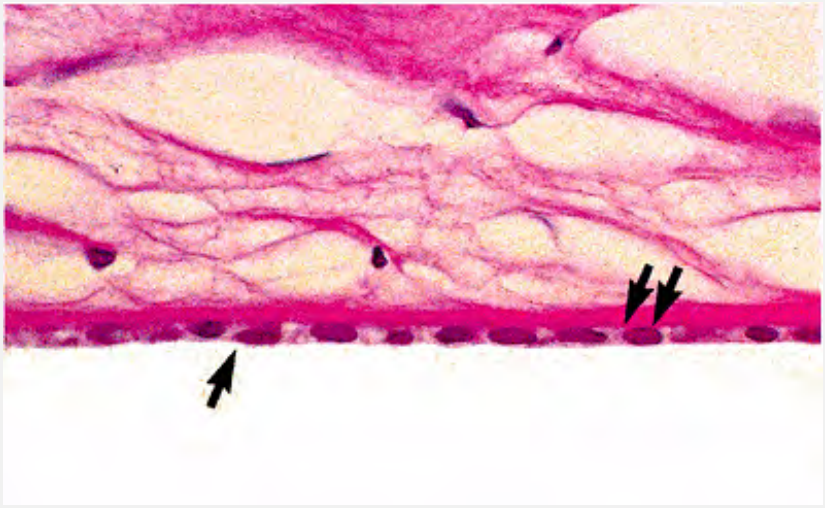

Figure 13.5 A thin monolayer of corneal endothelial cells (*arrow*) is adjacent to Descemet's membrane (*double arrows*). These cells are in direct contact with the aqueous humor of the anterior chamber (H&E, Ã—132).

Figure 13.6 Descemet's membrane (*single arrows*) is located

immediately posterior to the corneal stroma. The excrescences on the peripheral portion of Descemet's membrane (Hassall-Henle warts) (*double arrows*) represent an aging change. Descemet's membrane also thickens with age. (H&E, Ã—132.)

Corneal epithelium and endothelium are prone to being artifactitiously â€œrubbed-offâ€• during prosection of the tissue, and it is important to distinguish this artifact from the true loss of corneal epithelium and endothelium.

Sclera

The sclera, which accounts for approximately five-sixths of the surface area of the eye, begins at the periphery of the cornea and extends posteriorly to the optic nerve. The sclera's relatively rigid nature protects the eye from trauma and helps maintain intraocular pressure. Anteriorly, the sclera is visible underneath the transparent conjunctiva and is normally white in adults. The sclera varies in thickness, being about 0.8 mm thick near its junction with the cornea. At the insertions of the four rectus muscles (approximately 5 to 8 mm posterior to the corneoscleral junction), the sclera is at its thinnest, measuring approximately 0.3 mm. From this point posteriorly, the sclera gradually thickens and attains its maximal width of about 1.0 mm adjacent to the optic nerve.

The sclera has three components: the episclera, the stroma, and the lamina fusca. The episclera, its most superficial part, is located between the fibrous structure that envelopes the globe (Tenon's capsule) and the underlying scleral stroma with which it merges. The episclera is composed of loosely arranged collagen fibers and fibroblasts embedded in an extracellular matrix. Occasional melanocytes and mononuclear leukocytes are also present. Anteriorly, the episclera is richly vascularized.

The largest component of the sclera is its stroma, which consists of

fibrous bands of collagen, occasional elastic fibers, and scattered fibroblasts (Figure 13.7). The corneal

and scleral stroma appear similar at the light microscopic level; but, when viewed by transmission electron microscopy, the individual collagen fibers within the sclera vary in diameter and are randomly arranged, in contrast to the orderly packed corneal collagen fibers of uniform diameter. This largely accounts for the opaque nature of the sclera.

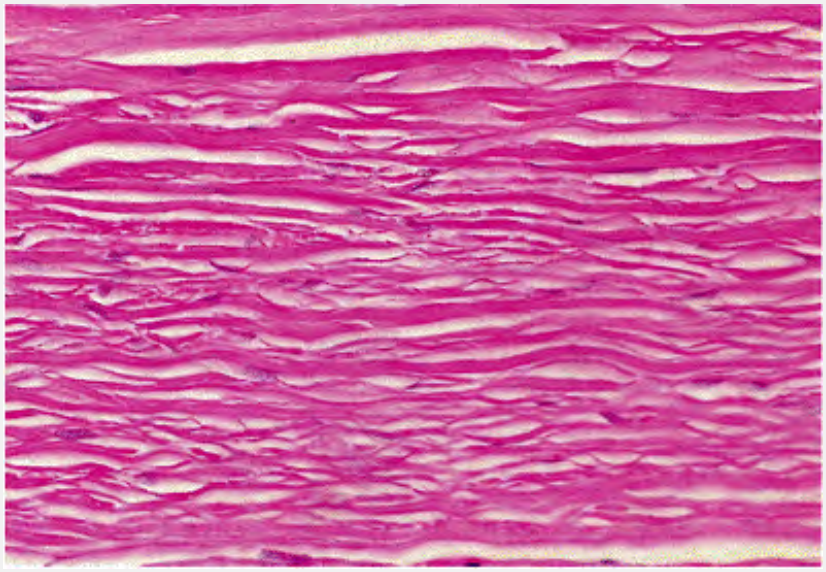

Figure 13.7 The scleral stroma is predominantly composed of collagen fibers that vary in diameter and are in haphazard array. Scattered fibroblasts occur between the collagen bundles. (H&E, Ã—100.)

Although the scleral stroma is relatively avascular, blood vessels, as well as accompanying nerves and scattered melanocytes, are present in perforating emissarial canals (Figure 13.8). The anterior ciliary arteries perforate the sclera near the insertion of the rectus muscles. Venous channels draining the iris, ciliary body, and choroid (vortex

veins) exit the sclera several millimeters posterior to the equator of the eye. The posterior ciliary arteries pass through the sclera near the optic nerve. In some individuals, a nerve in an emissarial canal near the corneoscleral junction may be prominent and attain a diameter of 1 to 2 mm. The nodular appearance of this so-called *nerve loop of Axenfeld* may mimic a neoplasm or conjunctival cyst clinically (9). To the unwary surgical pathologist, this totally normal nerve bundle may be mistaken for a neurofibroma (10).

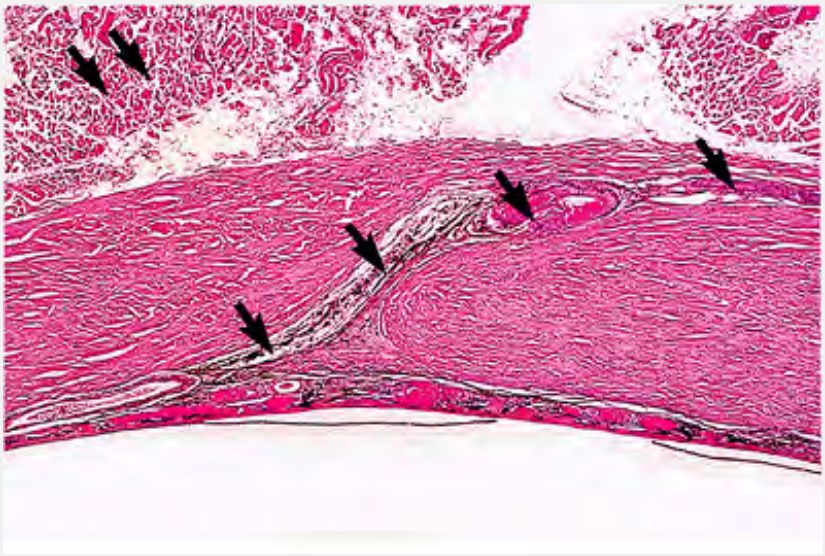

Figure 13.8 This figure illustrates a blood vessel that penetrates the sclera and extends to the prominently vascularized choroid through an emissarial canal (*single arrows*). Pigmented melanocytes are also present. The fibers of the inferior oblique muscle are present at the site of insertion upon the outer sclera (*double arrows*). (H&E, Ã—50.)

The innermost layer of the sclera, the lamina fusca, contains loose collagen fibers, fibroblasts, and scattered melanocytes. It represents a region of transition between the sclera and the underlying choroid. The sclera is weakly attached to the choroid below by thin fibers of

collagen.

With increasing age, several histologic changes occur in the sclera. Calcium may deposit diffusely between the individual collagen fibers throughout the entire scleral stroma. Localized abnormalities, known as senile scleral plaques, may occur just anterior to the insertion of the lateral or horizontal rectus muscles. These lesions are characterized by decreased stromal cellularity, abnormal collagen, and, in advanced cases, calcification (11).

Corneoscleral Limbus

The corneoscleral limbus, or junction, is not a distinct anatomic site but is a significant landmark clinically. Most surgical procedures on the anterior part of the eye are accomplished after access via an incision in the limbal area. For purposes of discussion, the trabecular meshwork and Schlemm's canal will be considered as part of the corneoscleral limbus.

The limbus is approximately 1.5 to 2.0 mm wide, and separate layers of the cornea merge with components of the sclera or conjunctiva in this area (Figure 13.9). The squamous epithelium of the cornea extends centrifugally beyond the limbus until it meets the epithelium of the bulbar conjunctiva. At the limbus, Bowman's layer of the cornea blends into the subepithelial tissues of the conjunctiva, and the corneal and scleral stroma become continuous with each other. Descemet's membrane abruptly terminates in the limbal region and gives rise to the clinically significant landmark known as Schwalbe's ring. In about 15% of eyes, a prominent area of thickening is identified histologically at this site (Figure 13.10) (2). Immediately adjacent to Schwalbe's ring is the most anterior aspect of the trabecular meshwork. Both the trabecular meshwork and Schlemm's canal constitute the apparatus responsible for the removal of aqueous humor from the eye (Figure 13.11). Aqueous humor drainage occurs in the angle between the anterior surface of the iris and the sclera. Histologically, the meshwork appears as a collection

of finely branching and delicately pigmented connective tissue bands. The cells, which line the trabecular meshwork, are continuous with the corneal endothelium. Posteriorly, the trabecular meshwork extends to a roughly triangular-shaped projection of scleral connective tissue, known as the scleral spur.

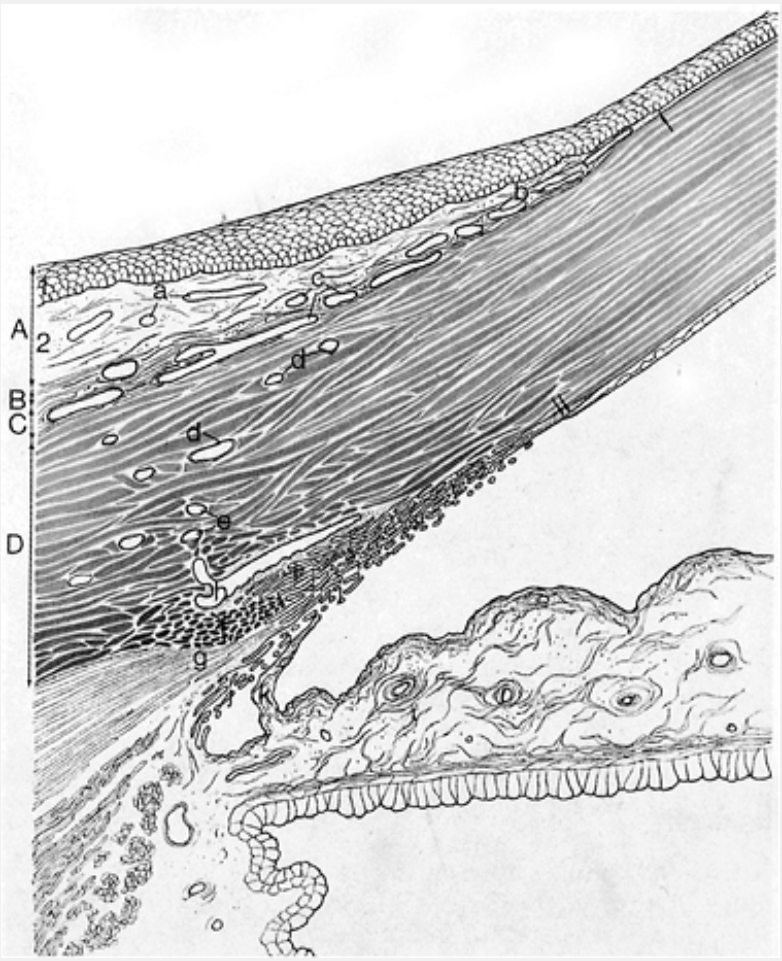

Figure 13.9 The corneoscleral limbus represents the junction of the peripheral cornea with the anterior sclera and is not a distinct anatomic site. Clinically, the limbus is an important landmark. The conjunctiva of the limbus (*A*) is composed of epithelium (*1*) and stroma (*2*). The thin connective tissue layer of Tenon's capsule (*B*) overlies the episclera (*C*). The corneal and

scleral stroma merge gradually in the area marked *D*. Vessels of the conjunctival stroma (*a, b*), episclera (*c*), and limbal plexus (*d, e*) are illustrated. The projection of collagen fibers known as the scleral spur (*f*) merges with the smooth muscle fibers of the ciliary body (*g*). Schlemm's canal (*h*) and the trabecular meshwork (*i, j*) are responsible for removal of aqueous humor from the eye. Occasionally, processes from the iris (*k*) insert upon the trabecular meshwork. Bowman's layer (*arrow*) and Descemet's membrane (*double arrows*) both terminate in the area of the limbus. (Reproduced with permission from: Hogan MJ, Alvarado JA, Weddell JE. *Histology of the Human Eye: An Atlas and Text.* Philadelphia: WB Saunders; 1971.
)

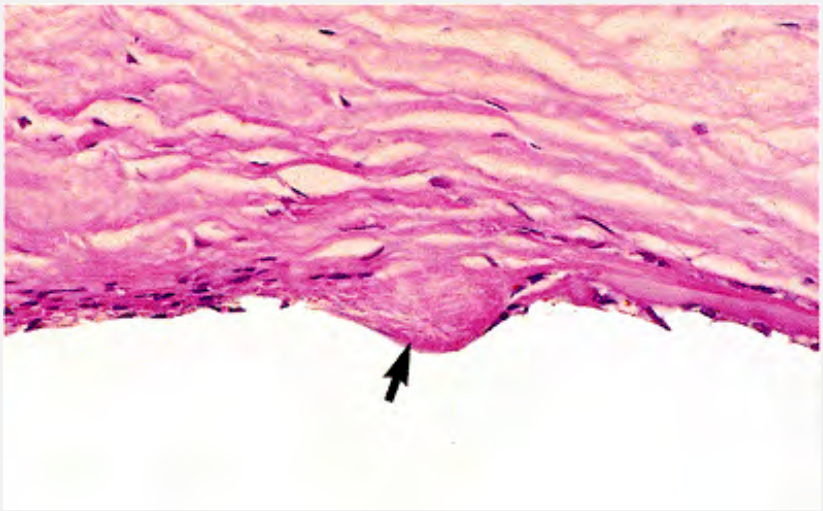

Figure 13.10 Schwalbe's ring is a significant clinical landmark in the limbal area and represents the peripheral termination of Descemet's membrane. Prominent Schwalbe's rings (*arrow*) are identified histologically in about 15% of eyes. (H&E, Ã—80.)

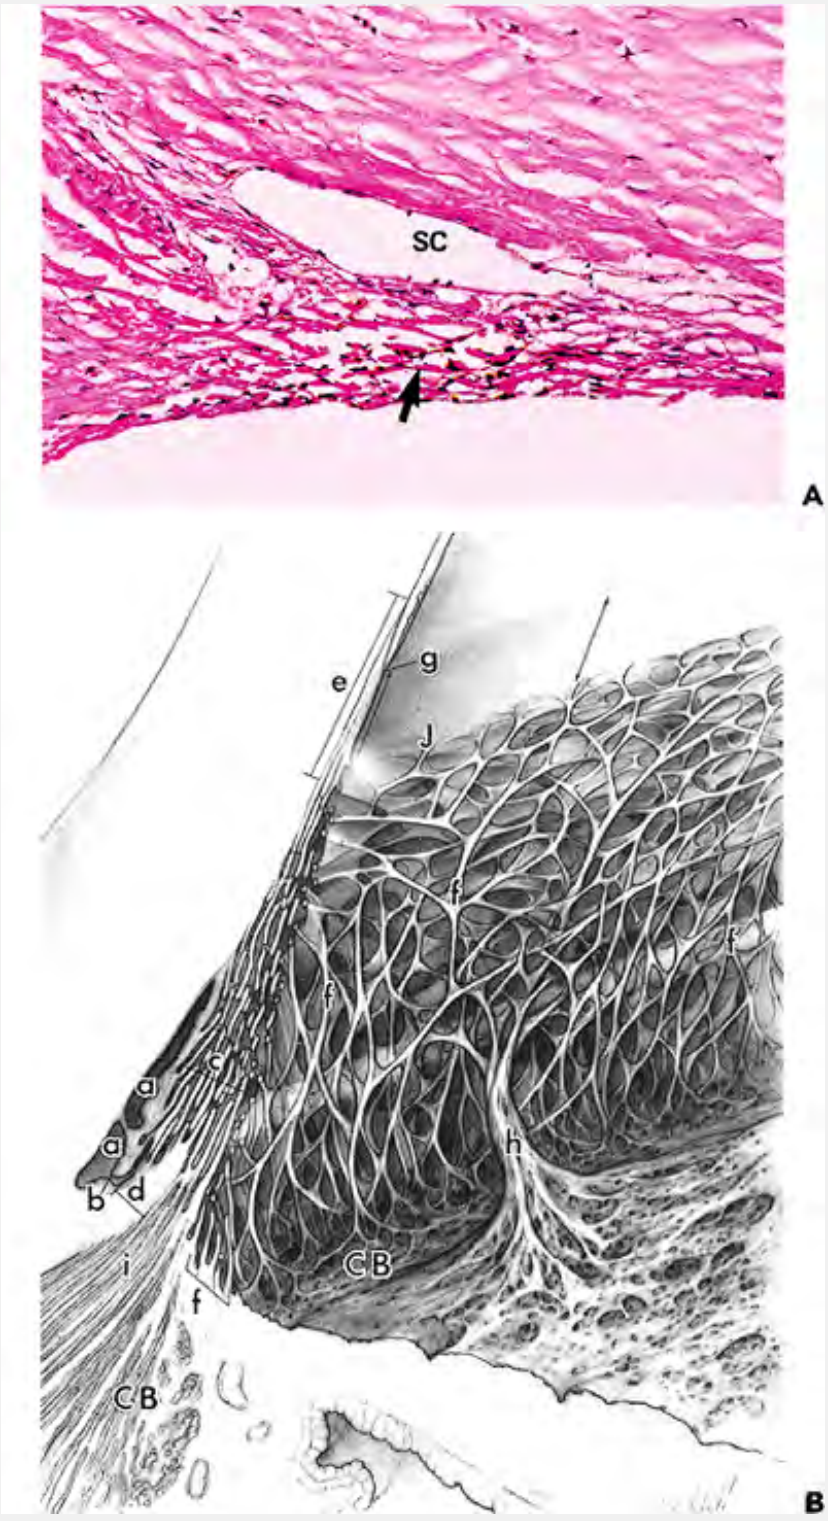

Figure 13.11 A. Located in the angle of the anterior chamber is

Schlemm's canal (*SC*) and the trabecular meshwork (*arrow*). Schlemm's canal is an endothelial channel that enables aqueous humor to drain from the eye. Aqueous humor reaches Schlemm's canal after percolating through the connective tissue strands of the trabecular meshwork. (H&E, Ã—66.) B. Structures within and near the angle of the anterior chamber are depicted in this drawing. In this illustration, Schlemm's canal (*a*) has two channels, one of which is in communication with a small collecting channel (*b*). The collecting channel is intimately associated with the limbal part of the trabecular meshwork (*c*). The scleral spur (*d*) is closely associated with the trabecular meshwork. Descemet's membrane terminates peripherally in the area denoted *e* and *g*. Some components (*f*) of the trabecular meshwork arise at the ciliary body (*CB*). Isolated strands of meshwork merge with a nearby process (*h*) from the anterior surface of the iris. A muscle of the ciliary body (*i*) attaches to the trabecular meshwork (*arrows*). The corneal endothelium merges with endothelial cells of the meshwork (*j*). (Reproduced with permission from:
Hogan MJ, Alvarado JA, Weddell JE. *Histology of the Human Eye: An Atlas and Text.* Philadelphia: WB Saunders; 1971.
)

Located slightly anterior and superficial to the trabecular meshwork is Schlemm's canal, an endothelial-lined venous channel that completely encircles the limbus. Because Schlemm's canal sometimes gives off smaller branches, two lumens are occasionally seen on histologic sections of the anterior chamber angle. Although the trabecular meshwork and Schlemm's canal appear to be in intimate contact in tissue sections, they are separated from each other by a thin layer of connective tissue and separate endothelial linings. Aqueous humor percolates among the delicate beams of the

trabecular meshwork before becoming transported to Schlemm's canal. Ultrastructural examination of this region discloses giant cytoplasmic vacuoles in the endothelial lining of Schlemm's canal, adjacent to the trabecular meshwork. These vacuoles are thought by some to contain fluid in the process of being transported from the trabecular meshwork into the lumen of Schlemm's canal (12). Once in Schlemm's canal, aqueous humor drains into the episcleral venous plexus by way of numerous small collector channels. Prolonged obstruction to the outflow of aqueous humor results in increased intraocular pressure and glaucoma.

Conjunctiva, Caruncle, and Plica Semilunaris

The conjunctiva is a thin continuous mucous membrane lining the inner surface of the eyelids and much of the anterior surface of the eye. In addition to its protective function, the conjunctiva allows the eyelids to move smoothly over the globe. The conjunctival epithelium is composed of two to five layers of columnar cells and rests upon a basal lamina. Within the conjunctival epithelium are goblet cells that secrete mucoid material that becomes incorporated into the tear film (Figure 13.12). Melanocytes are present in the basal epithelial layers and, like melanocytes in the skin, transfer melanosomes into adjacent epithelial cells. These pigmented epithelial cells are numerous in dark-skinned individuals (Figure 13.13). The loose, fibrovascular subepithelial connective tissue of the conjunctival stroma normally contains nerve cells, melanocytes, and accessory lacrimal glands. Lymphoid follicles with germinal centers reside in the conjunctiva (Figure 13.14), particularly in areas where the conjunctiva lining the inner surface of the eyelid merges with the portion covering the eyeball (superior and inferior fornices); scattered lymphocytes are not unusual within the conjunctiva. Hence, their presence is not indicative of chronic conjunctivitis unless both plasma cells and significant numbers of lymphocytes are present.

Three distinct areas of the conjunctiva are recognized (Figure 13.15): the palpebral conjunctiva, the bulbar conjunctiva, and the conjunctiva lining the fornices.

The morphologic attributes of the conjunctiva vary in different parts of this tissue. Although goblet cells exist throughout the epithelium of the bulbar conjunctiva, they

are more common in the inferior and nasal parts. Goblet cells are particularly abundant in the forniceal regions. The conjunctival stroma is thickest in the fornices and bulbar areas and thinnest in the palpebral conjunctiva and at the corneoscleral limbus, where small conjunctival papillae, known as the pallisades of Vogt, are evident. The palpebral conjunctiva is firmly attached to the inner surface of the eyelids, but the bulbar conjunctiva is loosely adherent to the underlying sclera by thin connective tissue strands.

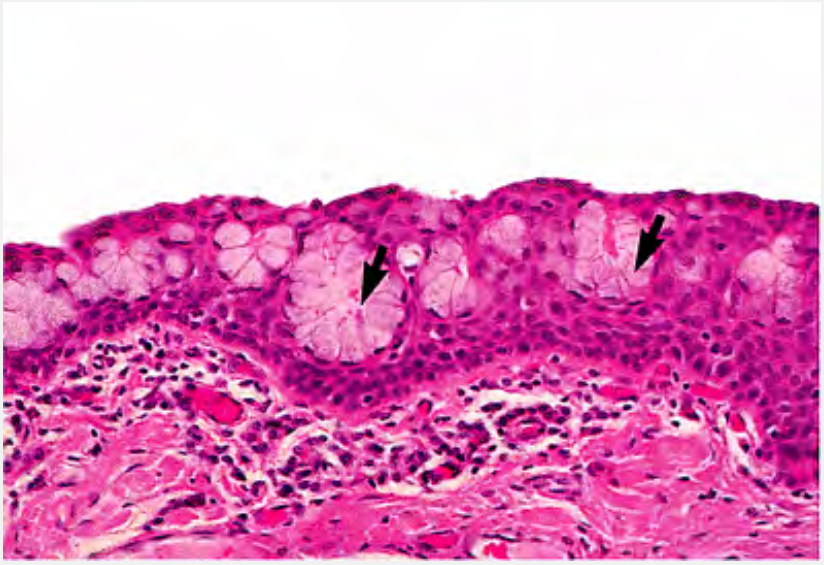

Figure 13.12 Goblet cells (*arrows*) are prominent in this section of conjunctival epithelium. Scattered mononuclear cells are often present in apparently healthy individuals in the underlying conjunctival stroma. (H&E, Ã—66.)

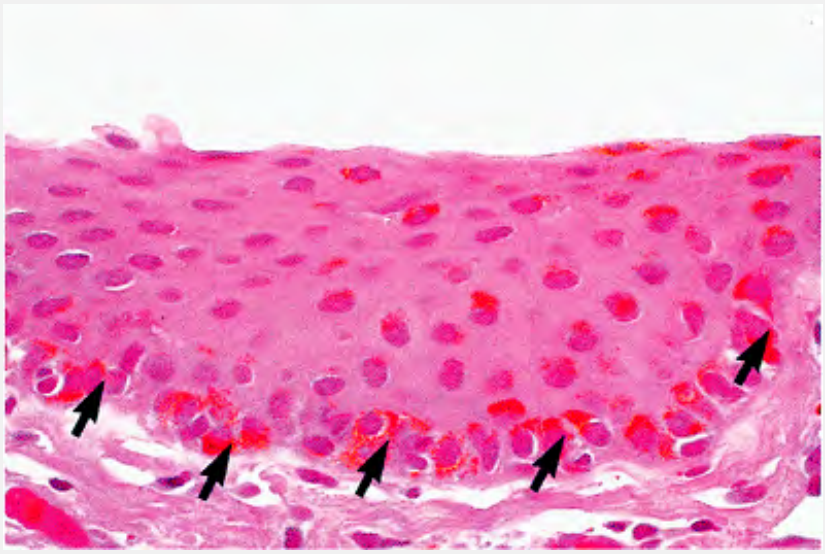

Figure 13.13 In dark-skinned individuals, the basal layers of the conjunctival epithelium are pigmented (*arrows*) (H&E, Ã—160).

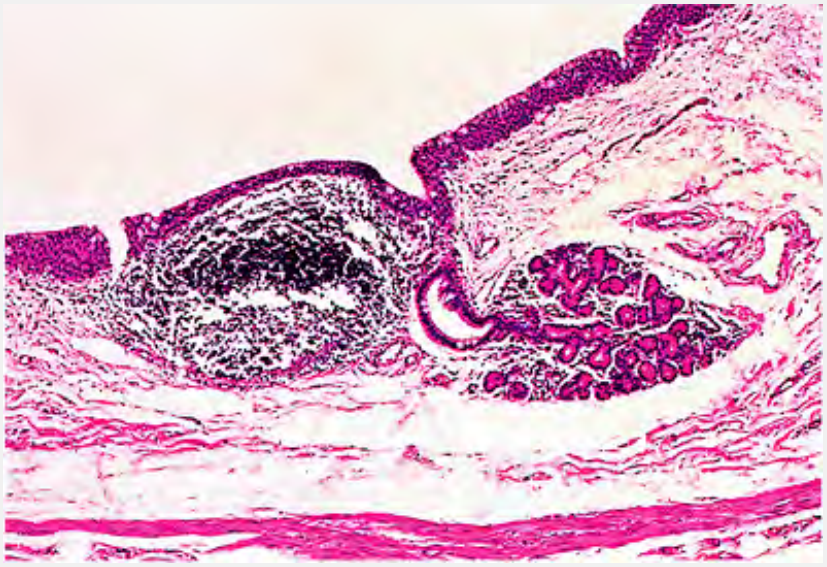

Figure 13.14 A small lymphoid follicle and island of accessory

lacrimal tissue are present in the stroma of the palpebral conjunctiva (H&E, Ã—25).

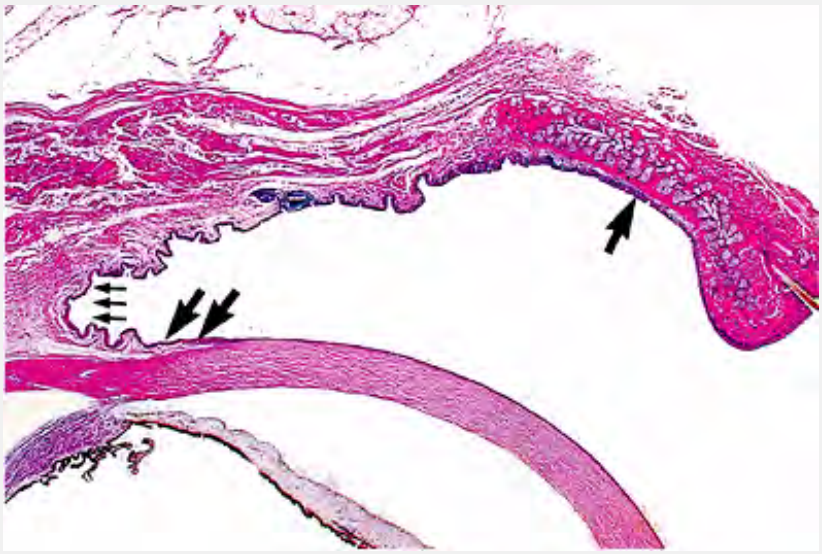

Figure 13.15 The conjunctiva can be divided into three parts. The palpebral conjunctiva (*arrow*) lines the posterior surface of the eyelid. The bulbar conjunctiva (*double arrows*) extends from the limbus over the anterior sclera. The bulbar and palpebral conjunctiva converge upon the conjunctiva of the superior and inferior fornices (*triple arrows*). (H&E,Ã—2.5.)

The palpebral conjunctiva, which lines the posterior surface of the eyelids, extends from the fornices to the mu-cocutaneous junction at the eyelid margins, where the epithelium of the conjunctiva merges abruptly with the epidermis of the anterior surface of the eyelids. The palpebral conjunctiva contains several infoldings of epithelium (crypts of Henle). Islands of accessory lacrimal glands that are morphologically identical to the main tear-producing gland within the orbit occur within the palpebral conjunctiva. The subconjunctival

tissue of the upper fornix may contain over 40 such glands, but fewer than 10 accessory lacrimal glands are present in the lower fornix (glands of Krause). The upper eyelids have approximately two to five accessory lacrimal glands (glands of Wolfring) located at the superior aspect of the tarsus. The bulbar conjunctiva begins at the limbus, at which point the corneal epithelium gradually becomes replaced by conjunctival epithelium and continues over the sclera to the superior and inferior fornices. There, the conjunctiva is thrown into small folds before becoming the palpebral conjunctiva.

Both the caruncle and plica semilunaris (semilunar fold) represent specialized segments of the conjunctiva (Figure 13.16). The caruncle is the nodular mass of fleshy tissue located in the medial interpalpebral angle of the eye. Its surface is covered by a stratified nonkeratinized squamous epithelium. The subepithelial stroma of the caruncle contains hair follicles, smooth muscle, sebaceous glands, adipose connective tissue, and, occasionally, accessory lacrimal glands and sweat glands. The plica semilunaris, an arc-shaped fold of conjunctiva located immediately lateral to the caruncle, is thought to be a vestigial remnant of the nictitating membrane of lower species. The histologic features of the plica semilunaris are similar to those in other areas of the conjunctiva, except that the epithelium contains abundant goblet cells and, rarely, cartilage is present within the stroma.

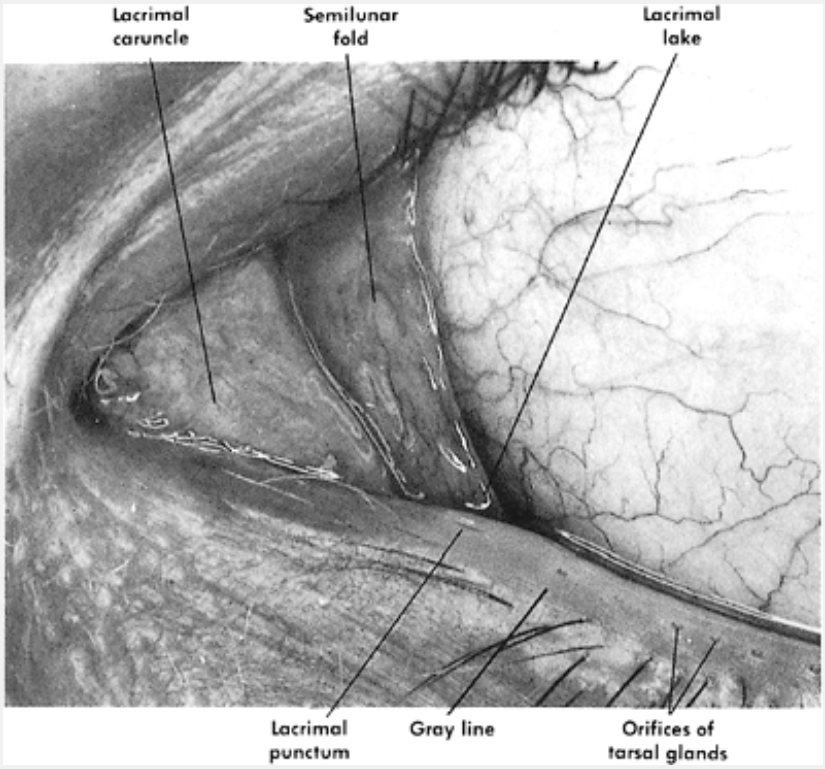

Figure 13.16 The caruncle and semilunar fold are specialized portions of the conjunctiva and are located in the medial interpalpebral angle of the eye. Before tears enter the lacrimal drainage apparatus through the lacrimal punctum, they accumulate at the medial canthus (lacrimal lake). The demarcation between the conjunctival and cutaneous portions of the eyelid is discernible clinically at the so-called *gray line.* The secretions of the meibomian glands (tarsal glands) reach the surface of the eyelids at small orifices. )

The Uveal Tract

Located between the outer scleral covering and the inner retina is the uveal tract, which begins anteriorly as the iris, extends to the ciliary body, and then to the choroid posteriorly. The designated term *uvea* is derived from the Latin word *uva* (grape) because this portion of the eye was thought to somewhat resemble the dark color of a grape after the sclera and cornea are stripped from the globe.

The Iris

The iris is a thin diaphragm of tissue with a central opening, the pupil, which functions to regulate the amount of

light reaching the retina (Figure 13.17). Muscles within the iris dilate or constrict the pupil in response to sympathetic or parasympathetic nerve impulses. The diameter of the iris is approximately 21 mm, whereas the diameter of the pupil ranges from 1 to 8 mm. The iris is thinnest at its point of attachment with the ciliary body peripherally, the iris root. Normally, the iris rests gently upon the crystalline lens and, therefore, bulges slightly forward. Structurally and developmentally, the iris consists of two main parts: the stroma and the posterior epithelial lining.

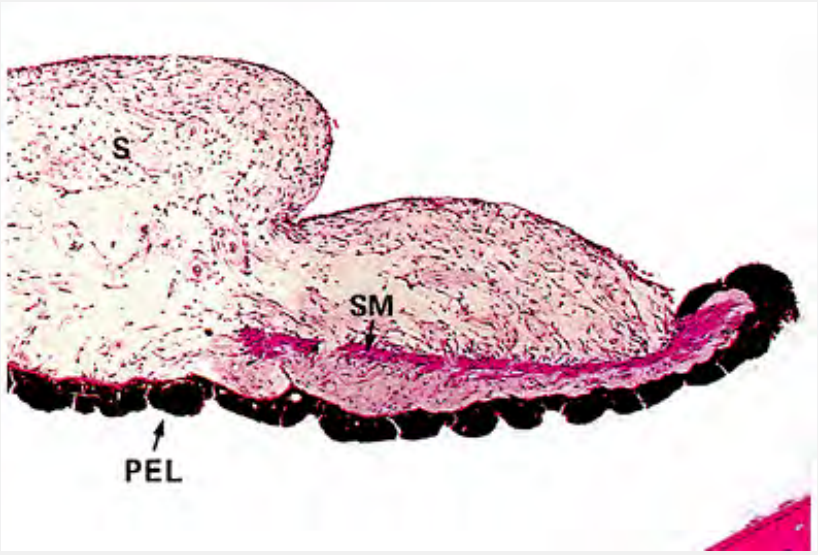

Figure 13.17 The iris is composed of stroma (*S*) and a posterior epithelial lining (*PEL*). The sphincter muscle (*SM*) of the iris is evident within the stroma. The pigmented posterior epithelial lining normally extends around the lip of the pupil anteriorly for a short distance. (H&E, Ã—25.)

Numerous ridges and depressions may be identified in tissue sections of the anterior iris stroma. These correspond to the contraction folds and furrows seen on clinical examination. The anterior surface of the iris lacks a cellular lining. The stroma contains melanocytes, nerve cells, blood vessels, and smooth muscle in a loose connective tissue background. The color of the iris is due to the number of stromal melanocytes present. Lightly pigmented individuals with blue irises have relatively few stromal melanocytes. In contrast, darkly pigmented individuals with brown irises have numerous melanocytes within the iris stroma (Figure 13.18). In addition to melanocytes, melanosome-containing macrophages are also scattered within the iris stroma, particularly at the iris root. A thick collar of collagen fibers normally surrounds the blood vessels within the iris stroma. To the inexperienced observer, these normal vessels may appear to

have arteriolosclerosis. In the pathologic process of iris neovascularization, thin-walled blood vessels, which lack such a collagenous coat, cover the anterior surface of the iris.

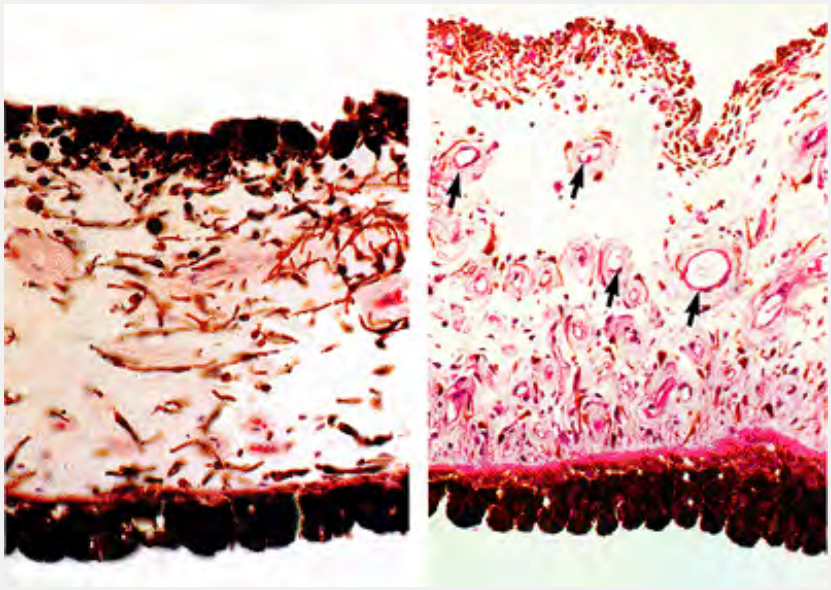

Figure 13.18 The color of the iris is due to the number of stromal melanocytes, which are more abundant in the stroma of an individual with a brown iris (*left*) than with a blue iris (*right*). The amount of pigment in the posterior epithelial lining is similar in irises of different color. Blood vessels in the iris stroma are normally surrounded by a thick collar of collagen fibers (*arrows*); this should not be confused as arteriolosclerosis. In contrast to the posterior surface of the iris, the anterior iris lacks a cellular lining. (Left, H&E, Ã—66; right, H&E, Ã—66.)

The sphincter muscle (sphincter pupillae), a bundle of circularly arranged smooth muscle innervated by parasympathetic nerves, acts to constrict the pupil. Located within the posterior stroma of the pupillary zone, the sphincter pupillae is nearly 1 mm wide. Radially oriented smooth muscle fibers with scattered cytoplasmic

melanosomes are also located within the stroma of the iris (dilator pupillae). Innervated by sympathetic nerves, this muscle is active in pupil dilatation.

Posteriorly, the iris is lined by two separate but closely apposed epithelial layers derived from neuroectoderm. The cells of the anterior epithelial layer, which are in direct contact with the posterior aspect of the stroma, are continuous with smooth muscle fibers of the dilator pupillae; the sphincter pupillae are of similar developmental origin. The posterior iris pigment epithelial layer is in direct contact

with the aqueous humor of the posterior chamber. The cytoplasm of both epithelial layers contains numerous melanosomes (approximately 1 Âµm in diameter), which are larger than those of the iris stroma (diameter of about 0.5 Âµm). The number of melanosomes in the iris epithelial layers does not vary significantly between lightly and darkly pigmented individuals. In persons with ocular and oculocutaneous albinism, the pigmented epithelia, as well as the stromal melanocytes, contain fewer melanin granules than in normal individuals. The pigmented epithelia of the iris normally extend around the lip of the pupil anteriorly for a short distance. In certain pathologic conditions, fibrovascular tissue on the anterior surface of the iris everts the pupillary margin and pulls the pigmented epithelia onto the anterior surface of the iris. This displaced pigmented epithelium may be apparent clinically and is known as ectropion uveae.

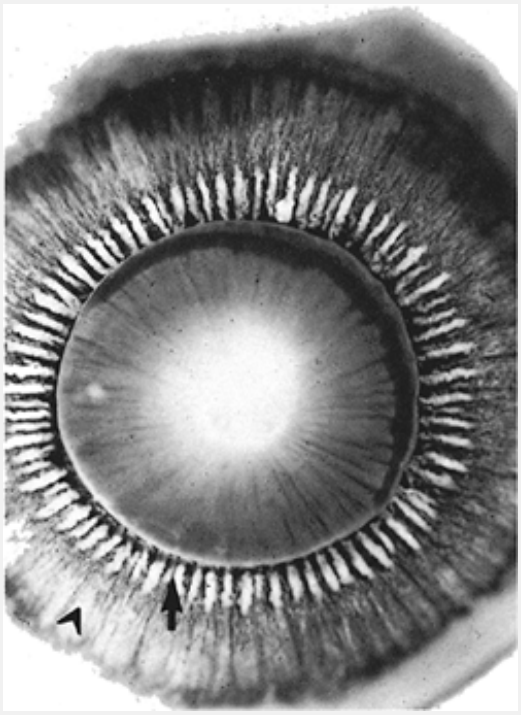

Figure 13.19 The lens and ciliary body are viewed from behind in this photograph. The ciliary body has two components: the pars plicata and the pars plana. The pars plicata contains about 70 sagitally oriented folds, or ciliary processes (*arrow*). The pars plicata gradually merges with the flat pars plana (*arrowhead*). (Reproduced with permission from:
Klintworth GK, Landers MB III. *The Eye: Structure and Function.* Baltimore: Williams & Wilkins; 1976.
)

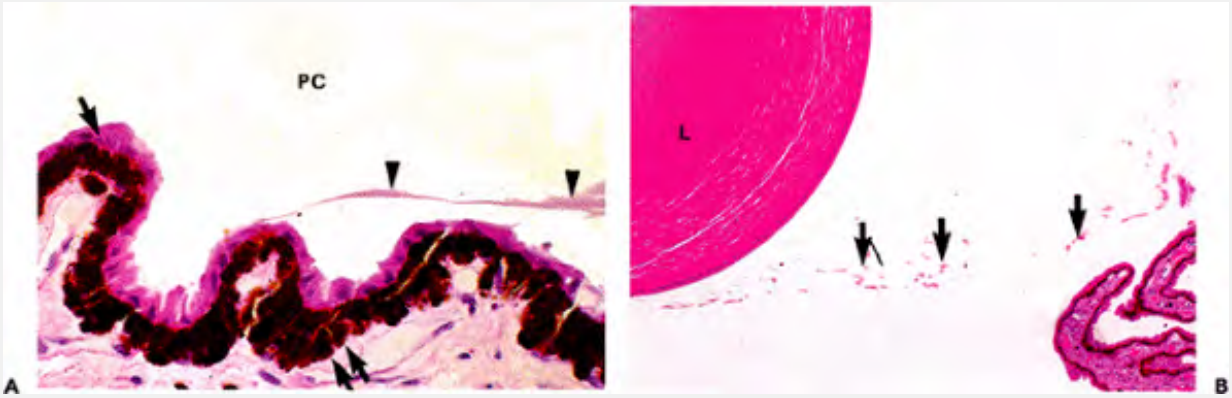

Figure 13.20 A. The epithelium of the ciliary body has two distinct layers. The inner nonpigmented layer (*arrow*) is in direct contact with the aqueous humor of the posterior chamber (*PC*). The outer pigmented epithelial layer (*double arrows*) is adjacent to the underlying stroma. Acellular eosinophilic fibers attach to the crests of the nonpigmented epithelium of the pars plicata (zonules) (*arrowheads*). Zonules do not originate in the valleys between the ciliary processes (H&E, Ã—132). B. Zonular fibers (*arrows*) span between the pars plicata of the ciliary body (right) and the lens (*L*) and hold the lens in place (H&E, Ã—25).

The Ciliary Body

The middle segment of the uveal tract, the ciliary body, is located between the iris and the choroid. Situated interior to the anterior sclera, it is made up of two ring-shaped components: the pars plicata and the pars plana (Figure 13.19). The anteriormost aspect of the ciliary body, the pars plicata begins at the scleral spur and contains approximately 70 sagitally oriented folds (approximately 2 mm long and 0.8 mm high). Continuous with these folds, the flat pars plana, which is approximately 4 mm wide, merges posteriorly with the serrated anterior border of the retina (ora serrata). Both portions of

the ciliary body consist of epithelium, stroma, and smooth muscle.

The ciliary epithelium embraces two distinct layers, both of which share a similar development derivation from neural ectoderm (Figure 13.20). The inner epithelial layer is virtually nonpigmented and is contiguous with the aqueous humor of the posterior chamber. At the ora serrata, the sensory retina converges into the nonpigmented ciliary epithelial monolayer, which extends anteriorly until it

becomes the posterior epithelial layer of the iris. In contrast, the outer ciliary epithelial layer is pigmented and unites with the retinal pigment epithelium at the ora serrata. The pigmented epithelium of the ciliary body overlies a periodic acid-Schiff (PAS) â€“ positive basal lamina that is closely adherent to the adjacent stroma. The basal lamina of the pigmented epithelium can become conspicuously thickened in diabetes mellitus. Acellular fibers, known as zonules (Figure 13.20), attach the crests of the nonpigmented ciliary epithelium in the pars plicata to the capsule of the crystalline lens.

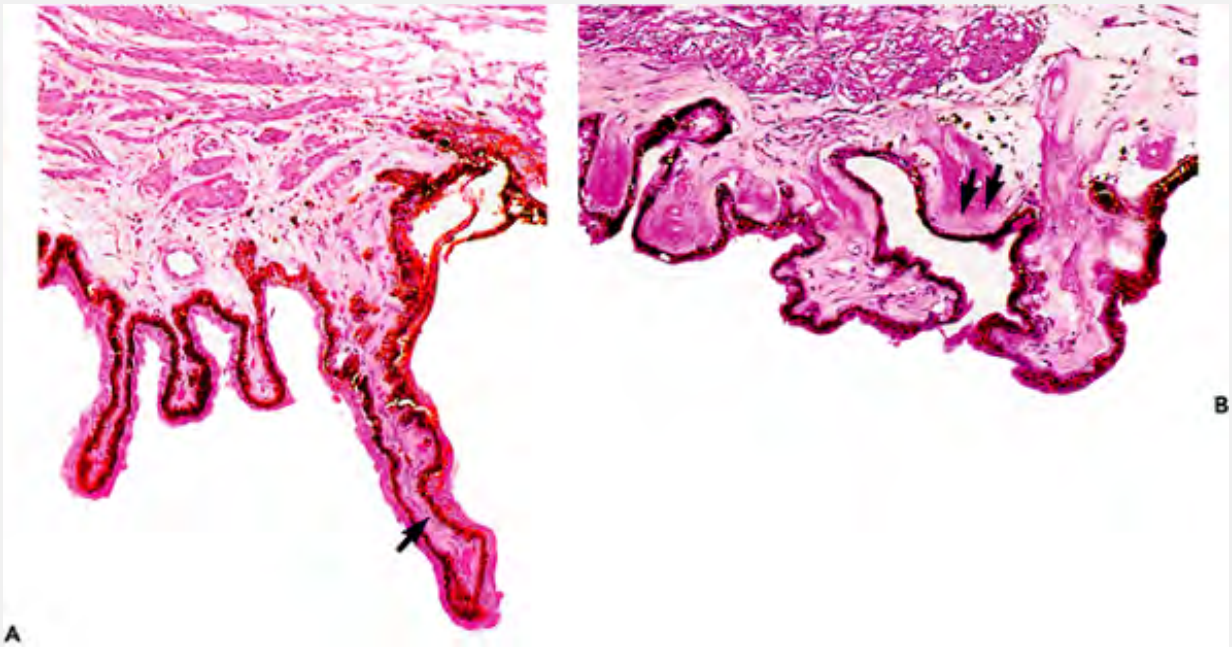

Figure 13.21 The pars plicata of the ciliary body changes with

age. A. In infancy the stroma of the ciliary processes is sparse (*arrow*). B. The stroma continues to expand until adulthood; and, with advancing age, the ciliary processes become hyalinized (*double arrows*). (A, H&E, Ã—40; B, H&E, Ã—40.)

The stroma of the ciliary body, composed of fibroblasts, blood vessels, nerve cells, and melanocytes, is most abundant in the ciliary processes of the pars plicata and least plentiful in the valleys between these processes and in the pars plana. During infancy, the stroma of the ciliary body is sparse (Figure 13.21, *left*), but it expands until adulthood. With advanced age, the ciliary body stroma becomes hyalinized (Figure 13.21, *right*) and frequently calcifies.

The smooth muscle of the ciliary body (Figure 13.22) forms three distinct bundles. The outermost muscle runs in a longitudinal, or meridonal, direction, whereas the middle layer contains radially oriented fibers and the innermost muscle cells are aligned in a circular fashion. In routinely processed globes, histologic differentiation of these three muscular layers is difficult. Muscles of the ciliary body attach in large part to the scleral spur. The ciliary muscle assists in accommodation. As it contracts, the ciliary body extends forward, reducing pressure on the zonules and enabling the lens to become less concaveâ€”and thereby increasing its refractive power.

Choroid

The richly vascularized choroid (Figure 13.23) extends from the ciliary body to the optic nerve. Its inner aspect is firmly adherent to the retinal pigment epithelium. The outer surface of the choroid is loosely attached to the overlying sclera. Bruch's membrane delineates the choroid from the overlying retinal pigment epithelium and is approximately 2 to 4 Âµm thick. Although Bruch's membrane appears as a thin eosinophilic layer in tissue sections, ultrastructural

analysis has disclosed it to be composed of five distinct layers: the basal lamina of the overlying retinal pigment epithelium, a collagenous layer, an elastic fiber-rich component, another collagenous portion, and the

basal lamina of the endothelial cells of the underlying capillary network (choriocapillaris). Located in the innermost choroidal stroma adjacent to Bruch's membrane, the choriocapillaris connects with arterial and venous channels from vessels in the outer choroidal stroma. Its function is to nourish the outer retinal layers. With age, Bruch's membrane thickens and commonly acquires focal excrescences known as drusen (Figure 13.24). Both drusen and Bruch's membrane may calcify.

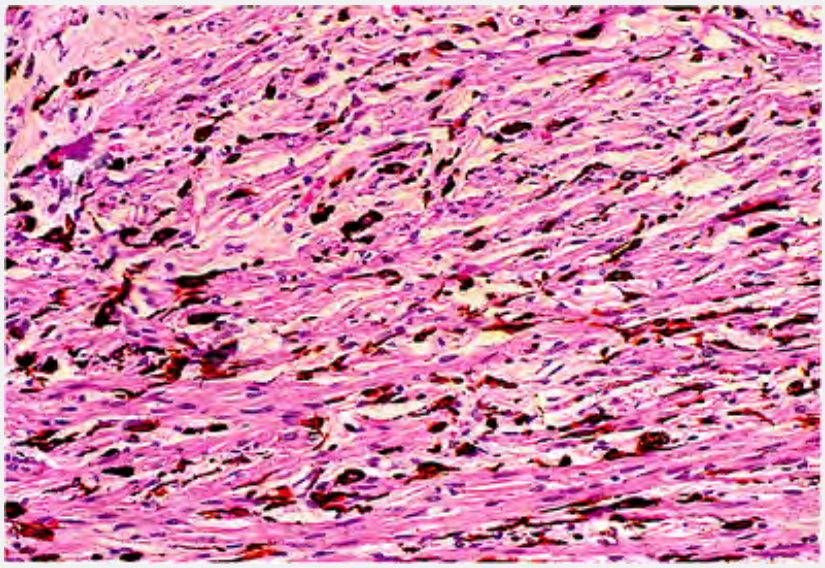

Figure 13.22 Smooth muscle constitutes a large portion of the ciliary body. Pigmented melanocytes are often present in between the smooth muscle bundles (H&E, Ã—66.)

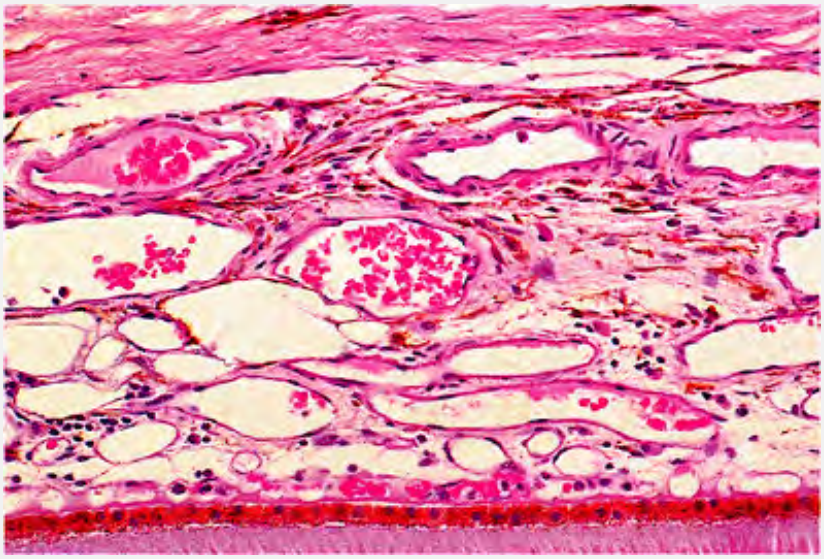

Figure 13.23 This photomicrograph illustrates the well-vascularized choroid. At the top of the figure, the choroid abuts the sclera. The single layer of retinal pigment epithelium is present at the bottom of the figure. (H&E, Ã—66.)

The choroidal stroma is thinnest anteriorly, near the ciliary body, where it is approximately 0.1 mm thick. Posteriorly, at the optic nerve, the choroidal stroma thickens to nearly 0.22 mm. The tenuous connection between the choroidal stroma and the sclera is responsible for both the pathologic and artifactual separations often seen between these two layers in histologic sections. The stroma contains abundant pigmented melanocytes (Figure 13.25), which are more numerous in heavily pigmented individuals than in persons with little pigment. Collagen fibers, some smooth muscle, neurons of the autonomic nervous system, and a prominent vascular system are also present. Large- and medium-sized arteries (branches of the posterior ciliary arteries) and veins (vortex veins) are situated in the outermost choroid.

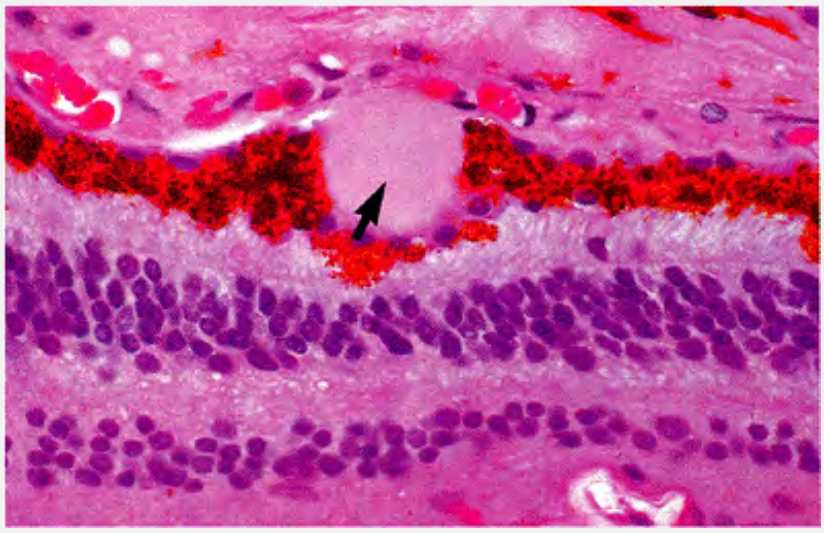

Figure 13.24 An amorphous excrescence (*arrow*) in Bruch's membrane appears to extend into the underlying retina. Such so-called *drusen* are common and occasionally calcify. (H&E, Ã—160.)

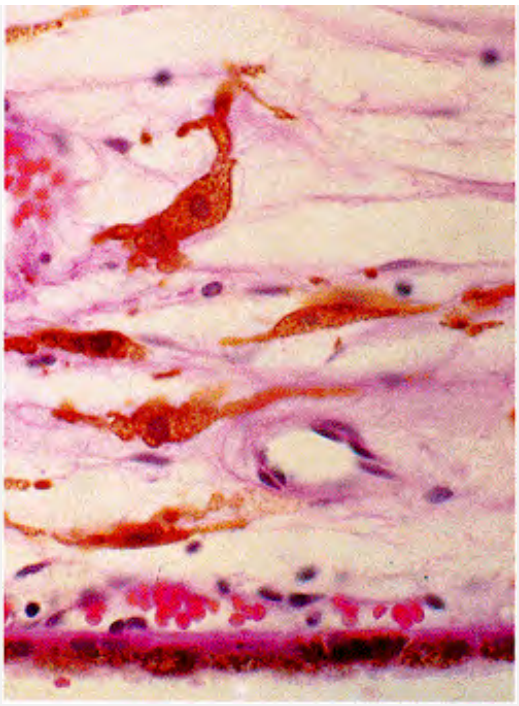

Figure 13.25 Numerous pigmented melanocytes are located within the choroidal stroma (H&E, Ã—160.)

Retina

The cellular components of the retina include the photoreceptors (rods and cones), a variety of different neurons (ganglion, bipolar, horizontal, and amacrine cells), and neuroglial cells (MÃ¼ller cells and astrocytes). Many of these special types of cells can only be detected with the aid of specific staining techniques. These constituents of the retina are stratified into several distinct layers (Figure 13.26). The rods and cones comprise the outermost part of the sensory retina and are closely apposed to the retinal pigment epithelium. The retina's anterior boundary has a serrated edge (ora serrata), at which point it is approximately 0.1 mm thick. Cysts develop in the peripheral retina (peripheral cystoid degeneration) in virtually everyone over age 20 (13) (Figures 13.27, 13.28). Here,

the retina converges into a single layer of nonpigmented epithelium, which continues anteriorly to where it merges with the nonpigmented epithelium of the ciliary body (Figure 13.28). Posteriorly, the retina extends to the optic nerve, where it is approximately 0.5 to 0.6 mm thick. The sensory retina is in direct

contact with the vitreous humor and lies interior to the retinal pigment epithelium, which defines the outermost border of the retina.

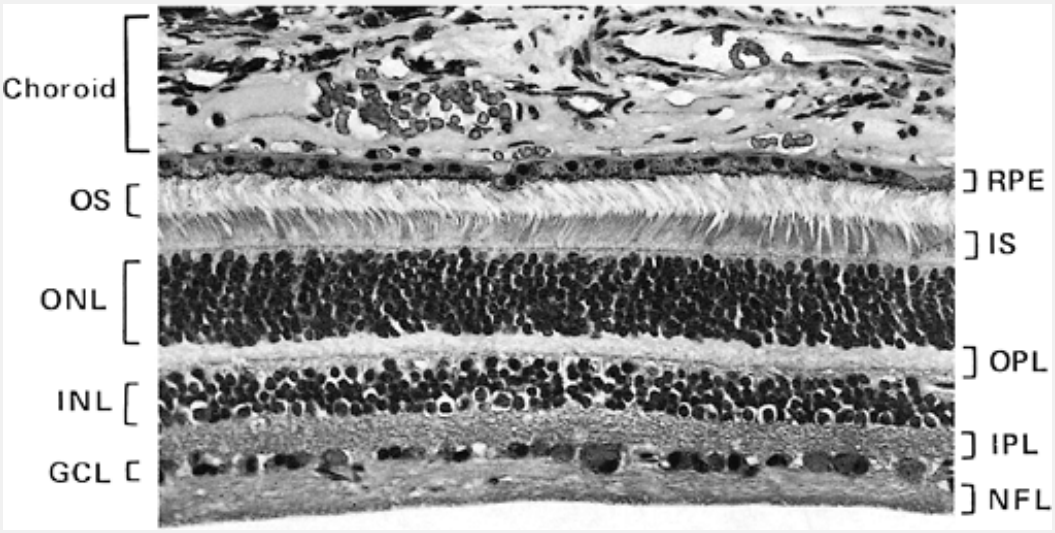

Figure 13.26 The cellular components of the retina are organized in well-defined layers. The choroid is directly above the retinal pigment epithelium (*RPE*) in this figure. Specialized extensions of the photoreceptors known as the outer and inner segments (*OS* and*IS*) are located immediately adjacent to the RPE. Cell bodies of the photoreceptors are present in the outer nuclear layer (*ONL*); synapses between the bipolar cells, horizontal cells, and the photoreceptors occur in the outer plexiform layer (*OPL*); the inner nuclear layer (*INL*) embraces nuclei of the amacrine, bipolar, horizontal, and MÃ¼ller's cells; the inner plexiform (*IPL*) contains axons and dendrites of

amacrine, bipolar, and ganglion cells; ganglion cell bodies are located in the ganglion cell layer (*GCL*); the nerve fiber layer (*NFL*) contains ganglion cell axons. (Reproduced with permission from:
Klintworth GK, Landers MB III. *The Eye: Structure and Function.* Baltimore: Williams & Wilkins; 1976.
)

The retinal pigment epithelium is a monolayer of cells. These epithelial cells contain numerous intracytoplasmic melanosomes; cellular processes envelope part of the overlying rods and cones as shown by transmission electron microscopy. The phagocytic function of the retinal pigment epithelium assists in the turnover of the photoreceptor elements. Undigested products of phagoliposomes culminate in the progressively increasing number of lipofuscin granules that accumulate within the retinal pigment epithelium, with time.

Some photoreceptors are cylindrical in appearance (rods), whereas others are conical-shaped and somewhat longer and thicker (cones). Internal to the photoreceptors is the outer plexiform layer, formed from cell processes of the horizontal and bipolar cells and axonal extensions of the rods and cones. The inner nuclear layer embraces the nuclei of several cell types (the bipolar, MÃ¼ller, horizontal, and amacrine cells). Constituents of the inner plexiform layer include bipolar and amacrine cell axons and dendrites of the ganglion cells. Near the vitreal aspect of the retina is the ganglion cell layer, composed predominantly of ganglion cell bodies. The axons of these large neurons make up the nerve fiber layer; these processes are usually unmyelinated; but, as an incidental developmental anomaly, bundles of some nerve fibers are occasionally myelinated. In older individuals, basophilic PAS-positive intracellular rounded bodies (corpora amylacea), indistinguishable from similar structures in the brain, often accumulate in the nerve fiber layer of the retina near the

optic disc. By light microscopy, two acellular zones can be distinguished within the retina: the external and internal limiting membranes. The so-called *external limiting membrane* is located between the photoreceptors and the outer nuclear layer. The membrane represents firm junctions between MÃ¼ller cells and adjacent photoreceptors (zonula adherens). The basal lamina of the MÃ¼ller cells accounts for the hyalin structure seen on light microscopy and is known as the *internal limiting membrane*. Similar to the neuroglial tissue of the brain, by immunohistochemistry the neuronal cells of the retina show strong immunopositivity to synaptophysin (Figure 13.29) and NeuN (*Neu*ronal *N*uclei) (14) (Figure 13.30). Neurofilament protein highlights the axons of the

nerve fiber layer as they continue posteriorly to enter the optic nerve. Glial cells and their processes react with glial fibrillary acidic protein (GFAP) (Figure 13.31).

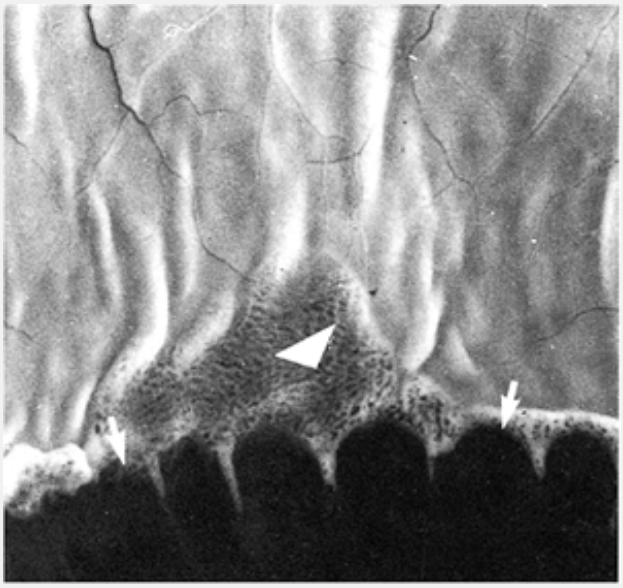

Figure 13.27 The ora serrata marks the anterior boundary of the retina. An almost invariable finding in the retina of all human eyes after the age of 20 is peripheral cystoid degeneration.

Macroscopically, the peripheral retina immediately behind the ora serrata (*arrows*) has a focally vacuolated appearance (*arrowhead*). (Reproduced with permission from: Klintworth GK, Landers MB III. *The Eye: Structure and Function.* Baltimore: Williams & Wilkins; 1976.
)

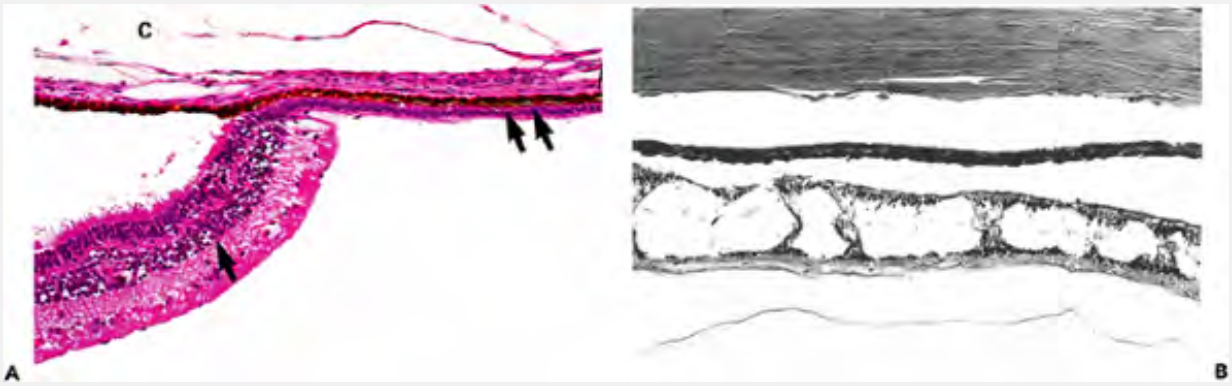

Figure 13.28 A. At the ora serrata, the multilayered retina (*arrow*) converges with the single layer of nonpigmented epithelium of the ciliary body (*double arrows*). The retina is loosely attached to the choroid (*C*) in the region of the ora serrata and is artifactually separated from it in this figure (H&E,Ã—50). B. Microscopically, peripheral cystoid degeneration is characterized by the presence of numerous cystlike spaces within the retina. (Reproduced with permission from: Klintworth GK, Landers MB III. *The Eye: Structure and Function*. Baltimore; Williams & Wilkins, 1976.
)

Light passes through the entire sensory retina before it is converted by the photoreceptor cells into electric impulses. The impulses are

eventually transmitted to the visual cortex in the occipital lobe of the brain through a complex series of intercellular connections.

The retina varies in structure in different sites (Figure 13.32). A yellow specialized portion of the retina is located in the posterior pole of the eye (in an area slightly temporal to the optic disc). This is the macula lutea (yellow spot), where the bipolar and ganglion cells contain the pigment xanthophyll. In the macular region of the retina, the ganglion cells are several layers thick. The center of the macula contains a slightly depressed area (the fovea centralis) measuring almost 1.5 mm in diameter; it is responsible for most visual acuity. The walls of the fovea centralis are known as the clivus, and the precise center is designated the foveola. Blood vessels are absent in the foveola, which measures approximately 0.4 mm in diameter. The inner layers of the retina are displaced peripherally in the foveola so that only photoreceptors, the outer nuclear layer, and outer plexiform layer are present. Cones are located within the foveola, but rods are absent.

The microvasculature of the normal retina is composed of branches of the central retinal artery and tributaries of the central retinal vein. It contains arterioles, venules, and intervening capillaries (Figure 13.33). In capillaries from normal individuals, endothelial cells and pericytes are present in a ratio of approximately 1:1. The retinal microvasculature is affected in hypertension, diabetes mellitus, and other conditions. Capillary microaneurysms and the loss of capillary pericytes are characteristics of diabetic retinopathy. These are best visualized in flat preparations of the retina after trypsin digestion of the retinal cells.

Artifacts of the Retina

It is necessary to distinguish a true detachment of the sensory retina from the retinal pigment epithelium from an artifactitious retinal detachment in the same location. True retinal detachments are characterized by the presence of blood or eosinophilic proteinaceous

fluid in the space between the two retinal layers (Figure 13.34), rounded edges at the site of the retinal break, photoreceptor elements of one fold of retina adjacent to the internal

limiting membrane of another fold (Zimmerman's sign), an absence of photoreceptor outer segments (except in a very acute detachment), and the presence of cyst-like spaces within the detached retina. In contrast, artifactitious retinal detachments typically lack subretinal fluid that is rich in eosinophilic protein or blood, have squared-off edges at the site of the break with intact photoreceptor outer segments, and fragments of pigment epithelium cell debris are adherent to the photoreceptor outer segments (Figure 13.35) (15).

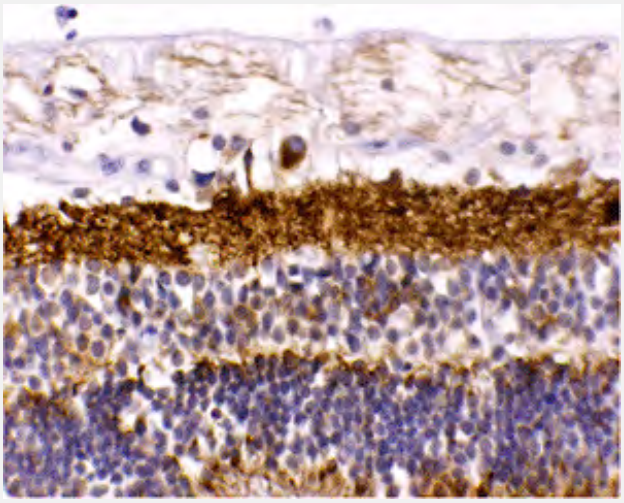

Figure 13.29 Synaptophysin immunopositivity is present within the ganglion cell layer, inner and outer nuclear layers, and inner and outer plexiform layers (Ã—40).

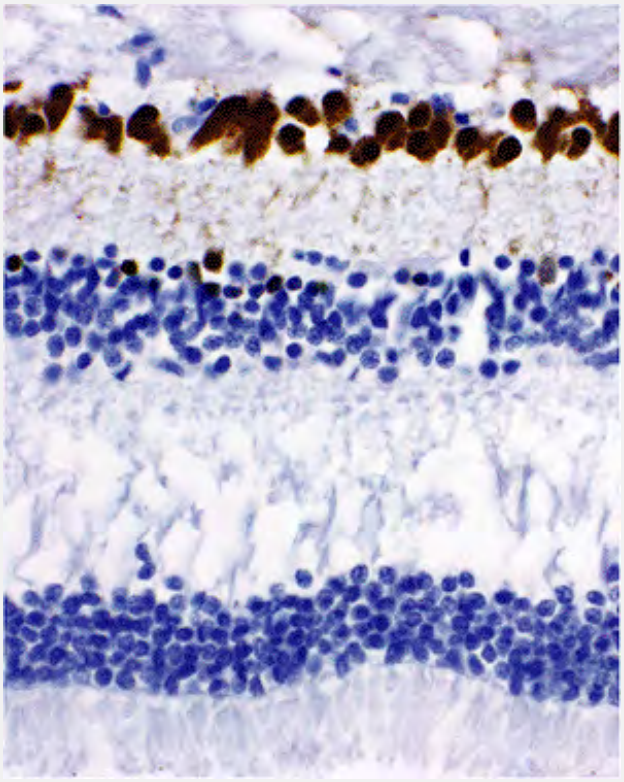

Figure 13.30 Reactivity with the immunohistochemical marker NeuN is restricted to neurons of the ganglion cell layer and a few cells in the inner nuclear layer (Ã—40).

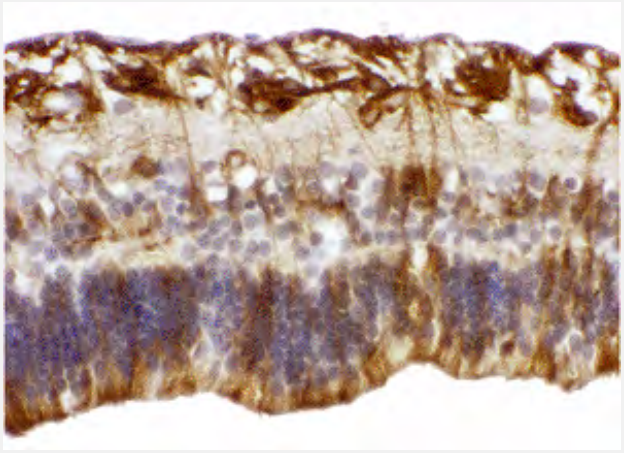

Figure 13.31 Glial fibrillary acidic protein (GFAP) highlights the retinal glia and their processes (Ã—40).

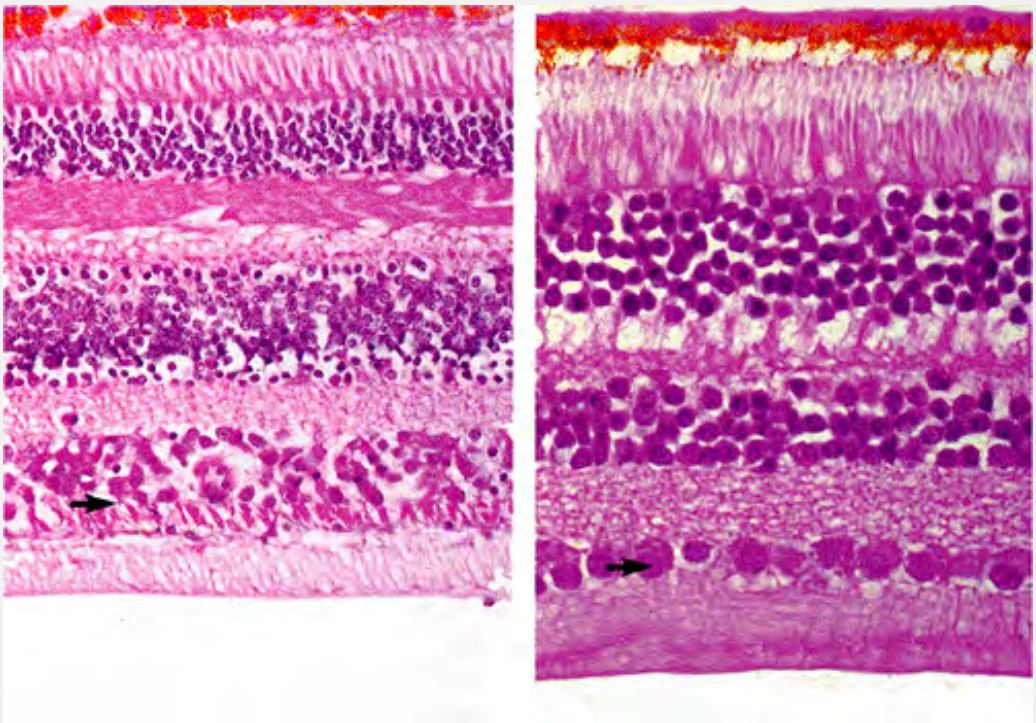

Figure 13.32 The retina has regional histologic variations. In

the macular region (*left*), the ganglion cells (*arrow*) are multilayered. In areas outside of the macula (*right*), ganglion cells (*arrow*) form a single layer. (Left, H&E, Ã—80; right, H&E, Ã—160.)

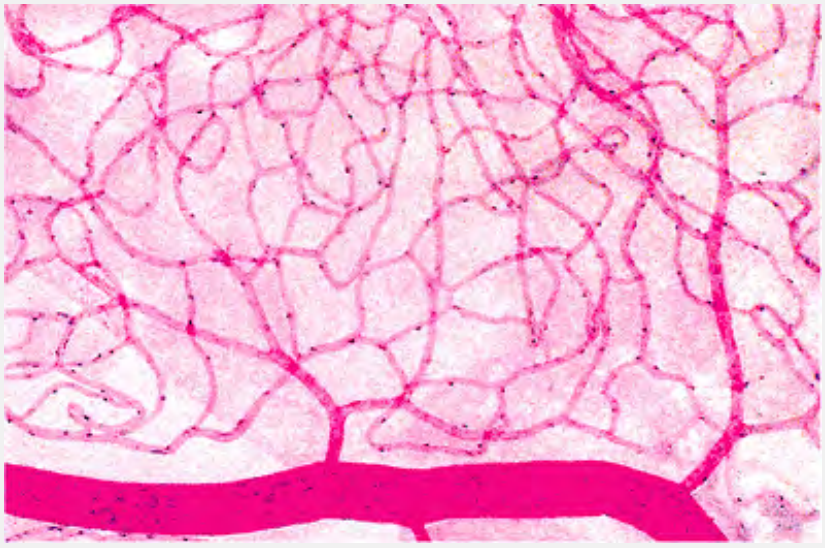

Figure 13.33 This flat preparation of a normal retina following trypsin digestion discloses retinal capillaries adjacent to a retinal arteriole (H&E, Ã—25).

At the ora serrata, the sensory retina of neonates and children folds inwardly upon itself (Lange's fold) in eyes that have been subjected to a fixative such as formalin (Figure 13.36). This artifact of fixation is not observed in the living eye or in unfixed enucleated eyes that have been sectioned to observe the peripheral retina. Lange's fold is thought to result from traction on the peripheral retina by a shortening of the vitreous humor base and posterior lens zonules caused by tissue fixation. After the age of 20 years, Lange's fold is not observed, presumably because the peripheral retina has become firmly bound to the subjacent retinal pigment epithelium. The

convexity of this artifact of fixation is directed anteriorly and axially in neonates; but, in older infants and children, the fold is initiated some distance from the ora serrata, apparently because of a propensity for peripheral retinal adhesions to the subjacent retinal pigment epithelium with increasing age. In contrast to a true retinal

detachment, subretinal fluid is not present between the layers of the sensory retina in Lange's fold (16).

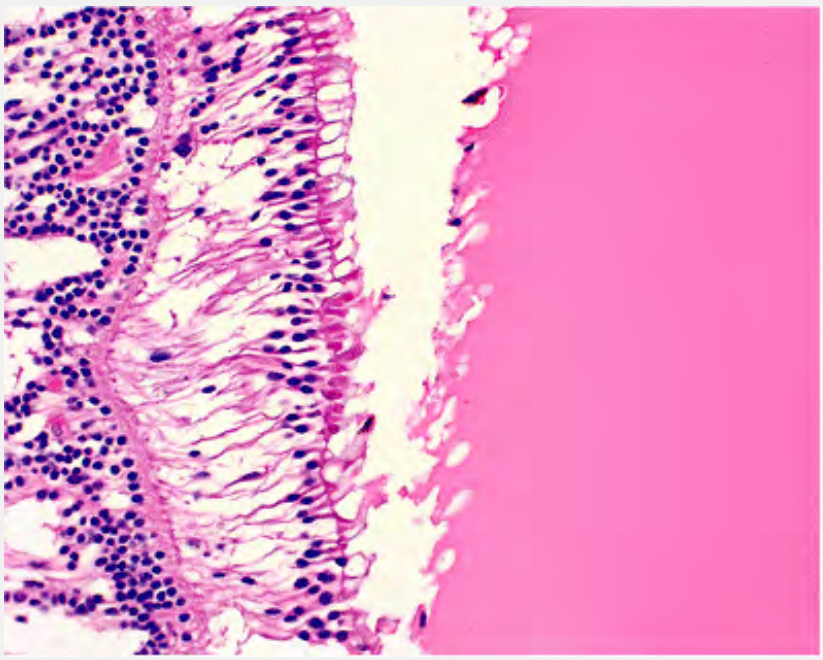

Figure 13.34 A feature of a true retinal detachment is the presence of eosinophilic proteinaceous fluid within the subretinal space (H&E, Ã—20).

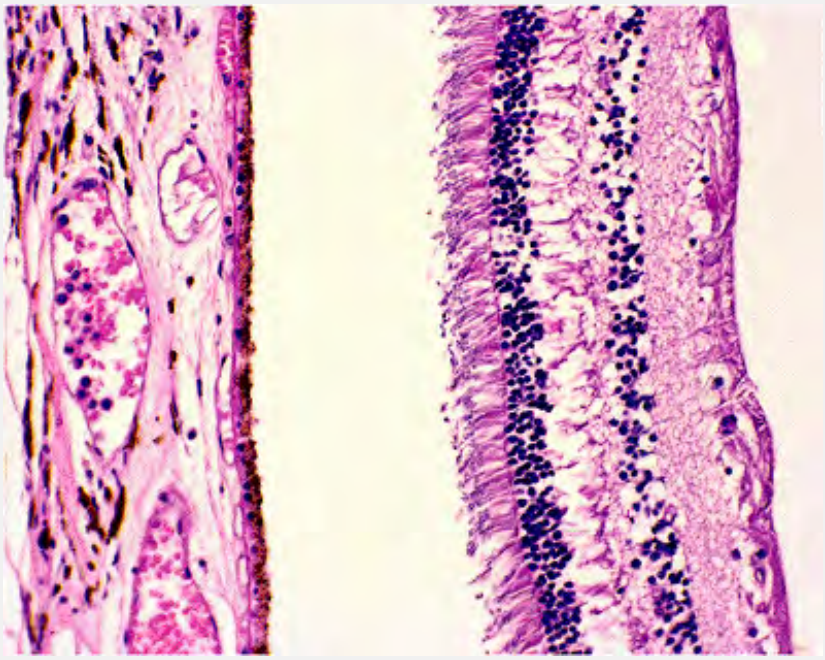

Figure 13.35 Artifactual retinal detachments are characterized by retinal pigment epithelium granules within the tips of the photoreceptors and the absence of subretinal eosinophilic fluid (H&E, Ã—20).

Figure 13.36 Lange's fold is a postmortem artifact usually seen in infant eyes. At the ora serrata, the peripheral retina typically takes on a bowed or concave appearance anteriorly. The absence of subretinal fluid distinguishes this from a true retinal detachment (H&E, Ã—10).

The Optic Nerve

More than one million axons from the retinal nerve fiber layer converge at the optic nerve head, which accounts for the physiologic blind spot in the normal visual field and represents the beginning of the optic nerve. The central retinal artery and vein traverse the optic nerve; and, within a slight depression at the origin of the nerve, they are surrounded by glial tissue (Figure 13.37). From the optic nerve head, the axons extend for approximately 1 mm to a sievelike partition of connective tissue in the sclera (the lamina cribrosa) through which the nerve fibers pass on their way to the brain. Over one thousand nerve fiber bundles surrounded by astrocytes,

oligodendroglia, and collagenous septae (Figure 13.38) can be identified in cross sections of the optic nerve, which is a tract of the central nervous system. Like the brain, the optic nerve is surrounded by dura, arachnoid, and pia mater. Small focal meningothelial proliferations occasionally form within the leptomeninges surrounding the optic nerve. Some orbital meningiomas presumably arise from them. Laminated products of the meningothelial cells (psammoma bodies) sometimes occur in the arachnoid mater (Figure 13.39). Pigmented melanocytes are sometimes encountered within the leptomeninges and optic nerve head.

After leaving the globe, each optic nerve continues posteriorly through the orbit to its respective optic foramen, and then to the optic chiasm before terminating in the lateral geniculate bodies.

At the level of the lamina cribrosa, the axons within the optic nerve become myelinated by concentric membranous processes of the oligodendroglia. The rather abrupt transition between myelinated and nonmyelinated nerve fibers is eminently appreciated in tissue sections stained with Luxol fast blue or other dyes with an affinity for myelin (Figure 13.40). As the axons acquire myelin coats, the diameter of the optic nerve doubles to nearly 3 mm. Located within the central core of the optic nerve, adjacent to the globe, is the central retinal artery and vein. Both of these vascular channels exit the nerve some 8 to 15 mm posterior to the lamina cribrosa; the channels are not evident within tissue sections of the optic nerve closer to the brain. The orbital portion of the optic nerve extends some 25 mm from the lamina cribrosa to the optic foramen at the apex of the orbit. If the optic nerve becomes compressed during enucleation of the globe, some optic nerve tissue may extrude into the eye and become dislodged into the lumen of blood vessels near the optic disc, between the sensory retina and the retinal pigment epithelium, and even into the vitreous humor. Neural tissue within the optic nerve may become displaced in a manner comparable to the â€œtoothpasteâ€• artifact of the

spinal cord that follows a traumatic insinuation of white matter into the grey matter. This artifact should not be mistaken for ectopic intraocular nervous tissue, tumors, giant drusen, vitreous humor worms, or subretinal exudates (17). With age, corpora amylacea, similar to those in the retina and brain, may become evident in the optic nerve.

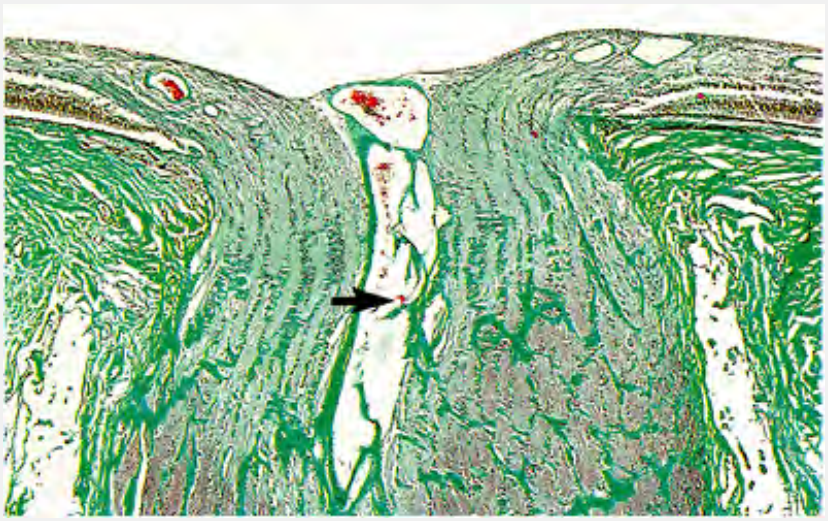

Figure 13.37 The optic nerve penetrates the sclera near the posterior pole of the eye. This histologic section contains the central retinal artery (*arrow*) in the central part of the optic nerve. Both the central retinal artery and the central retinal vein traverse the optic nerve until they exit the nerve about 8 to 15 mm posterior to the eyeball. (Masson's trichrome, Ã—10.)

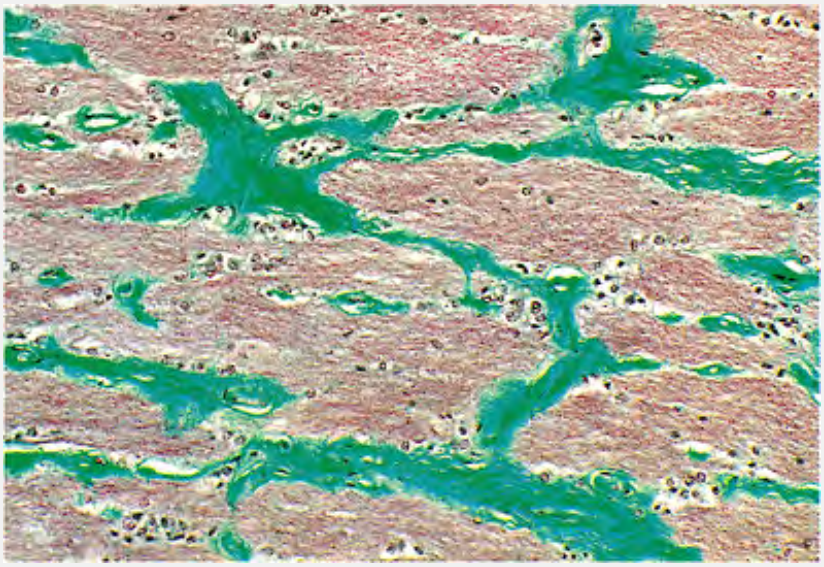

Figure 13.38 Nerve fiber bundles within the optic nerve are surrounded by thin collagenous septae (Masson's trichrome, Ã—50).

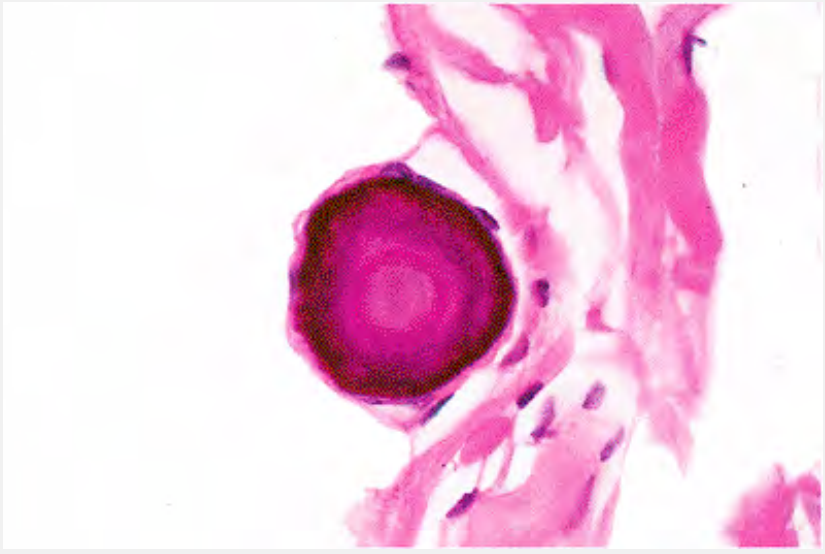

Figure 13.39 Laminated psammoma bodies, such as this one,

are often closely associated with the meningothelial cells of optic nerve (H&E, Ã—160).

Figure 13.40 The abrupt transition between nonmyelinated (*arrow*) and myelinated (*double arrows*) nerve fibers of the normal optic nerve at the level of the lamina cribrosa (*arrowheads*) is dramatically illustrated in this tissue section stained with a dye that has an affinity for myelin (Luxol fast blue, Ã—10).

The Crystalline Lens

The biconvex ocular lens (Figure 13.41) is located directly behind the pupil and in front of the anterior face of the vitreous humor. In the adult, it measures approximately 10 mm in diameter and 4 to 5 mm in width. The lens is held in place by zonules that connect it to the pars plicata of the ciliary body. The lens is encircled by a collagen- and carbohydrate-rich capsule that serves as the site of attachment for the zonules. The capsule over the anterior surface of the lens thickens with time. At 2 to 3 years of age, the anterior capsule is almost 8 to 15 Âµm wide and increases to 14 to 21 Âµm by 35 years (Figure 13.42). The posterior lens capsule reaches its maximum thickness at about 35 years of age (4â€“23 Âµm) and then diminishes to 2 to 9 Âµm after age 70 years (Figure 13.43) (2). Directly interior to the anterior lens capsule is a single layer of cuboidal epithelium. These cells extend to about the level of the lens equator; they do not normally exist posterior to this point. Proliferating epithelial cells elongate at the lens equator and become displaced toward the center of the lens, known as the lens nucleus, where they are retained for life. This process continues throughout life, and the long slender cells are designated lens fibers. In the peripheral part of the lens near the equator, the fibers retain their nuclei; but, as the fibers become displaced toward the center of the lens, their nuclei disintegrate so that the center of the lens lacks nuclei. In some cataractous lenses, such as the cataract of rubella, the fibers within the center of the lens retain their nuclei.

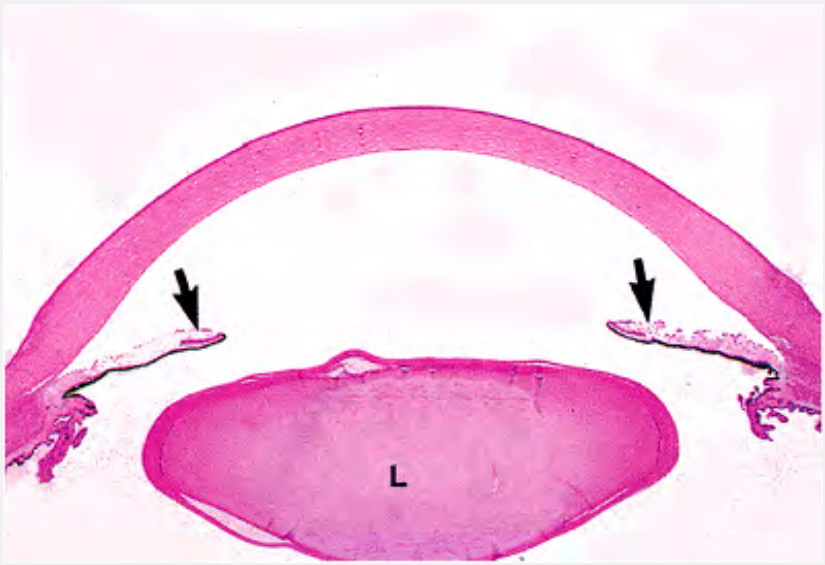

Figure 13.41 The crystalline lens (*L*) is situated just posterior to the pupil and iris (*arrows*) (H&E, Ã—2.5).

The normally transparent lens commonly opacifies with age. Discrete globules of degenerate lens fibers may form. They are frequently accompanied by the presence of an extension of epithelial cells posterior to the equator. The high density of the lens fibers makes it difficult to obtain histologic sections of the lens that are free from artifact.

Infant eyes can demonstrate an artifact of fixation resulting in an umbilicated, dimpled, or concave configuration of the posterior surface of the lens (18) (Figure 13.44).

Intraocular Compartments

The eye accommodates two major fluid-containing intraocular compartments. One is filled with aqueous humor, the other with vitreous humor. The aqueous humor compartment is divided into an anterior and posterior chamber (Figure 13.45). The anterior chamber

is delineated in front by the cornea, peripherally by the drainage angle of the eye, and posteriorly by the pupil and the iris. The small posterior chamber is situated between the pigmented epithelia of the iris, the ciliary body, the anterior face of the vitreous humor, and the lens.

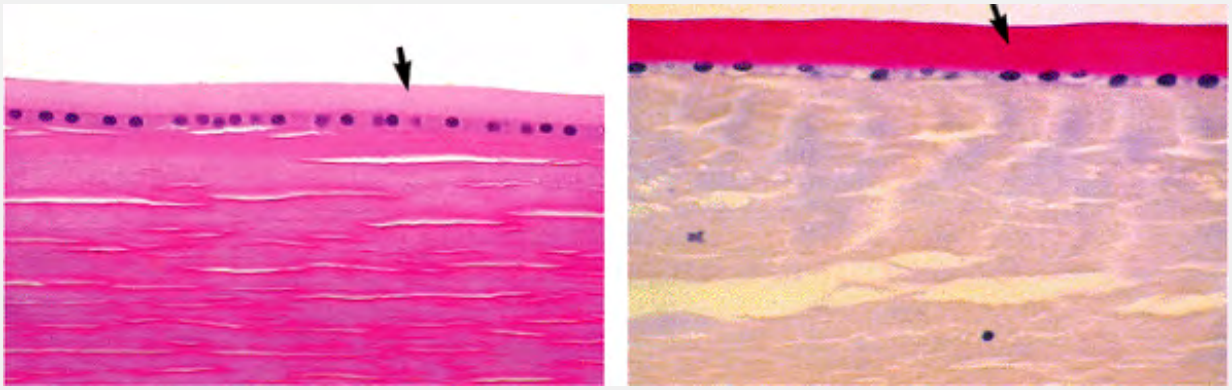

Figure 13.42 The anterior lens capsule (*arrow*) appears as an eosinophilic acellular band overlying a single layer of epithelial cells in hematoxylin and eosin-stained preparations (*left*). The lens capsule is rich in carbohydrate and reacts intensely with the periodic acid-Schiff stain (*arrow*) (*right*). (Left, H&E, Ã—132; right, PAS, Ã—160.)

Figure 13.43 Posteriorly, the lens capsule (*arrow*) is thinner than anteriorly, and epithelial cells are absent (H&E, Ã—132).

Figure 13.44 Infant eye demonstrating an artifact of fixation resulting in a posterior concave or umbilicated appearance of the lens. This figure also illustrates an artifactual absence of most of

the corneal epithelium (H&E, Ã—1).

The aqueous humor, a watery solution that does not normally stain with routine histologic techniques, is produced by the ciliary body and flows forward through the aperture of the pupil to the anterior chamber, where it leaves the eye through the trabecular meshwork and Schlemm's canal. The anterior chamber contains approximately 0.25 ml of aqueous humor; the posterior chamber has a volume of only approximately 0.06 ml. Normal human aqueous humor has a density slightly greater than water; and, like plasma, it contains protein, ascorbic acid, electrolytes, and glucose. The major differences between

aqueous humor and plasma are the relatively low-protein and high-ascorbic acid concentration of aqueous humor, relative to plasma.

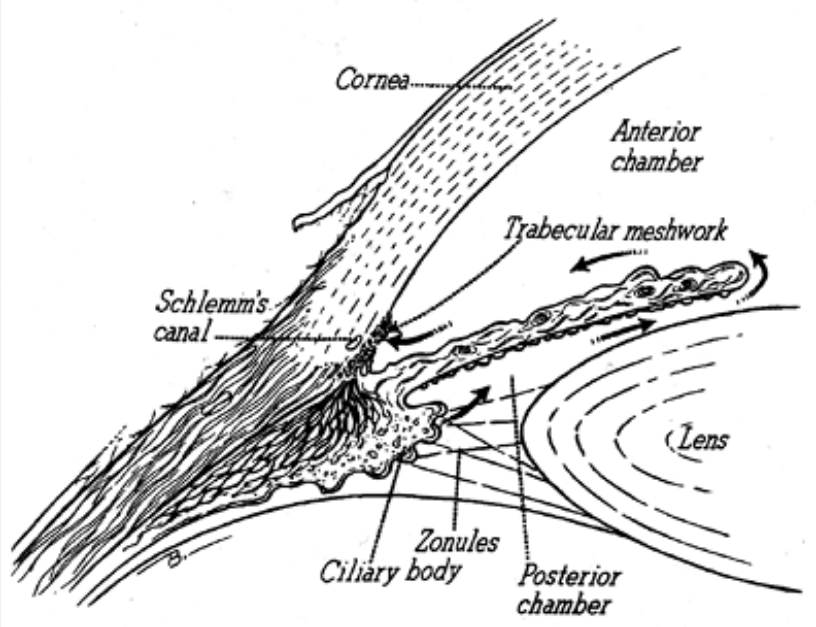

Figure 13.45 The anterior chamber is defined by the cornea, anterior surface of the iris, and pupil. The boundaries of the

much smaller posterior chamber include the posterior surface of the iris, the ciliary body, and the anterior face of the vitreous humor. Aqueous humor is produced by the ciliary body and circulates from the posterior chamber through the pupil into the anterior chamber. Aqueous humor drains from the eye by way of the trabecular meshwork and Schlemm's canal. (Reproduced with permission from:
Klintworth GK, Landers MB III. *The Eye: Structure and Function*. Baltimore: Williams & Wilkins; 1976.
)

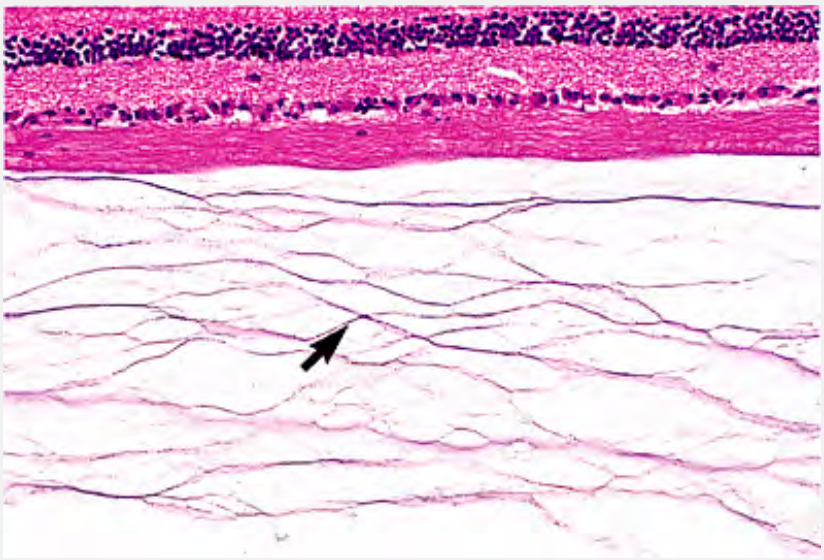

Figure 13.46 The vitreous humor (*arrow*) appears as an amorphous material in standard tissue sections (H&E, Ã—50).

The vitreous humor extends from the sensory retina to the lens and contains a gel-like material composed of water, protein, hyaluronic acid, and a small population of cells, designated hyalocytes, which are rarely noted in standard tissue sections. These tissue

macrophages are thought to synthesize collagen and hyaluronic acid. The gelatinous consistency of the vitreous humor is due to a framework of numerous, randomly oriented collagen fibrils. The concentration of glucose and ascorbic acid is much lower than in the aqueous humor, whereas the concentration of soluble protein is similar to that of the aqueous humor (19). The vitreous humor is attached securely to the retina at the ora serrata and near the optic disc. Occasionally, vitreous humor may be identified as an amorphous acellular material on hematoxylin and eosin-stained sections (Figure 13.46).

The Eyelids

The eyelids (Figure 13.47) can be divided into cutaneous and conjunctival portions. The cutaneous segment of the eyelid is composed of a stratified squamous epidermis overlying a loosely arranged dermis, beneath which is muscular tissue. The eyelids contain several types of skin appendages. Sebaceous glands deposit their secretions, together with decomposed whole cells, via ducts into hair follicles of the eyelashes (glands of Zeis) or into ducts that open into the lid margins (meibomian glands) (Figure 13.48). Apocrine glands, whose secretions represent the pinched-off luminal aspect of the lining acinar cells, also open into the follicles of the eyelashes (glands of Moll) (Figure 13.49). In addition, the dermis of the eyelid contains eccrine sweat glands, which discharge secretions directly onto the skin via a convoluted duct. The subcutaneous portion of the upper and lower eyelids contains concentrically arranged skeletal muscle fibers (orbicularis oculi) but very little adipose connective tissue. Striated muscle of the palpebral portion of the levator palpebrae superioris is also present in the upper eyelid; it terminates in a dense fibrocollagenous aponeurosis. Small bundles of smooth muscle fibers (MÃ¼ller's muscle) are located within the upper and lower eyelids.

The junction between the cutaneous and conjunctival parts of the

eyelid is demarcated clinically by a sulcus (the gray line), located between the ducts of the meibomian glands and the eyelashes. The conjunctival portion of the eyelid is made up of dense connective tissue containing the meibomian glands and the palpebral conjunctiva (Figure 13.50). The tarsus, located immediately posterior to the muscles of the eyelid, accounts for most of the rigidity of the eyelids and is covered posteriorly by conjunctival epithelium and a thin subepithelial stroma. As described earlier, accessory lacrimal glands are present in the palpebral conjunctiva.

The presence of more prominent subcutaneous, suborbicularis, and pretarsal fat tissue in the upper eyelid (the pretarsal fat pad) distinguishes an Asian eyelid from a Caucasian eyelid (20).

The Orbit

The posterior and peripheral borders of the orbit are defined by bones of the skull, face, and nose. At the anterior orbital margin, the periosteum of the orbital bones gives rise to a dense connective tissue sheet (the orbital septum) (Figure 13.47A), which extends forward to insert into the eyelids. Tissue posterior to this septum is considered to be within the orbit. In the human adult, the orbit measures approximately 40 mm in height, 45 mm in depth, and has a volume of almost 30 mL. Several bony canals allow for transmission of blood vessels and nerves into and out of the orbit, posteriorly. The contents of the orbit are organized in a complex three-dimensional arrangement (Figure 13.51). Aside from the eye, the optic nerve and its meningeal coverings, Tenon's capsule, the extraocular muscles, the lacrimal gland, blood vessels, and a delicate framework of fibroadipose connective tissue constitute the major components of the orbit.

The only epithelial structure normally present in the orbit is the lacrimal gland (Figure 13.52). Closely apposed to the globe and situated in the superolateral aspect of the orbit, this gland is traditionally divided into two parts: a larger orbital lobe and a

smaller palpebral lobe. About a dozen ducts from the lacrimal gland open into the superior conjunctival fornices and transmit their secretions into the tear film. The lacrimal gland is not encapsulated, and thin fibroconnective tissue septae divide the tissue into lobules

P.367

P.368

P.369

composed of acini and lined by columnar-shaped cells. Occasionally, some lobules extend posteriorly behind the globe. Most cells are serous in type and contain scattered intracytoplasmic fat droplets and granules. Mucinous cells similar to those of salivary glands are not usually present in the acini but may be identified in the ducts. In addition to secretory cells, the lining of the larger peripheral ducts within the lacrimal gland contain myoepithelial cells external to the serous cells. Occasional lymphocytes and plasma cells are commonly present between the acini of the lacrimal gland.

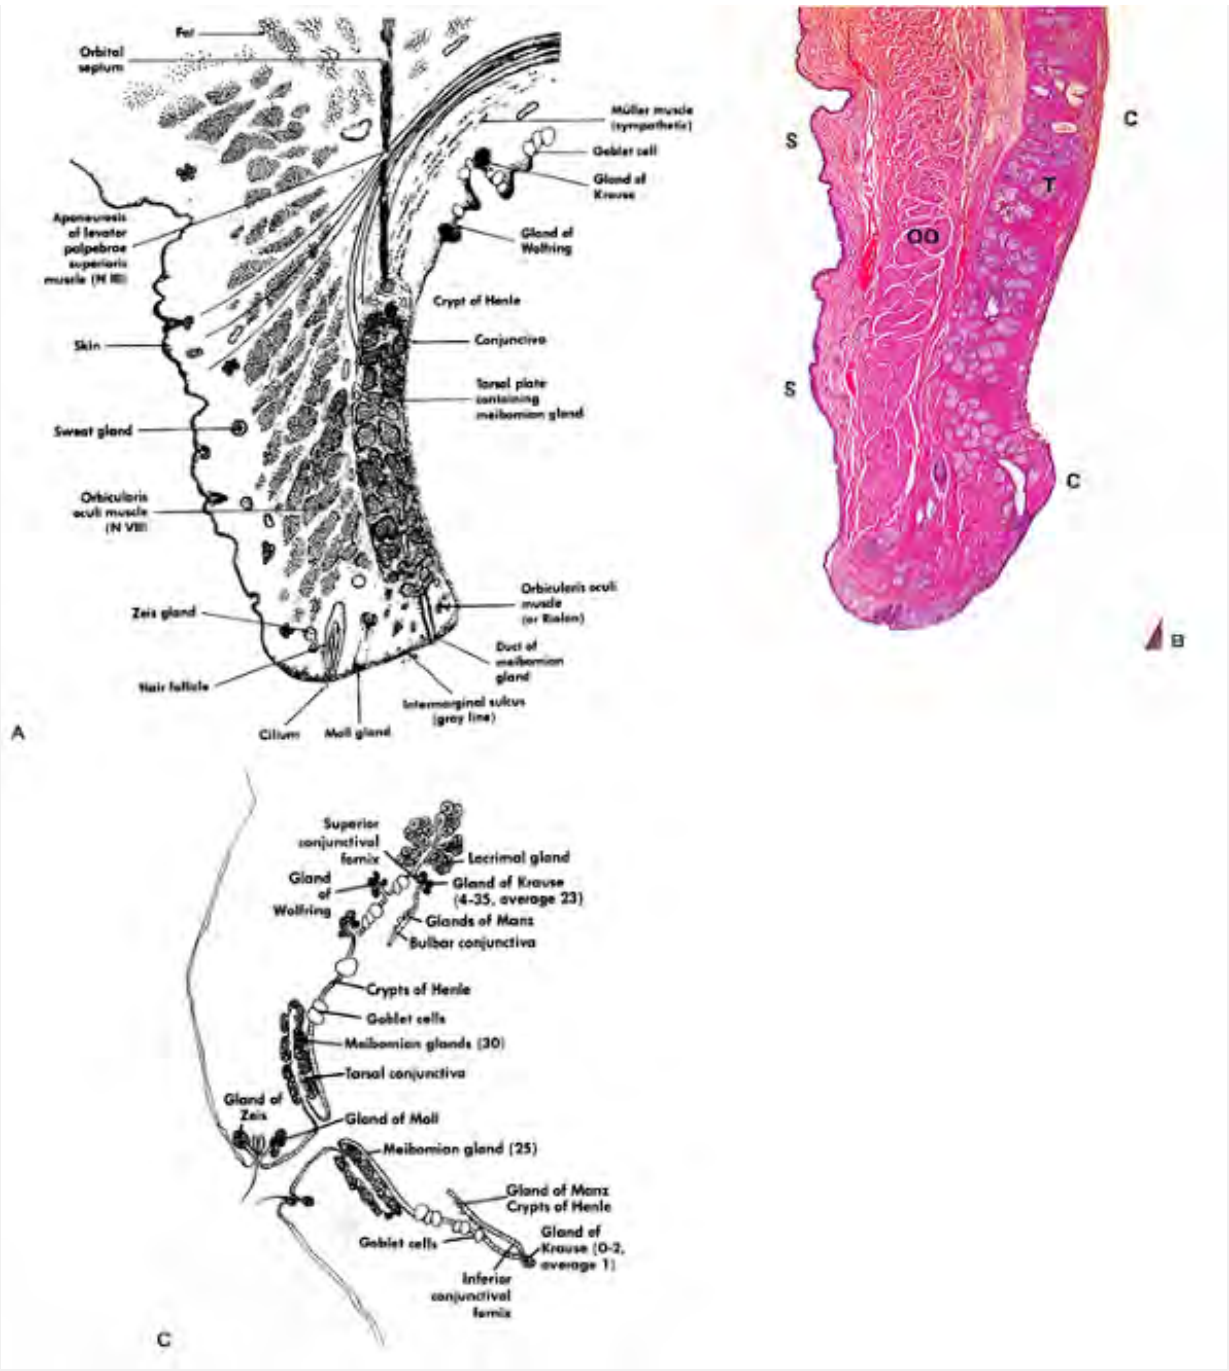

Figure 13.47 A. Components of the eyelid as illustrated on this drawing include skin and cutaneous appendages, muscle, connective tissue, and conjunctiva. (Reproduced with permission from FW Newell. *Ophthalmology: Principles and Concepts*. 6th ed. St.

Louis: CV Mosby; 1986.
) B. The skin surface (*S*), the orbicularis oculi muscle (*OO*), the tarsus (*T*), and the conjunctiva (*C*) are evident in this histologic section of an eyelid (H&E, Ã—3.3). C. Multiple foci of accessory lacrimal gland tissue (glands of Krause and Wolfring) are present in the eyelids. (Reproduced with permission from:
Newell FW. *Ophthalmology: Principles and Concepts*. 6th ed. St. Louis: CV Mosby; 1986.
)

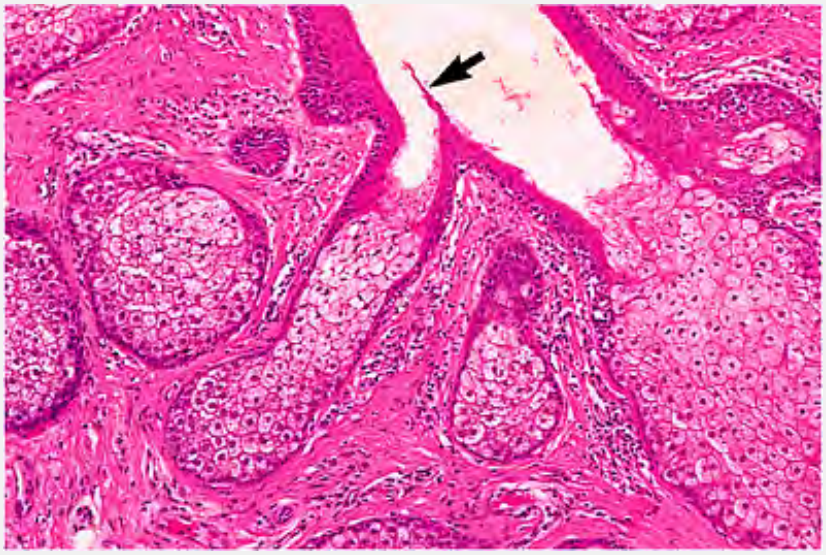

Figure 13.48 Modified sebaceous glands, the meibomian glands, deposit secretions into ducts that open onto the eyelids. A valve is evident (*arrow*) in this duct of a meibomian gland. (H&E, Ã—33.)

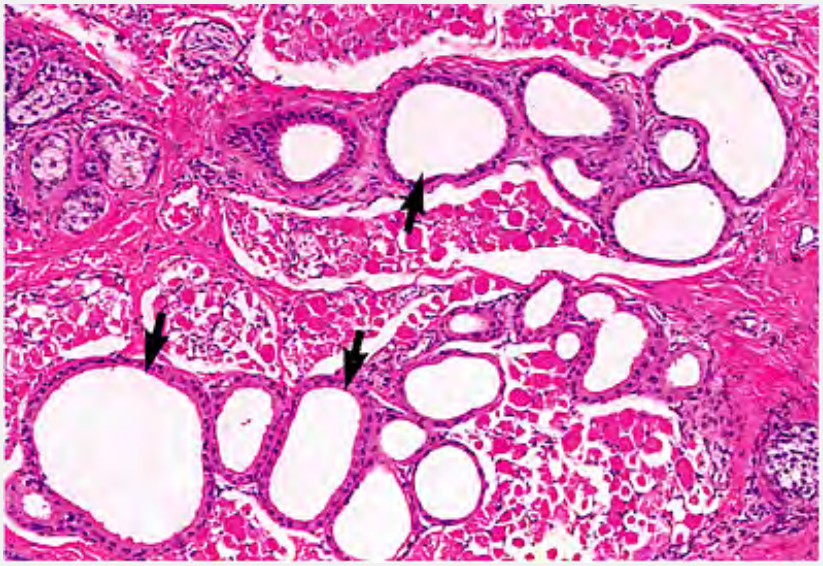

Figure 13.49 Apocrine glands (glands of Moll) (*arrows*) occur in the eyelid and open into the follicles of the eyelashes (H&E, Ã—33).

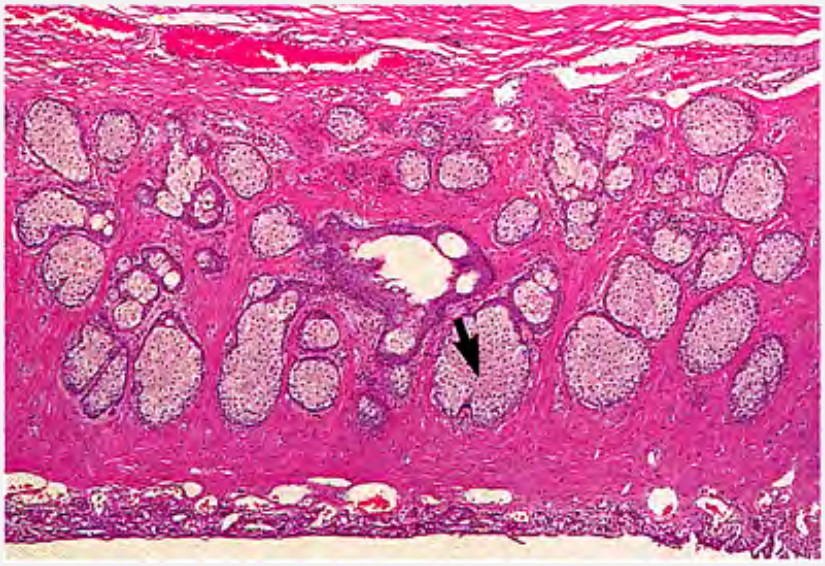

Figure 13.50 The tarsus, composed of dense fibrous tissue,

contains the meibomian glands (*arrow*). The palpebral conjunctiva is immediately beneath the tarsus at the bottom of this figure. (H&E, Ã—13.2.)

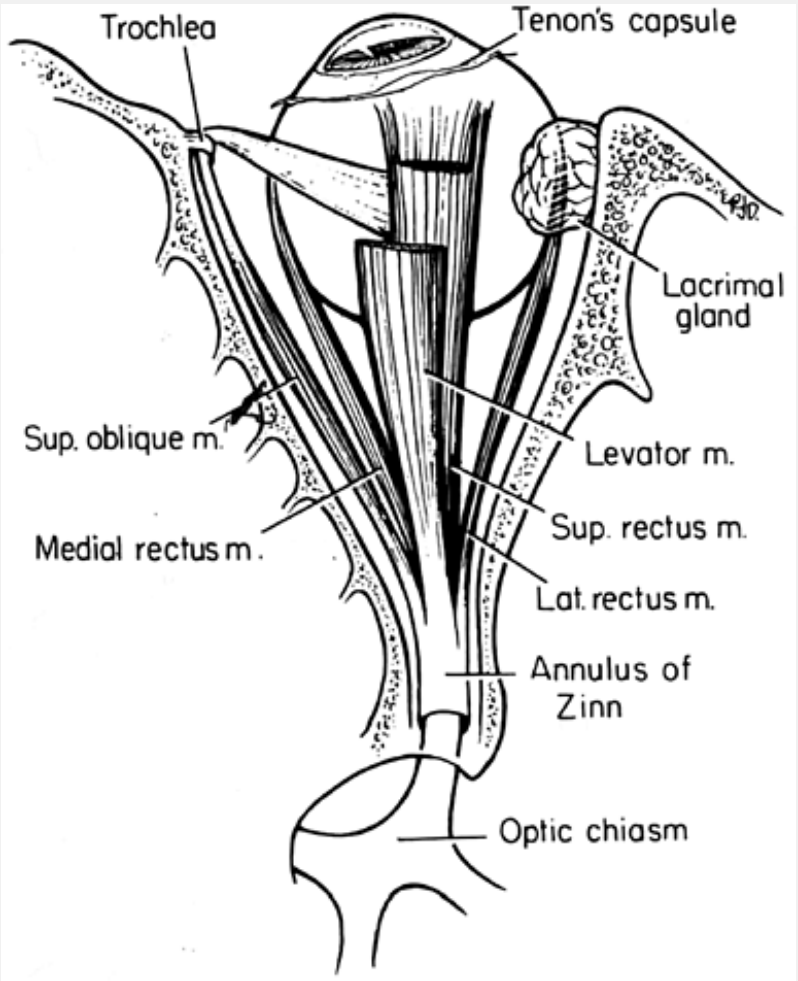

Figure 13.51 The bony cavity of the orbit contains the eyeball and its fibrous covering (Tenon's capsule), the cartilagenous trochlea, the lacrimal gland, and the extraocular muscles. The trochlea and the lacrimal gland are located within the superonasal and superotemporal aspects of the orbit respectively. Some of the extraocular muscles originate from a ring of fibrous tissue in the posterior orbit known as the annulus

of Zinn. (Reproduced with permission from: Tasman W, Jaeger EA, eds. *Duane's Clinical Ophthalmology*. Vol. 2. Philadelphia: JB Lippincott; 1989.)

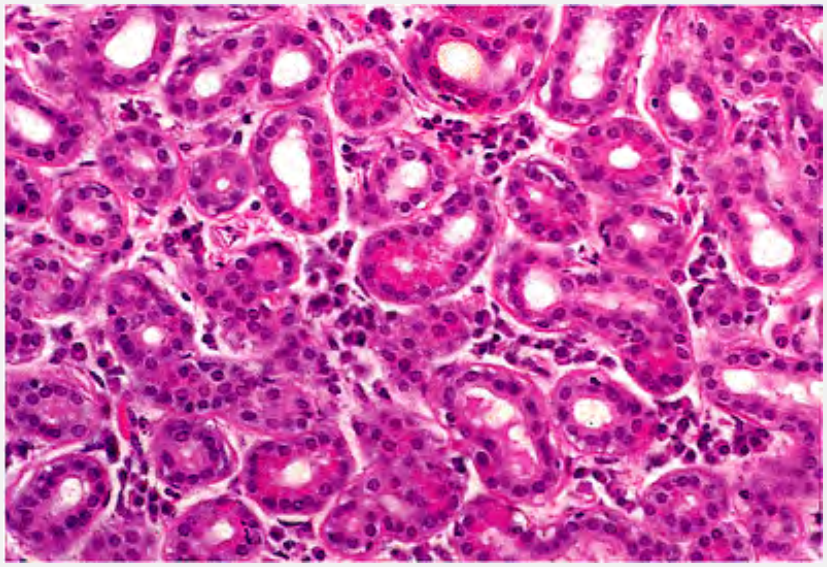

Figure 13.52 Acini of the lacrimal gland are lined by columnar-shaped epithelial cells. Scattered lymphocytes and plasma cells are normally present in the gland. (H&E, Ã—80.)

The orbit contains the cranial nerves, which innervate the extrinsic muscles of the eye (oculomotor, trochlear, and abducens nerves) and branches of the ophthalmic division of the trigeminal nerve, as well as parasympathetic and sympathetic nerves that innervate the cornea, conjunctiva, and the muscles of the ciliary body and iris. Neurons of the ciliary ganglion, which is located near the optic nerve close to the orbital apex and which measures approximately 2 mm in diameter, receive parasympathetic and sympathetic nerve fibers.

Other constituents of the orbit include smooth muscle (Figure 13.53)

(21) and the arc-shaped structure (trochlea), through which the tendon of the superior oblique muscle passes before insertion upon the eyeball (Figure 13.54). The trochlea is the only cartilaginous structure normally present in the orbit. It arises from the superior nasal aspect of the frontal bone.

Lymphatic channels do not exist in the orbit according to traditional teaching; but this point is disputed because lymphangiomas develop in the orbit on rare occasions (22). The orbit normally lacks lymphoid tissue but contains scattered lymphocytes. These cells presumably give rise to the monoclonal and polyclonal lymphoid proliferations that frequently develop within the orbit, creating diagnostic and prognostic difficulty for the pathologist (23).

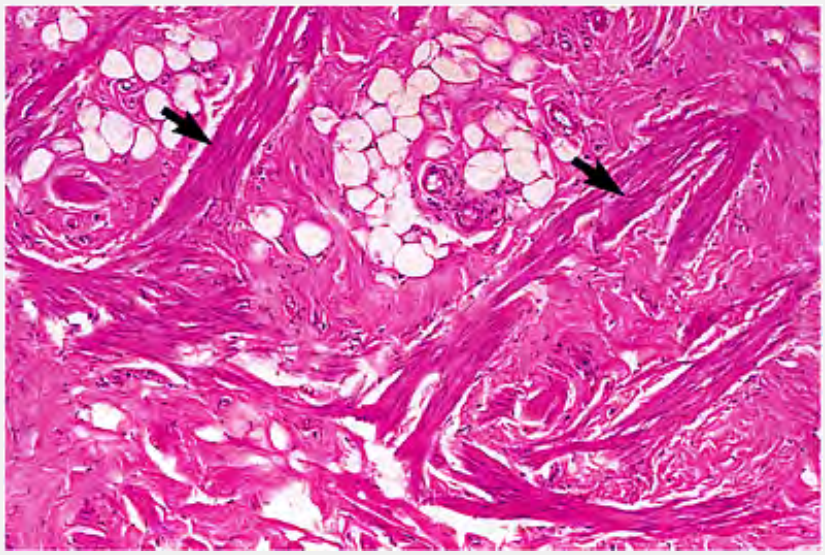

Figure 13.53 Smooth muscle bundles (*arrows*) are present in the soft tissues of the orbit (H&E, Ã—10).

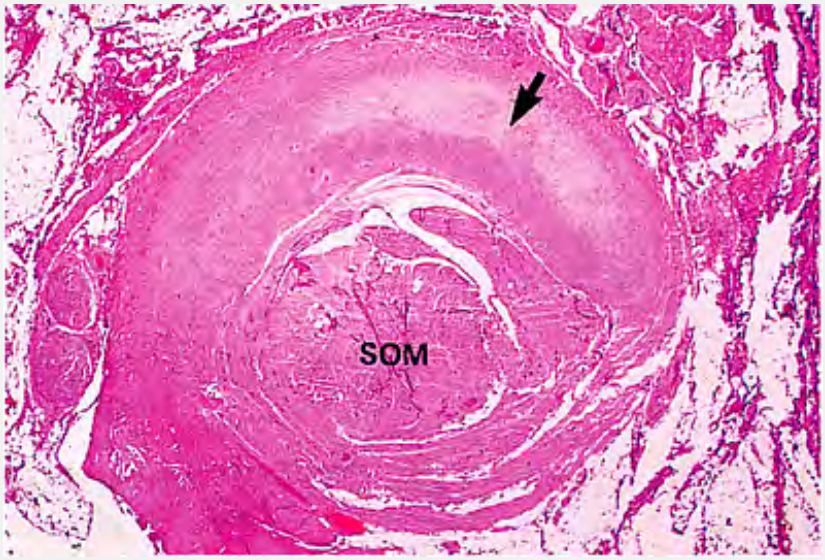

Figure 13.54 The arc-shaped trochlea (*arrow*), the only cartilaginous structure of the normal orbit, envelops the skeletal muscle fibers of the superior oblique muscle (*SOM*) (H&E, Ã—5).

Lacrimal Drainage Apparatus

The lacrimal drainage apparatus (Figure 13.55), composed of the puncta, canaliculi, lacrimal sac, and the nasolacrimal duct, collects the tears and drains them to the nose. Tear fluid drains toward the medial canthus and then passes through an opening in the medial aspect of each eyelid, known as the lacrimal punctum. The puncta drain into the lacrimal canaliculi, tubular structures approximately 0.5 mm in diameter. Initially, The canaliculi are oriented vertically but, within 2 mm of their origin, bend at right angles to become almost horizontal within the eyelids. The distal portions of the canaliculi exit the

upper and lower eyelids. They merge to form the lacrimal sac, which is encased by bones located in the inferomedial wall of the orbit. A

duct (the nasolacrimal duct) that is nearly 1 cm long drains the lacrimal sac into the inferior nasal meatus of the nose. The epithelium lining the lacrimal drainage apparatus varies in different regions. In the canaliculi, it is a nonkeratinizing stratified squamous epithelium (Figure 13.56), but in the lacrimal sac and duct, the epithelium is stratified columnar in type and contains mucus-secreting goblet cells surrounded by connective tissue (Figure 13.57).

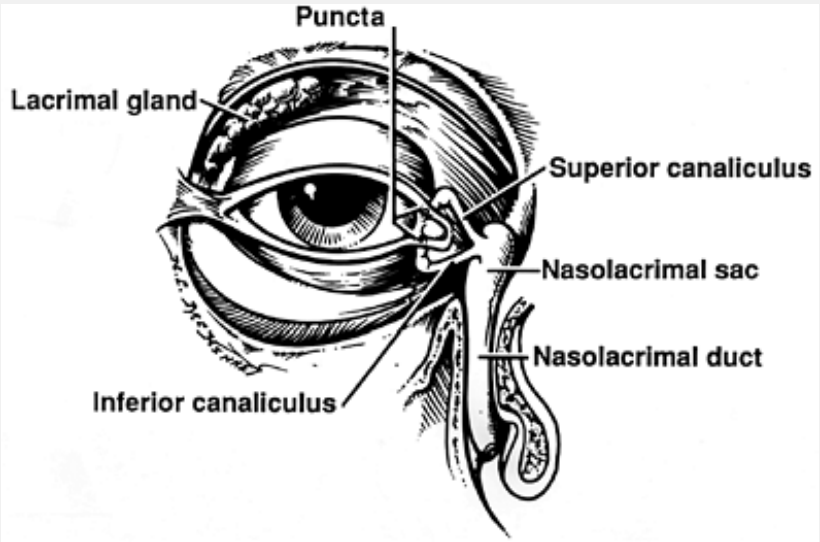

Figure 13.55 The lacrimal gland and drainage apparatus are illustrated here. The lacrimal gland is located in the superotemporal aspect of the orbit and contributes secretions to the tear film. Tears enter the canaliculi through the puncta and drain through the nasolacrimal sac and duct to eventually reach the inferior meatus within the nose.

Figure 13.56 The lacrimal canaliculi are lined by nonkeratinizing stratified squamous epithelium and are surrounded by fibrous tissue (H&E, Ã—13.2).

Figure 13.57 The epithelium of the lacrimal sacs and ducts is stratified columnar and contains goblet cells (H&E, Ã—50).

The Ear and Temporal Bone

Bruce M. Wenig
Leslie Michaels

Introduction

The ear can be considered as three distinct regions, or compartments, to include the external ear, the middle ear and temporal bone, and the inner ear (Figure 14.1).

- The external ear consists of the auricle (pinna), external auditory canal (or meatus), and the tympanic membrane at the medial end of the auditory canal.
- The middle ear cavity includes the ossicles, auditory (eustachian or pharyngotympanic) tube connecting the middle ear space to the nasopharynx, and expansion of the middle ear cavity in the form of air cells in the temporal bone.
- The inner ear is embedded in the petrous portion of the temporal bone and consists of a membranous (otic) labyrinth that lies within a dense bone referred to as the otic capsule, which is excavated to form the osseous (periotic) labyrinth (1).

The inner ear is the sense organ for both hearing and balance. The

external and middle ears are the sound-conducting apparatus for the auditory part of the inner ear.

External Ear

Embryology

The external ear develops from the first brachial groove. The external auricle (pinna) forms from the fusion of the auricular hillocks or tubercles (a group of mesenchymal tissue swellings from the first and second branchial arches) that lie around the external portion of the first branchial groove (2). The external auditory canal is considered a normal remnant of the first branchial groove. The tympanic membrane forms from the first and second branchial pouches and the first branchial groove (2). The ectoderm of the first

branchial groove gives rise to the epithelium on the external side; the endoderm from the first branchial pouch gives rise to the epithelium on the internal side; and the mesoderm of the first and second branchial pouches gives rise to the connective tissue lying between the external and internal epithelia (Figure 14.2) (2).

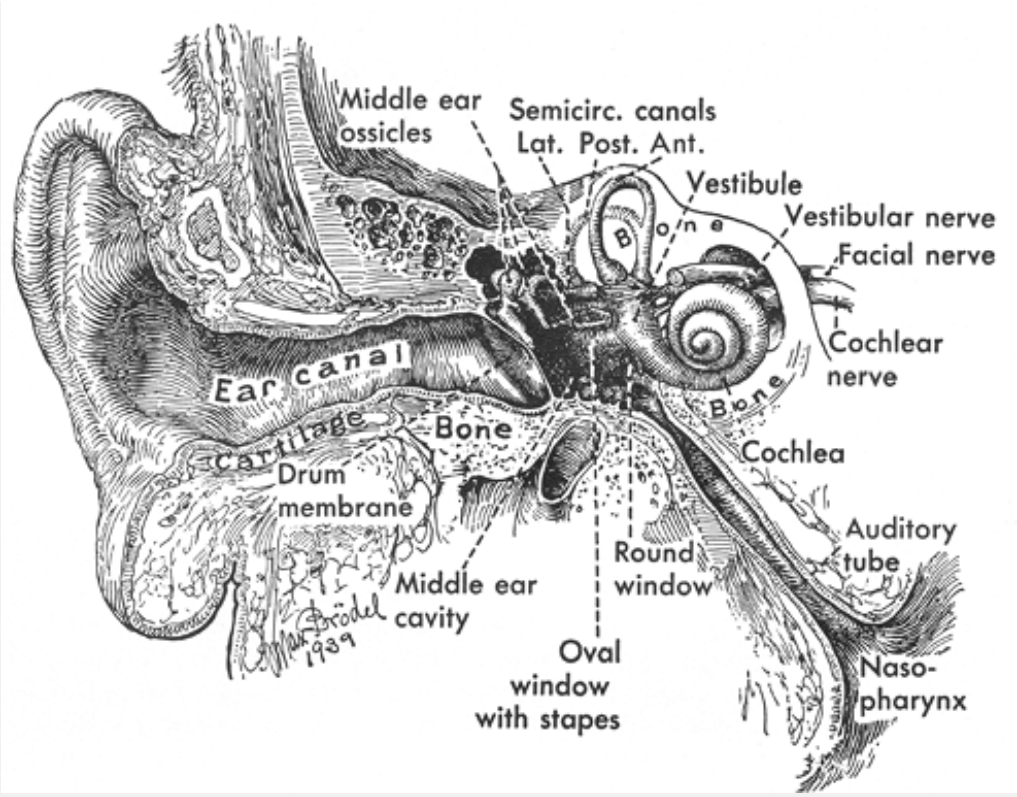

Figure 14.1 Modified coronal section through the ear and temporal bone depicting the anatomic compartments of the ear: the external, middle, and inner ears (Reprinted with permission from:
Hollinshead WH. The ear. In: Hollinshead WH, ed. *Anatomy for Surgeons*. 3rd ed. Philadelphia: Harper and Row; 1982:159â€“221
).

Anatomy

The anatomy of the external ear is seen in Figure 14.3. The outer portion of the external ear includes the auricle leading into the external auditory canal. The skeleton of the auricle consists of a single plate of elastic cartilage conforming to the shape of the ear.

The lobule is the only part of the auricle that is devoid of skeletal support. The cartilage of the auricle is continuous with that of the external auditory canal.

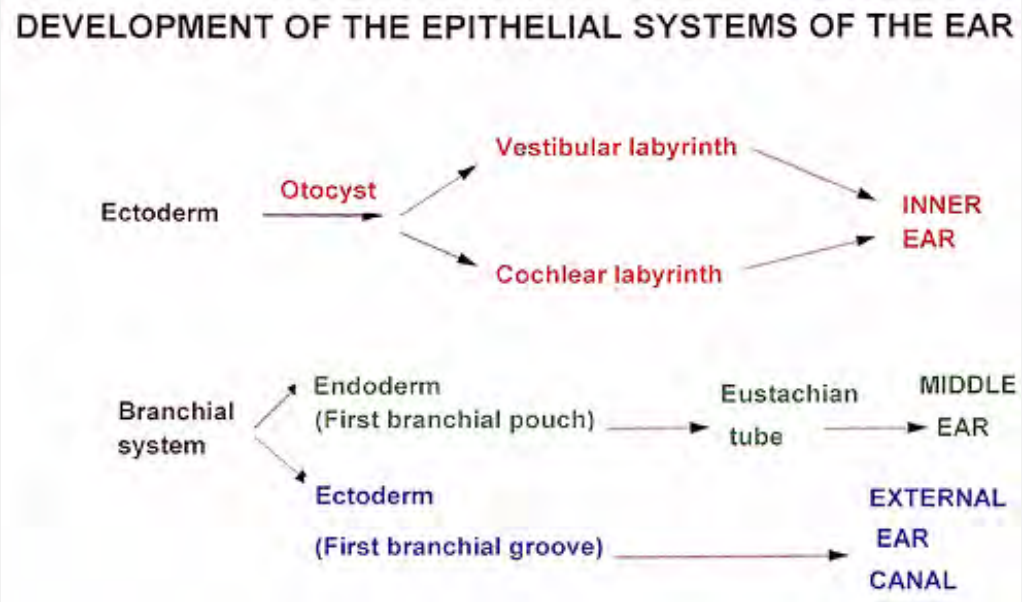

Figure 14.2 Diagrammatic representation of the embryology of the epithelia of the inner, middle, and external ears.

The auricle is attached to the bony skull by three ligaments: anterior, superior, and posterior (1). The anterior ligament attaches the helix and the tragus to the zygomatic process. The superior ligament attaches the spine of the helix to the superior margin of the bony external meatus. The posterior ligament attaches the medial surface (eminence) of the concha to the mastoid process. The auricle is anchored through its continuity with the cartilage of the meatus and through the skin and extrinsic muscles.

The extrinsic muscles of the ear include the anterior, superior, and posterior auricular muscles. These muscles are usually functionless but may be subject to voluntary control (as in ear â€œwigglingâ€•).

There are also small intrinsic muscles in connection with the cartilage of the external ear, but they are of no apparent importance. The extrinsic and intrinsic muscles of the ear are innervated by the facial nerve.

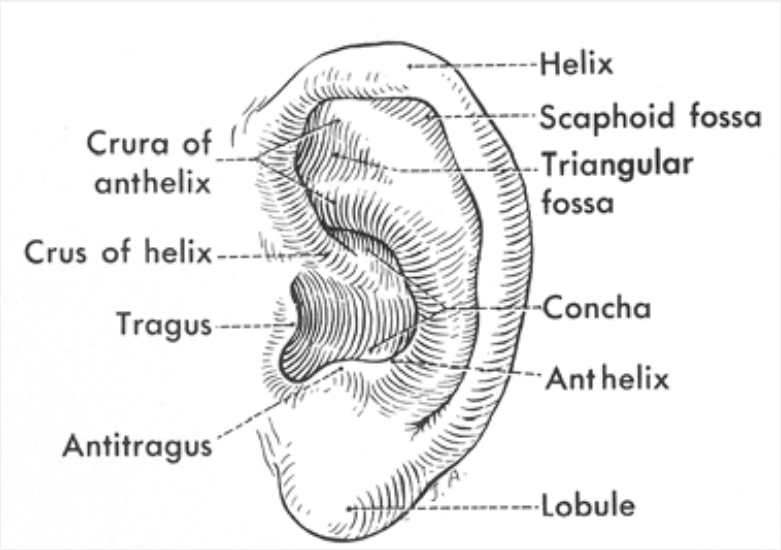

Figure 14.3 Anatomy of the external ear.

The external auditory canal or meatus extends from the concha to its medial limit, which is the external aspect of the tympanic membrane. The lateral portion of its wall consists of cartilage and connective tissue (1); the medial portion of its wall consists of bone. The cartilaginous part of the external auditory canal constitutes slightly less than half its total length. Inconstant fissures, referred to as the fissures of Santorini, occur in the cartilage; these fissures may transmit infection from the canal to the parotid gland and superficial mastoid regions, or vice versa. The bony part of the canal is formed by both the tympanic part and the petrous part of the temporal bone. The anterior, inferior, and lower posterior parts of the bony wall are formed by the C-shaped part of the temporal bone developed from

the annulus tympanicus of the fetus. However, the annulus is incomplete in the posterosuperior part of the wall, and this part of the wall in adults is formed by the squamous and petrous parts of the temporal bone. In adults, the anterior and inferior walls of the cartilaginous canal are closely related to the parotid gland. The anterior wall of the bony canal is closely related to the mandibular condyle, the posterior wall to the mastoid air cells, and the medial portion of the superior wall to the epitympanic recess.

The tympanic membrane (eardrum) is situated obliquely at the end of the external auditory canal, sloping medially both from above downward and from behind forward. The tympanic membrane is a fibrous sheet interposed between the external auditory canal and the middle ear cavity (Figure 14.4). The connective tissue interposed between these two layers consists of radiating fibers that are attached to the manubrium of the malleus and are reinforced peripherally by circular fibers. The latter are thickened at the margin of the tympanic membrane to form a fibrocartilaginous ring (annulus fibrocartilagineus membranae tympani), attaching the tympanic membrane to the tympanic sulcus of the temporal bone. In the upper portion of the tympanic membrane, there is a limited area where the connective tissue fibers are lacking; this area is referred to as the pars flaccida, or Schrapnell's membrane. In this area, the tympanic portion of the temporal bone is deficient; this gap is referred to as the tympanic incisure, or the notch of Rivinus. The tympanic membrane attaches to the temporal bone. The remainder of the tympanic membrane, in which there are intact connective tissue fibers, is referred to as the pars tensa.

The outer aspect of the tympanic membrane is concave. The center of the concavity is referred to as the umbo, which is the strong point of attachment of the manubrium of the malleus to the tympanic membrane. In the anteriosuperior portion of the tympanic membrane, the lateral process of the malleus is attached; from this point of attachment, the anterior and posterior mallear folds pass to the cartilaginous annulus and separate the pars flaccida from the

pars tensa. In otoscopic examinations of the tympanic membrane, the bright area of light reflection present downward and forward from the umbo is referred to as the â€œcone of light.â€•

Histology

Histologically, the auricle is essentially a cutaneous structure composed of keratinizing, stratified squamous epithelium with associated cutaneous adnexal structures that include hair follicles, sebaceous glands, and eccrine sweat glands (Figure 14.5). In addition to the hair follicles and sebaceous glands, the outer third of the external auditory canal is noteworthy for the presence of modified apocrine glands (called ceruminal glands) that replace the eccrine glands seen in the auricular dermis (Figure 14.6). Ceruminal glands produce cerumen and are arranged in clusters

composed of cuboidal cells with eosinophilic cytoplasm, often containing a granular, golden-yellow pigment. These cells have secretory droplets along their luminal border. Peripheral to the secretory cells are flattened myoepithelial cells. The ducts of the ceruminal glands terminate in the hair follicle or on the skin. The ducts of ceruminal glands lack apocrine or myoepithelial cells. In the inner portion of the external auditory canal, ceruminal glands and the other adnexal structures are absent.

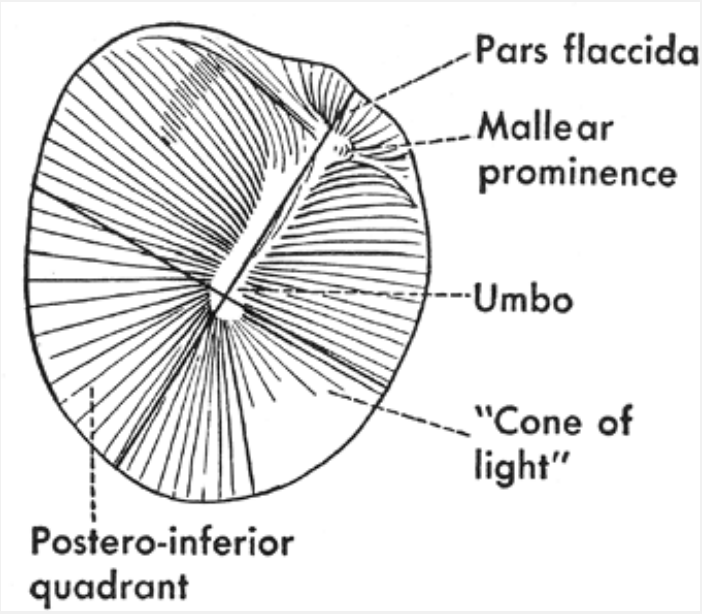

Figure 14.4 External (lateral) view of the tympanic membrane.

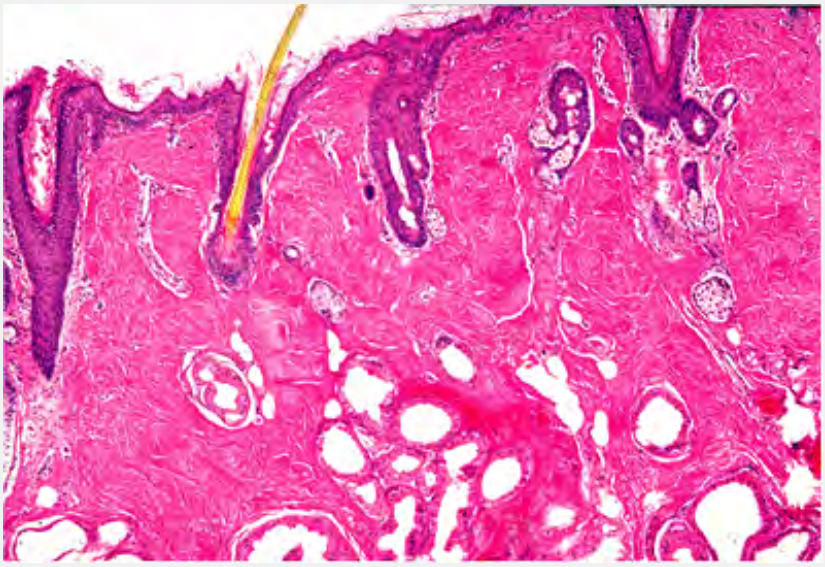

Figure 14.5 The auricle is a cutaneous structure histologically composed of keratinizing stratified squamous epithelium with

associated cutaneous adnexal structures that include hair follicles, sebaceous glands, and eccrine sweat glands.

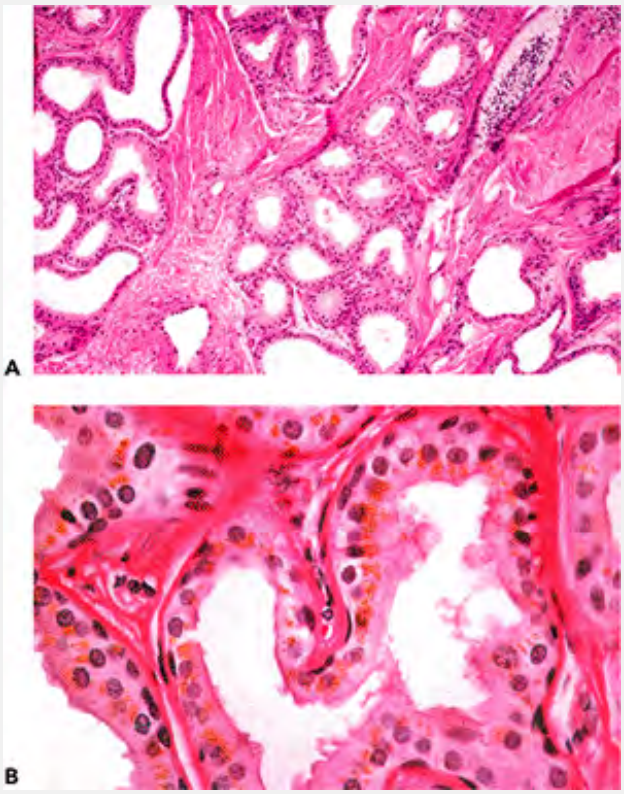

Figure 14.6 In addition to the hair follicles and sebaceous glands, the outer third of the external auditory canal is noteworthy for the presence of modified apocrine glands called ceruminal glands that replace the eccrine glands seen in the auricular dermis. A. Ceruminal glands are submucosal in location and are arranged in clusters or lobules. B. Ceruminal glands are composed of two cell layers, including the inner or secretory cells (containing intracytoplasmic cerumen and appearing as granular, golden-yellow pigmentation) and flattened-appearing myoepithelial cells located peripheral to the secretory cells. Focally, the secretory cells show holocrine (decapitation) type secretion.

The subcutaneous tissue is composed of fibroconnective tissue, fat, and elastic-type fibrocartilage, which gives the auricle its structural support (Figure 14.7). The ear lobe is devoid of cartilage and is replaced by a pad of adipose tissue. The perichondrium is composed of loose vascular connective tissue.

Similar to the auricle, the external auditory canal is lined by keratinizing squamous epithelium that extends to include the entire canal and covers the external aspect of the tympanic membrane. The tympanic membrane has a central bilaminated zone, including lateral radially arranged

and medial circularly arranged collagenous fibers (Figure 14.8). The inner two-thirds of the external auditory canal contain bone rather than cartilage. Because adnexal structures are absent, there is relatively close apposition of the epithelium to the subjacent bone.

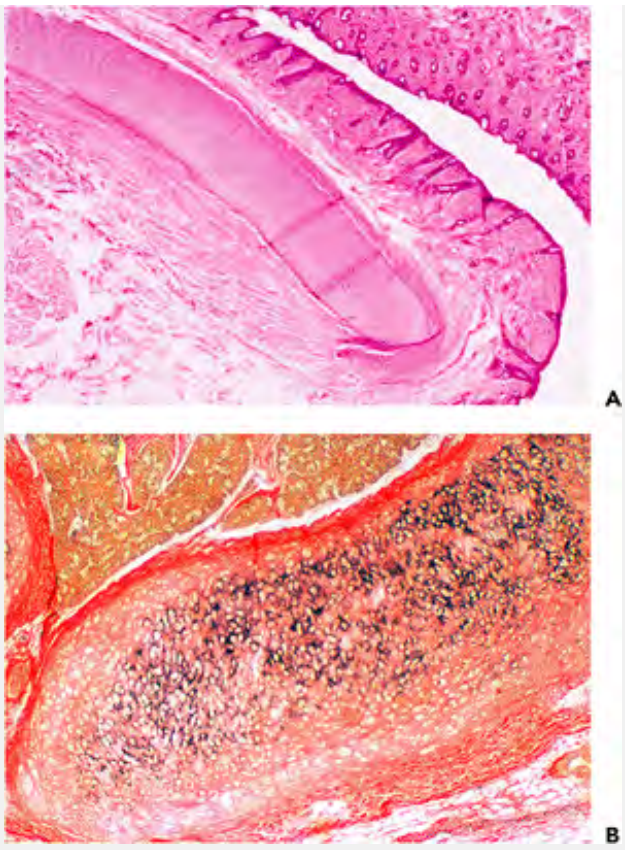

Figure 14.7 A. The cartilage of the external ear is elastic. B. Elastic stains show the abundant amount of elastic fibers (black staining) in the auricular cartilage.

Figure 14.8 Section of pars tensa of tympanic membrane. The following layers may be distinguished from left to right: middle ear epithelium, lamina propria, circular arrangement of collagenous fibers (i.e., at right angles to former layer), radial arrangement of collagenous fibers, lamina propria, and stratified squamous epithelium.

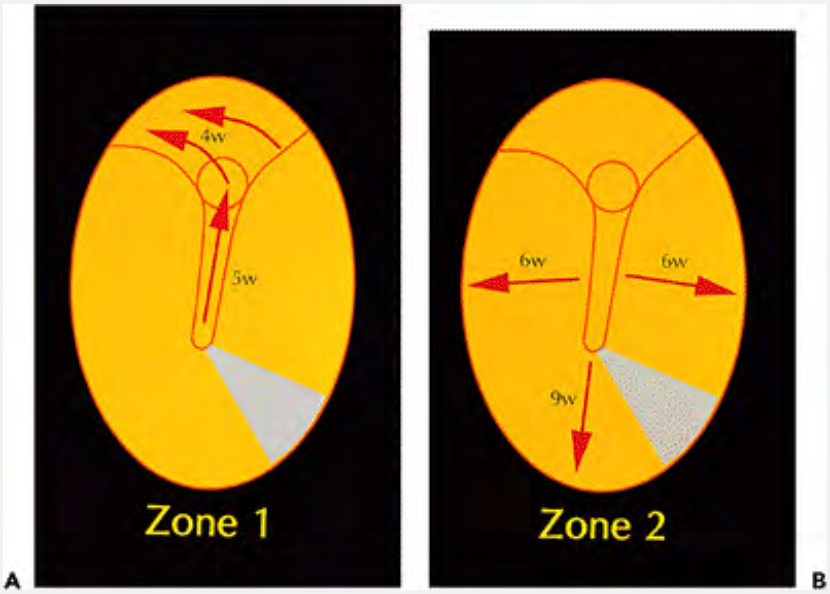

Figure 14.9 Summary of pathways of migration on tympanic membrane as determined by serial photography of dye markings. The tympanic membrane and adjacent deep external canal epithelium are depicted as being viewed en face. Two discrete pathways are present: A. passing upward along a tongue of epithelium and over the handle of the malleus to join epithelium, moving in a posterosuperior direction over the pars flaccida region (*Zone 1*), and B. a radial pathway moving centrifugally from the pars flaccida and handle of malleus regions to the periphery (*Zone 2*). The times given for each region are the weeks required for dye to be completely cleared from that region.

Auditory Epithelial Migration

Auditory epithelial migration represents the mechanism by which keratin is removed from the tympanic membrane. Without such a self-cleaning process, the keratin squames normally produced by the stratified squamous epithelium of the tympanic membrane would

continuously build up and interfere with the conduction of sound via the tympanic membrane. The entire epithelium, including keratin, moves from the tympanic membrane onto the deep external auditory canal. From the deep external auditory canal, the epithelium moves laterally to the junction of the deep (osseous) canal and the cartilaginous canal, where it is desquamated (3,4,5).

Auditory epithelial migration occurs in two separate and discrete pathways (Figure 14.9) (6). In one pathway, the epithelium moves upward over the handle of the malleus and then posterosuperiorly across the pars flaccida, moving laterally over the deep canal (Figure 14.10). The other pathway is radially moving away from the handle of the malleus and pars flaccida to the periphery of the tympanic membrane and then to the deep canal (Figure 14.11). Michaels and Soucek (3,4,5) have extensively evaluated the process of auditory epithelial migration and correlate the pathways to the development of the epithelia of the tympanic membrane and deep external canal in the embryo and fetus (6). The process of auditory epithelial migration has been felt to represent a possible pathogenesis for the development of cholesteatoma

(see below). However, there is no definitive evidence linking auditory epithelial migration to the development of cholesteatoma.

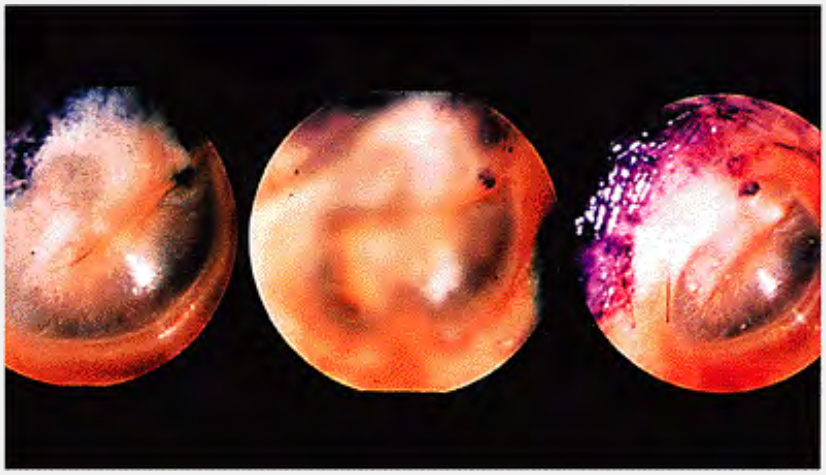

Figure 14.10 Pathway of auditory epithelial migration as shown by movement of blue dye daubed on tympanic membrane. Dye is seen on the day it was daubed, just anterior and inferior to the lateral process of the malleus. In the next photograph, taken 9 days later, it has moved posteriorly and superiorly to lie over that structure. Thirteen days later, in the third Photograph, it has crossed the pars flaccida region, moving in the same direction toward the external canal.

Middle Ear

Embryology

The middle ear space develops from invagination of the first branchial pouch (pharyngotympanic tube) from the primitive pharynx. The auditory tube and tympanic cavity develop from the endoderm of the first branchial pouch; the malleus and incus develop from the mesoderm of the first branchial arch (Meckel's cartilage), while the stapes develops from the mesoderm of the second branchial arch (Reichert's cartilage) (Figure 14.2) (2).

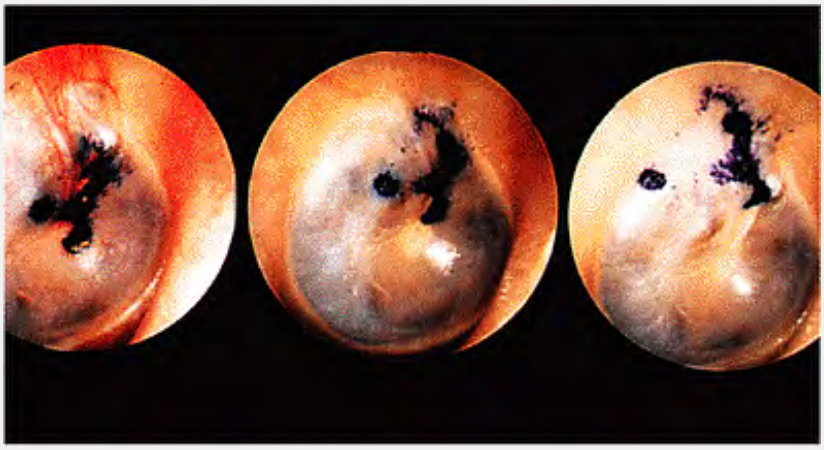

Figure 14.11 In this daubed tympanic membrane, an irregular array of dye is seen on the handle of malleus region on the sixth day after its deposition. By the fifteenth day, in the second photograph, a round dot that was just posterior to the handle of the malleus has separated and is commencing to travel backward; the main mass of dye is moving discretely upward along the handle of the malleus. This process has advanced on the twenty-seventh day in the third photograph, the posterior dye having reached the back edge of the tympanic membrane and the large mass now situated across the pars flaccida at an angle that has now changed to a posterosuperior one.

Anatomy

The middle ear, or tympanic cavity, lies within the temporal bone between the tympanic membrane and the squamous portions of the temporal bone laterally and the petrous portion of the temporal bone surrounding the inner ear medially. The anatomic limits of the tympanic cavity include (1,7,8):

- lateral or internal aspect made up by the tympanic membrane and squamous portion of the temporal bone

- medial aspect bordered by the petrous portion of the temporal bone
- superior (roof) delimited by the tegmen tympani (a thin plate of bone that separates the middle ear space from the cranial cavity)
- inferior (floor) aspect bordered by a thin plate of bone separating the tympanic cavity from the superior bulb of the internal jugular vein
- anterior aspect delimited by a thin plate of bone separating the tympanic cavity from the carotid canal (that houses the internal carotid artery)
- posterior aspect delimited by the petrous portion of the temporal bone, containing the mastoid antrum and mastoid air cells

The tympanic cavity communicates anteriorly with the nasopharynx by way of the auditory tube, and it communicates posteriorly with the mastoid air cells by way of the aditus and mastoid antrum.

The contents of the tympanic cavity include the ossicles (malleus, incus, and stapes), ligaments of the ossicles, tendons of the ossicular muscles, auditory tube, tympanic cavity proper, epitympanic recess, mastoid cavity, and chorda tympani of the facial nerve (cranial nerve VII). The middle and external ears function as conduits for sound conduction for the auditory part of the internal ear.

Lateral Wall

The tympanic cavity extends above the level of the tympanic membrane as the epitympanic recess (attic). In this area lie the head of the malleus and the body of the short process of the incus. The epitympanic recess projects laterally above the external acoustic meatus; it is this portion of the tympanic cavity that has a part of the squamous portion of the temporal bone as its lateral wall.

Roof

The roof of the tympanic cavity is the tegmen tympani, a thin plate of bone separating the middle ear cavity from the

cranial cavity. In children, the unossified petrosquamous suture of the tegmen tympani may allow the direct passage of infection from the middle ear to the meninges of the middle cranial fossa (1). In adults, especially in the setting of a long-standing history of chronic otitis media, compromise of the tegmen tympani may result in acquired encephalocele, in which glial-type tissue is present within the middle ear cavity. In adults, veins from the middle ear perforate the petrosquamous suture to end in the petrosquamous and the superior petrosal sinuses and may potentially transmit infection directly to the cranial venous sinuses (1).

Floor

The floor of the tympanic cavity is usually a thin plate of bone separating the cavity from the internal jugular vein. In the presence of a large superior bulb of the internal jugular vein, it may bulge into the middle ear and may present dehiscences (9).

Posterior Wall

The posterior wall of the tympanic cavity opens through the narrow aditus ad antrum in the wider mastoid (tympanic) antrum. Below the aditus is a relatively thin bone separating the tympanic cavity from the antrum, and it is from this posterior wall that the pyramidal eminence projects, with an aperture at its apex from which the tendon of the stapedius muscle is transmitted. Above and behind the pyramidal eminence, the facial nerve curves downward to change its course from horizontal to vertical. The chorda tympani, arising from the facial nerve, then enters the tympanic cavity through the canaliculus of the chorda in the posterior wall.

Anterior Wall

The lower part of the anterior wall is part of the petrous apex. This area consists of a thin plate of bone (which may be incomplete or may contain air cells) that separates the cavity from the carotid canal in which the internal carotid artery is located. The upper part of the anterior wall is deficient since the canal containing the tensor tympani muscle opens in this location, and immediately below this area is the tympanic orifice of the auditory tube.

Medial Wall

The medial wall of the tympanic cavity is the petrous portion of the temporal bone surrounding the internal ear and separating the middle ear cavity from the inner ear cavity.

Several markings of importance are found on its surface, including the broad prominence produced by the anterior end of the lateral semicircular canal and the prominence of the facial (fallopian) canal produced by the horizontal portion of the facial nerve in its course between the inner and middle ears. The cochleariform process transmits the tendon of the tensor tympani muscle. Its apex is the landmark for the position of the turn (geniculum, or external genu) between the anterolaterally and posteriorly directed horizontal portions of the facial nerve. Immediately below the facial canal is the fossula fenestrae vestibuli (the stapes niche); it contains the oval window, which is closed by the base of the stapes. Below the oval window is the promontory formed by the basal turn of the cochlea. The tympanic nerve plexus lies on the promontory. Below the back part of the promontory, the cochlear fossula (the round window niche) leads to the round window or fenestrae cochlea. Behind the promontory is a depression referred to as the sinus tympani, a site that may harbor infections and may transmit infections to the ampullary end of the posterior canal and posterior end of the lateral canal if the infection is deeply situated (1).

Middle Ear Ossicles and Muscles

The middle ear bones, or ossicles, include the malleus, incus, and stapes (Figure 14.12). The parts of the malleus include a head, upper and lower manubrium (handle), lateral process, and anterior process. The malleus is closely attached to the tympanic membrane by its manubrium (handle) and its lateral process, while its head projects above the epitympanic recess to articulate with the body of the incus. The anterior (long) process (processus gracilis) of the malleus extends obliquely downward from the neck toward the tympanosquamous fissure. In infants, the anterior process may reach the tympanosquamous fissure; but, in adults, the distal part is transformed to connective tissue, forming the anterior ligament of the malleus (1). The malleus is also attached to the tympanic wall by superior and lateral mallear ligaments. The lateral ligament attaches the neck of the malleus to the margin of the tympanic notch.

The parts of the incus include its body and the long and short processes. The body of the incus is fitted against the head of the malleus and lies in the epitympanic recess. The short process (crus) rests in a depression referred to as the fossa of the incus, which is situated in the posterior wall of the tympanic cavity below the aditus ad antrum. The long process (crus) of the incus descends parallel and slightly posteromedial to the manubrium of the malleus but at its lower end turns medial to articulate with the stapes (1). The incus is held in place by a posterior ligament that attaches to its short process and by a superior ligament to attach to the body. The knoblike expansion of the long crus of the incus (at the incudomallear joint) is referred to as the lenticular process.

The stapes is formed by its two crura, a head that lies at the junction of the crura and a footplate that lies on the oval window (Figure 14.13). The head of the stapes articulates with the incus. From its articulation with the incus, the

stapes passes almost horizontally to the oval (vestibular) window.

The footplate of the stapes is attached to the oval window by the annular ligament. The latter, a ring of elastic fibers, allows movement of the stapes but seals any potential space between its footplate and the edges of the oval window.

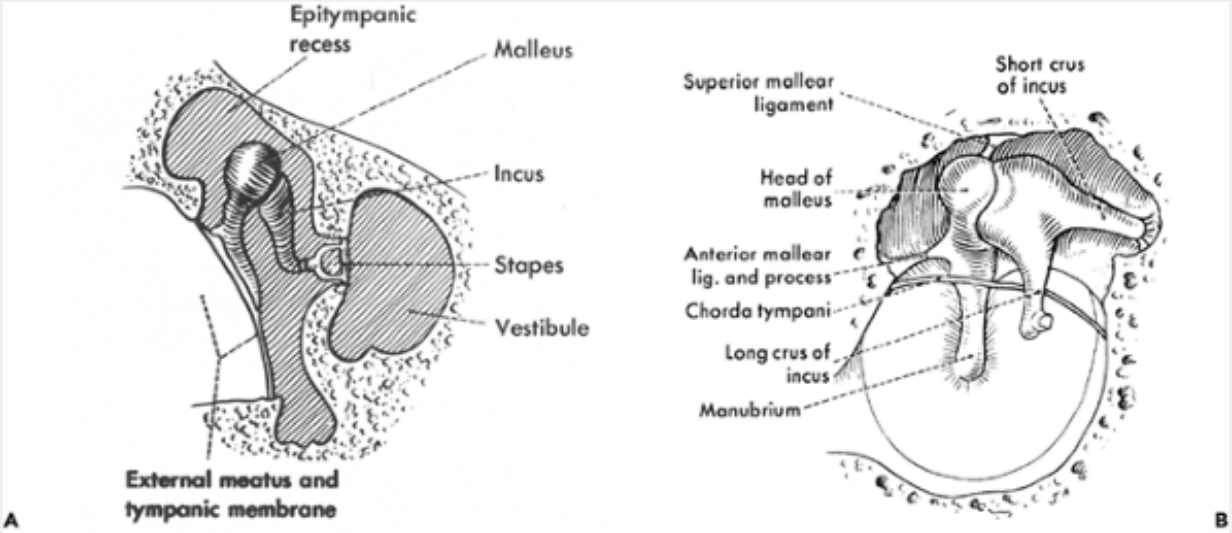

Figure 14.12 Diagrammatic depiction of the anatomy of the middle ear ossicles: A. frontal aspect (rotated through approximately 90Â°), and B. medial aspect. (Reprinted with permission from
Hollinshead WH. The ear. In: Hollinshead WH, ed. *Anatomy for Surgeons.* 3rd ed. Philadelphia: Harper & Row; 1982:159â€“122.

The incudomallear and incudostapedial joints are synovial (diarthroidal) (see below). In addition to their ligaments, the stapes and manubrium of the malleus have muscles attached to them. The stapedius muscle diminishes the excursion of the base of the stapes by its reflex contraction. Important functions ascribed to the stapedius muscle are to protect the inner ear from excessive sound and to improve discrimination for higher frequencies in speech. The stapedius muscle is innervated by a branch of the facial nerve.

Figure 14.13 Intact resected stapes, showing (from *left* to *right*) its head, two crura, and footplate.

The tensor tympani muscle draws the manubrium medially, thereby tightening the tympanic membrane. The tensor tympani muscle is felt to primarily protect against excessive noise but also functions, in conjunction with the tensor veli palitini muscle, to respond to swallowing and electric stimulation from the tongue. The action of these two muscles pumps air from the tympanic cavity into the auditory tube, forcing air into the nasopharynx and helping to open the isthmus (10). The tensor tympani muscle is innervated by a branch of the mandibular nerve.

Auditory (Eustachian or Pharyngotympanic) Tube

The auditory tube extends from its tympanic ostium high on the anterior wall of the tympanic cavity to a nasopharyngeal ostium situated posterior to the inferior nasal concha (1). The tube is not straight but slightly S-shaped. In the adult, the tympanic ostium is approximately 2 to 2.5 cm higher than is the nasopharyngeal end; the tube runs downward, medially, and anteriorly to the

nasopharynx. The length of the tube in adults varies from 31 to 38 mm (11). In infants, the tube is shorter, relatively wider, and more horizontal in its courseâ€”and, therefore, an easier pathway for infections ascending from the nasopharynx to the tympanic cavity.

The tube can be divided into an osseous portion and cartilaginous portion. The osseous portion or canal has a bony wall and is the lateral, or tympanic, third of the tube. The anteromedial two-thirds has a cartilaginous and connective tissue wall and is referred to as the cartilaginous portion of

the tube. The cartilaginous and osseous tubes meet at an obtuse angle.

Histology

Tympanic Cavity Proper

Histologically, the epithelial lining of the tympanic cavity is a single layer of respiratory epithelium of flattened to cuboidal epithelium (Figure 14.14). Under normal conditions, there are no glandular elements within the middle ear; the presence of glandular epithelium in the middle ear is abnormal (see below under Selective Abnormalities). Further, stratified squamous epithelium is not present in the tympanic cavity under normal conditions nor does squamous metaplasia occur in the middle ear (5). Ciliated pseudostratified columnar epithelium may be found in limited patches among the flattened or cuboidal epithelium.

Auditory Tube

The lining of the auditory tube is a low ciliated epithelium for much of its length except as it approaches its nasopharyngeal end, where it becomes ciliated pseudostratified columnar epithelium containing goblet cells. In its cartilaginous portion, it also contains

seromucinous glands (Figure 14.15). The auditory tubes contain a lymphoid component, particularly in children, that is referred to as Gerlach's tubal tonsil (Figure 14.16). Reactive hyperplasia of this lymphoid component, particularly in children, may close off the auditory tube, providing a desirable milieu for otitis media. The mucosa of the osseous portion of the auditory tube is separated from the carotid canal by a thin plate of bone measuring 1 mm in thickness (5). Dehiscence of the carotid canal is fairly frequent (12). Squamous carcinoma of the middle ear or auditory tube, a rare occurrence, may easily penetrate this area and gain access to the carotid artery, with the potential for widespread dissemination (13). The cartilage of the nasopharyngeal portion of the auditory tube is hyalin type.

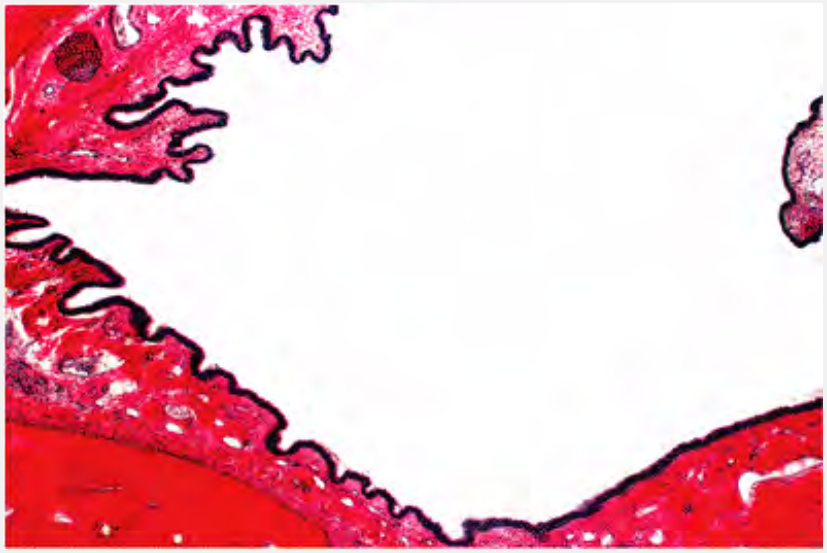

Figure 14.14 The epithelial lining of the tympanic cavity is a single layer of epithelium (cuboidal to respiratory). Under normal conditions, glands are not identified within the tympanic cavity.

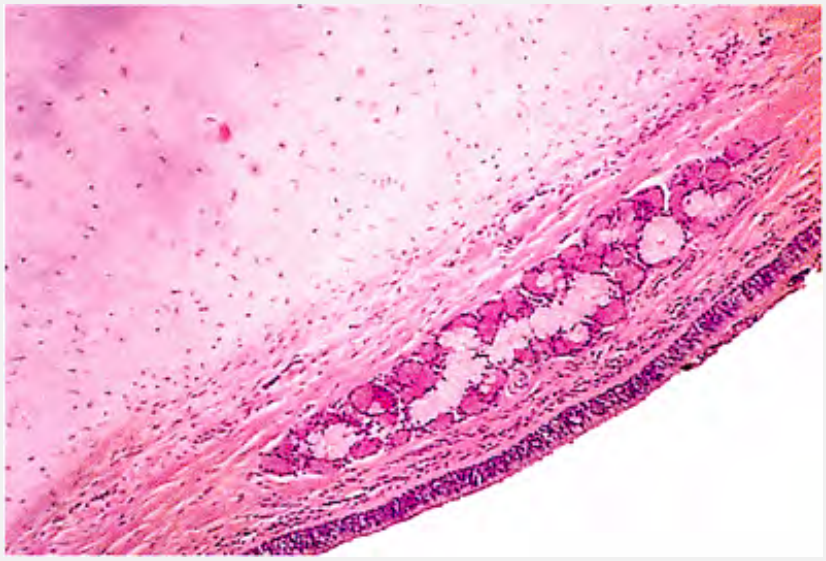

Figure 14.15 Cartilaginous portion of auditory tube with seromucinous glands.

Mastoid Air Cells

The mastoid air cells represent a network of intercommunicating spaces that emanate from the tympanic cavity (5). Each air cell is lined by flattened to cuboidal epithelium, which rests on periosteum that covers a thin frame of lamellar bone (Figure 14.17).

Pneumatization of the Temporal Bone

In the newborn, the rudimentary mastoid bone contains a single air space, the antrum, surrounded by diploic bone

containing hematopoietic elements (14). As the mastoid process develops, the marrow spaces hollows out. The mesenchymal component occupying the space is resorbed and the developing air-containing cells become lined by the advancing endodermal epithelium. The mastoid process is constantly pneumatized in adults,

although not in the infant. The cells grow out from the antrum, as well as from each other, forming complex interlocking chains of thin-walled cavities opening into each other. The antrum apparently always has air cells; the mastoid process is usually one of several types, including pneumatized (containing air cells), diploic (containing marrow), mixed (containing air cells and marrow), or sclerotic. Approximately 80% of mastoid are well pneumatized by the age of 3 or 4 years; but, in approximately 20% of people, normal pneumatization fails to occur (1,15).

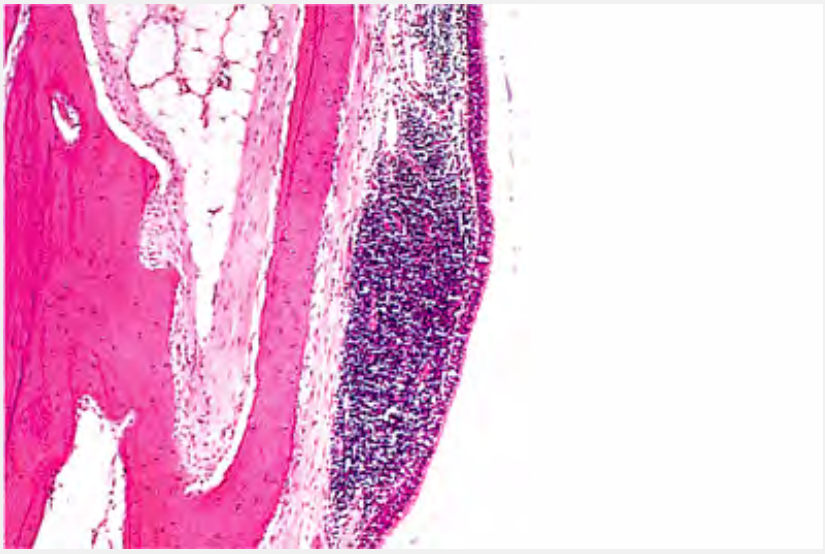

Figure 14.16 Mucosa of auditory tube. The lining is of ciliated columnar epithelium. In the lamina propria beneath, there are numerous lymphocytes that are probably the result of inflammation.

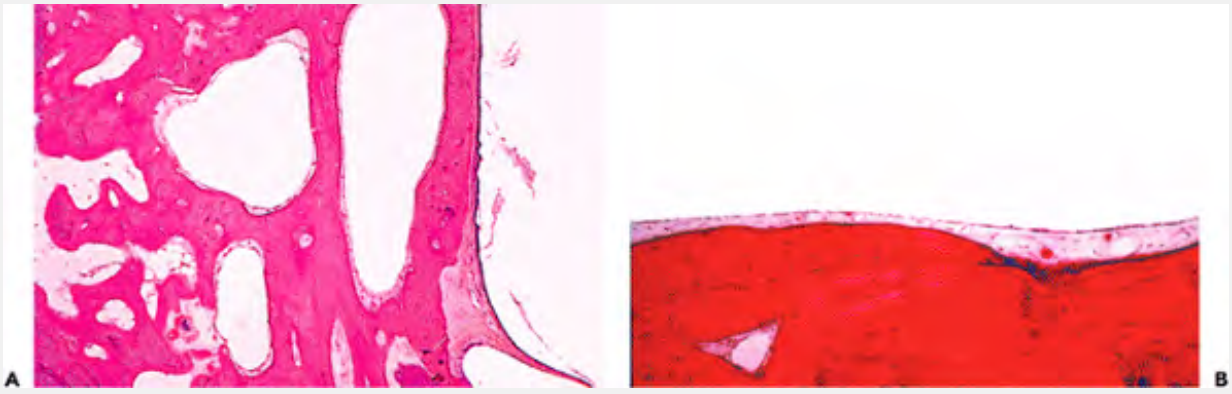

Figure 14.17 A. Mastoid air cells (*center*), tympanic membrane (*lower right*), and squamous epithelium of the osseous portion of the external canal (*right*). Note the thin covering of skin over the external ear canal and the proximity of bone to it. B. Higher magnification shows the very thin epithelial layer of the mastoid air cells resting on perisoteum covering lamellar bone.

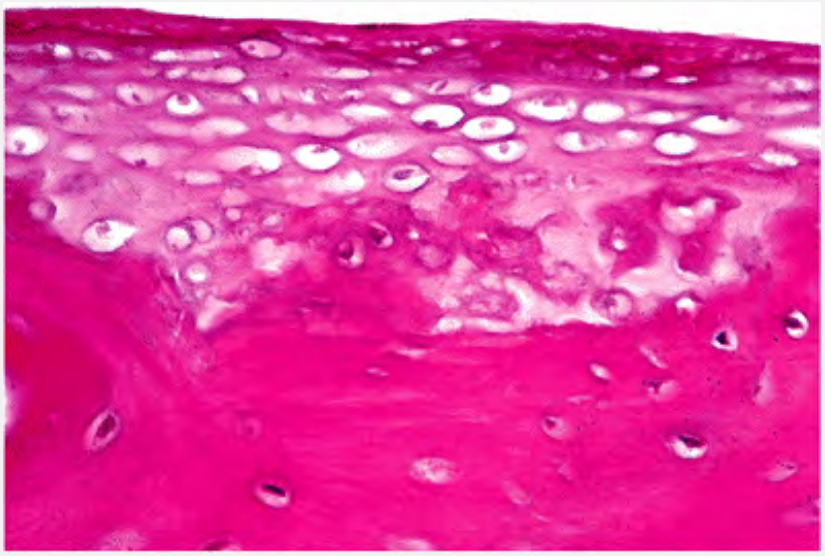

Figure 14.18 Stapes footplate showing persistence of cartilage.

Middle Ear Ossicles

The middle ear ossicles develop from cartilage with a single center of ossification for bone; there is no epiphyseal ossification. The persistence of cartilage in each of the ossicles (Figure 14.18) and the bifurcation of the stapes to form the crura with the obturator foramen between them distinguishes the middle ear ossicles from other long bones (5).

The head of the stapes is formed of endochondral bone with a cartilaginous cap at the incudostapedial joint. The crura of the stapes are formed of periosteal bone only. From the middle ear aspect of the stapes footplate to its vestibular surface, the histologic findings include the flattened to cuboidal epithelium of the tympanic cavity, a thin layer of bone, cartilage, and a single flattened (perilymphatic) epithelial cell layer (Figure 14.19).

Figure 14.19 Stapes footplate. Beneath the cubical epithelium of the middle ear (*above*), there is a thin layer of bone. Below this,

the footplate consists of cartilage, and there is a basal flattened layer of cells comprising the lining of the vestibule.

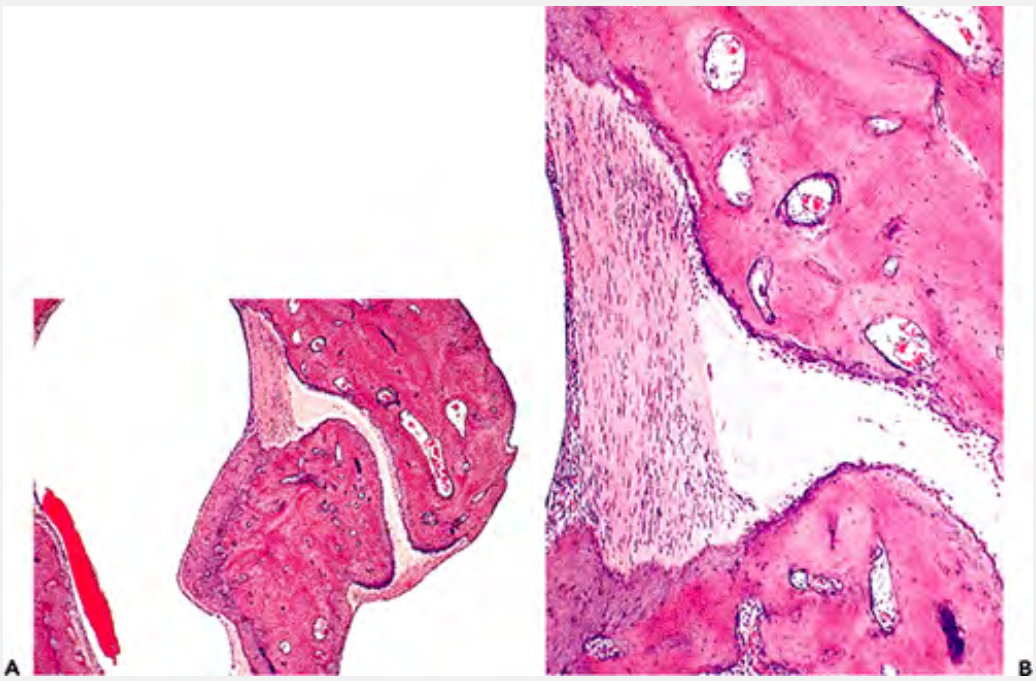

Figure 14.20 A. Incudomalleal joint. Note the joint capsule at each end of the joint. The joint space is occupied by the fibrocartilage of the articular disk. B. Higher power view of the incudomalleal joint; note one end of joint capsule and articular disk.

The malleus and incus have an outer covering of periosteal bone layer and an inner core of endochondral bone with well-formed haversian systems. The manubrium (handle) of the malleus is predominantly covered by retained cartilage rather than periosteal bone. The entire inner core of the manubrium, as well as the rest of the malleus, is composed of endochondral bone. The anterior process

is formed in membrane early in fetal life and merges with the malleus after its formation (5). At its superior aspect, the manubrium is separated from the tympanic membrane by a ligament covered by the middle ear epithelium. The short process of the incus shows a tip of unossified cartilage.

Middle Ear Joints

Both the incudomalleal and incudostapedial joints are diarthrodial. Middle ear epithelium is present on the outer surface of the joint capsule, and synovial membrane is present on its inner surface. The joint capsule is comprised of fibrous tissue with a high elastic fiber content (5). The articular disk, representing the space in between the articular ends, is comprised predominantly of fibrocartilage (Figure 14.20). The articular processes of both the malleus and the incus are covered by cartilage.

The annular ligment binds the cartilaginous edge of the stapes footplate to the cartilaginous rim of the vestibular window (stapediovestibular joint) (Figure 14.21) and is composed of fibrous tissue, with elastic fibers being prominent near the ligament surfaces (16). Cartilage also covers the articular surfaces of the stapediovestibular joints.

The fissula ante fenestrum is the canal linking the middle ear with the vestibule. It lies in the bone just anterior to the stapediovestibular joint and develops as a slit filled with fibrous tissue that is often with associated cartilage (Figure 14.22).

Middle Ear Muscles

The muscles of the middle ear, including the tensor tympani and stapedius muscles, are composed of a central tendon formed by elastic tissue with muscle fibers radiating from it (Figure 14.23). This configuration has been described as feather-shaped. The tensor tympani muscle has a prominent mature adipose tissue component

(Figure 14.24) that is believed to function as insulation for the cochlea against electric effects from its contraction (5).

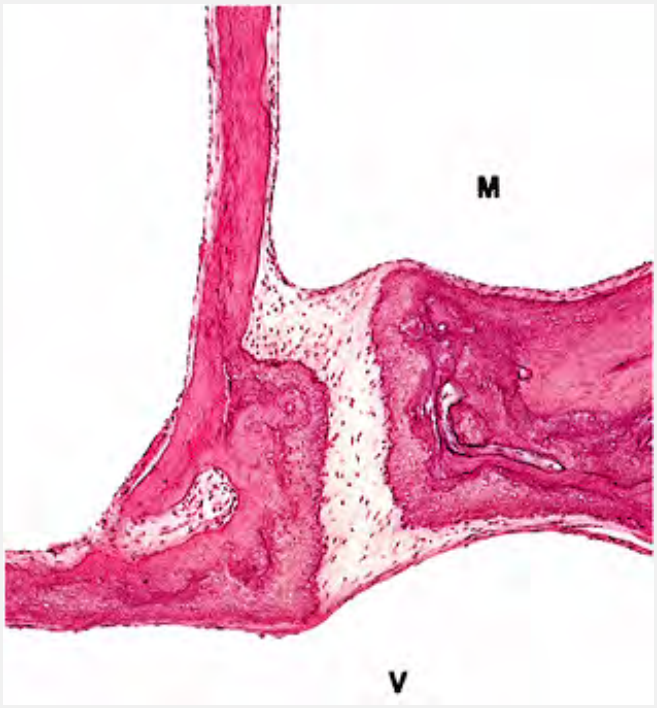

Figure 14.21 Stapediovestibular joint, part of footplate of stapes, adjacent bony labyrinthine wall, and crus of stapes. The footplate shows a lamina of cartilage on its vestibular surface, which is continuous with the cartilage of the stapediovestibular joint. (*M,* middle ear cavity; *V,* cavity of vestibule)

Inner Ear

Embryology

The first division of the ear to develop is the inner ear, which appears toward the end of the first month of gestation (2,17). The

membranous labyrinth, including the utricle, saccule, semicircular ducts, cochlear duct, and endolymphatic sac, arises from the placodal thickening of the ectoderm to become a closed otic vesicle (otocyst). The otic vesicle forms from the invagination of the surface ectoderm, located on either side of the neural plate, into the mesenchyme. This invagination eventually loses its connection with the surface ectoderm. The membranous labyrinth, which is essentially tubular and saccular is filled with fluid, the endolymph or endolymphatic fluid. The early development of the membranous labyrinth takes place in mesenchyme and subsequently in the cartilage destined to form the petrous portion of the temporal bone (1). The membranous labyrinth lies in cavities excavated from

this mesenchyme or cartilage. The space lying between the inner surface of the bony wall and the outer surface of the membranous labyrinth is the perilymphatic space. The perilymphatic space develops around the membranous labyrinth by fusion of mesenchymal spaces to form larger ones surrounding the membranous portion. The bony labyrinth, including the vestibule, semicircular canals and cochlea arises from the mesenchyme around the otic vesicle (2,17,18).

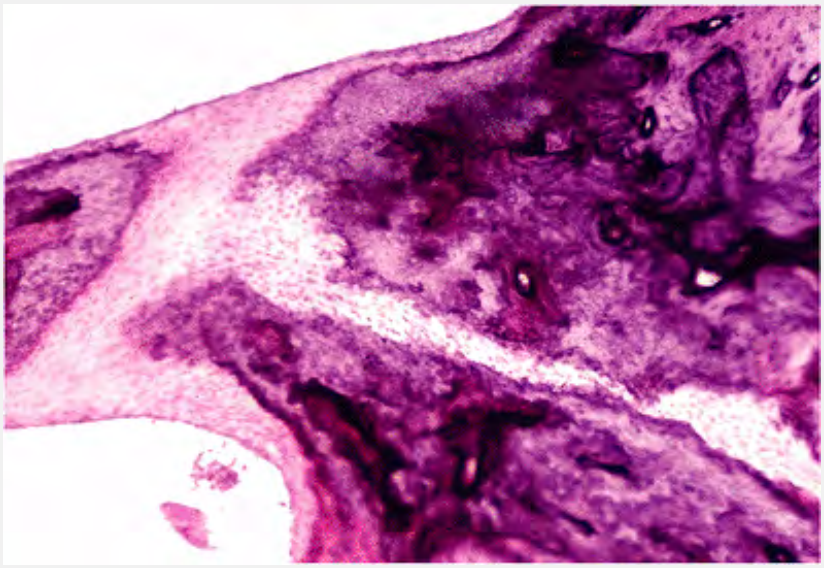

Figure 14.22 Fissula ante fenestrum is the canal within bone that links the middle ear with the vestibule and develops as a slit filled with fibrous tissue.

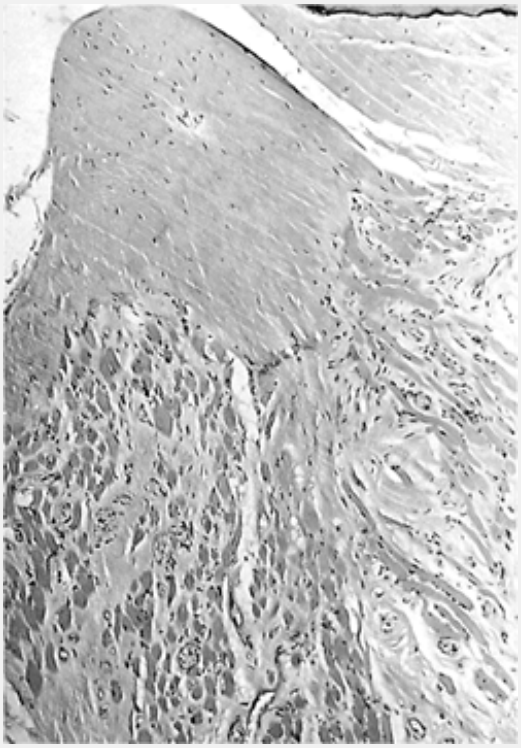

Figure 14.23 Stapedius muscle and tendon. The skeletal muscle fibers and fibrous bands between them radiate to a tendon.

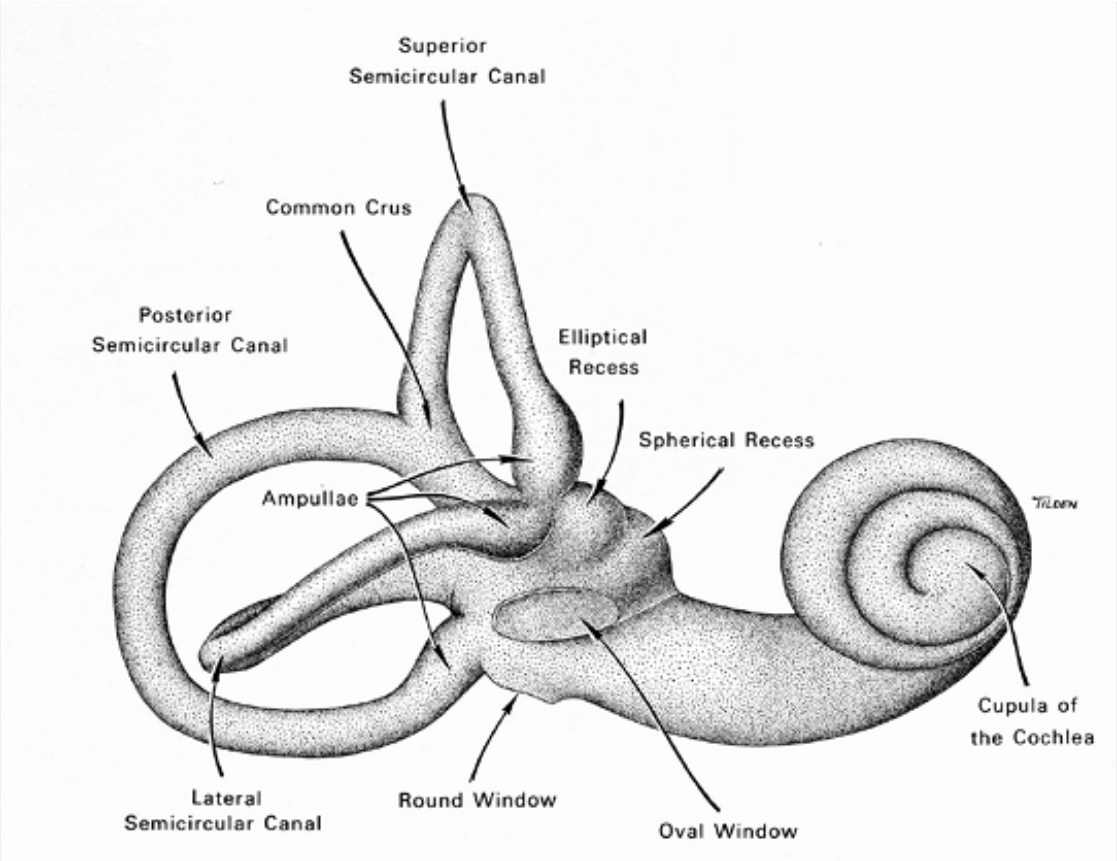

Figure 14.25 Schematic depicting the osseous labyrinth.

Anatomy

The internal (inner) ear, or labyrinth, is embedded within the petrous portion of the temporal bone and comprises the medial portion of the temporal bone adjacent to the cranial cavity. The inner ear contains the membranous labyrinth, which is surrounded by an osseous layer or bony shell termed the osseous (bony) labyrinth (Figure 14.25). The membranous labyrinth contains the cochlea, which is the organ of hearing, and the vestibular system, which is the system of balance (equilibrium).

Osseous Labyrinth (Otic Capsule)

The osseous labyrinth consists of the vestibule and cochlear capsule. The central portion of the osseous labyrinth cavity is the vestibule, a large ovoid perilymphatic space approximately 4 mm in diameter and containing both the saccule and utricle of the membranous labyrinth. In the floor of the bony vestibule are seen the elliptical recess for the anterior end of the utricle and, anterior and lateral to this, the spherical recess for the saccule. In the lateral wall of the vestibule is the oval window, in which the base of the stapes is situated. Through the stapes, the perilymph of the vestibule receives vibrations from the tympanic membrane and ossicular chain (set up by sound waves reaching the tympanic cavity). Along the medial wall and floor of the vestibule, where it abuts the lateral end of the internal acoustic meatus, are small openings for the entrance of the nerve branches to the vestibular portion of the ear (1).

The bony cochlea, a part of the otic capsule, is a hollowed spiral about two- to three-fourths turns, diminishing from a relatively broad base to a pointed cupula, or apex. It is so named because of its resemblance to a snail shell. The base of the cochlea lies against the anteromedial surface of the vestibule and next to the anterior surface of the lateral (blind) end of the internal auditory canal. A central core of bone called the modiolus runs forward from the cochlea but does not reach the cupula. It is around this central core that the spiral channels of the cochlea (perilymphatic and endolymphatic) are arranged. A layer of bone arranged in a spiral fashion unites the modiolus to the peripheral wall of the bony cochlea and separates successive spiral cavities from each other (1). The modiolus is hollow to accommodate

the cochlear nerve. The base of the modiolus lies against the lateral end of the internal auditory canal, to which the cochlear nerve runs.

The vestibular aqueduct extends through the otic capsule from the vestibule to the posterior cranial fossa, transmitting the

endolymphatic duct. The terminal end of the vestibular aqueduct is the endolymphatic sac, a dilated area that ends blindly outside the dura (1). The cochlear duct opens at one end into the lower end of the scala tympani and at the other end into the subarachnoid cavity (1). The issue as to whether the cochlear duct represents an open channel between the subarachnoid space and the perilymphatic space at the lower end of the scala tympani remains controversial (1). A possible role ascribed to the cochlear duct is to serve as part of the pressure-adjusting mechanism of the perilymph in conjunction with the round window (19,20,21).

Membranous Labyrinth

The membranous (otic) labyrinth is the spiral-appearing structure that resembles the shell of a snail. The principle components of the membranous labyrinth are the cochlear duct, utricle, saccule, ductus reuniens, semicircular canals with their ampullae, and the endolymphatic sac and duct.

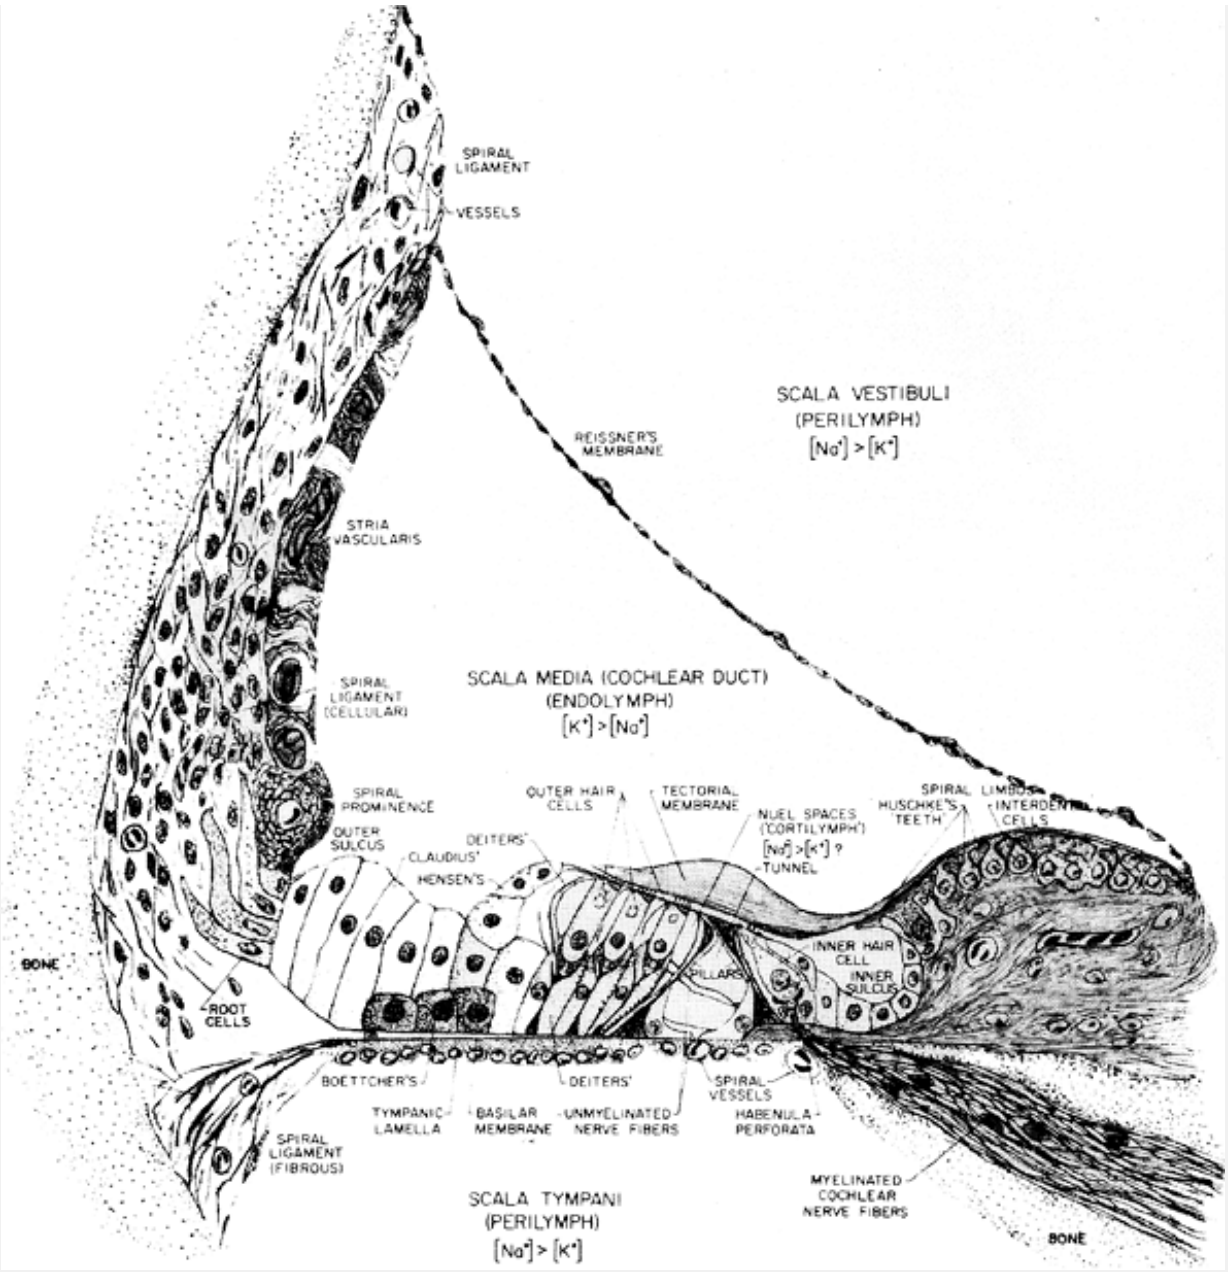

Figure 14.26 Schematic illustration of the membranous labyrinth, containing the cochlea (organ of hearing) and the vestibular (system of balance) systems. The relationship between the endolymph, containing scala media (cochlear duct), and the perilymph, containing scala vestibuli and scala tympani, is shown. (Reprinted with permission from:
Nager GT. Anatomy of the membranous cochlea and vestibular

labyrinth. In: Nager GT, ed. *Pathology of the Ear and Temporal Bone*. Baltimore: Williams & Wilkins; 1993:3â€“48.
)

Cochlear Duct

The membranous cochlea, or cochlear duct, is a cone-shaped spirally oriented membranous tube between the osseous spiral lamina and the outer osseous wall of the cochlea, to which it is attached (7). The cochlear duct, also referred to as the scala media, lies between the scala vestibuli and the scala tympani (Figure 14.26). These three compartments are fluid-filled. The cochlear duct, as well as the entire membranous labyrinth, contains endolymph. The scala vestibuli and the scala tympani contain perilymph. The cerebrospinal fluid communicates directly with the perilymphatic space through the cochlear aqueduct (perilymphatic duct) (Figure 14.27).

The cochlear duct contains the sensory end organ of hearing known as the spiral organ of Corti. The organ of Corti rests on the basilar membrane, which separates the

cochlear duct from the scala tympani (Figure 14.26). Together, the organ of Corti and the basilar membrane form the spiral membrane that is the floor or tympanic wall of the cochlear duct. The spiral ligament is a thickened, modified portion of periosteum of the bony cochlea, forming the outer curved wall of the cochlea duct and adjacent parts of the scalae. The scala tympani lies below the basilar membrane, while the scala vestibuli lies above the cochlear duct and is separated from it by Reissner's membrane. Reissner's membrane forms the roof of the cochlear duct. The scala tympani and scala vestibuli communicate with each other only at the apex, known as the helicotrema. The scala vestibuli winds toward the apex of the cochlea at the helicotrema, becoming the scala tympaniâ€”which, in turn, coils back toward the round window (Figure 14.28). The scala

vestibuli and the scala tympani communicate with the middle ear via the oval window and round window, respectively. The scala tympani ends blindly at the round window membrane, but the scala vestibuli opens up at that level into the perilymphatic space of the vestibulum. The cochlear duct connects with the vestibular system via ductus reuniens located at the saccule. In this way, the three semicircular canals that comprise the vestibular system are filled with endolymph.

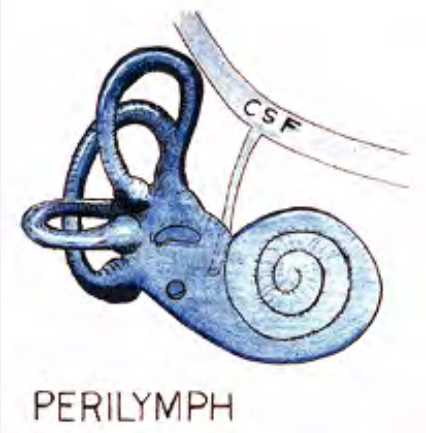

Figure 14.27 Schematic depicting the direct communication between the perilymphatic space and cerebrospinal fluid (*CSF*) through the cochlear aqueduct (perilymphatic duct).

Utricle

The utricle is an elongated to oval-shaped portion of the membranous labyrinth, lying superior to the saccule in the medial wall of the vestibule (Figure 14.29). It is larger in diameter than the semicircular ducts and receives both ends of each semicircular duct (for a total of five, since the anterior and posterior ducts share a common opening). The macule of the utricle, located on the inferior surface of the utricle (utricular recess), is a sensory end organ. The utriculosaccular duct usually arises from the utricle; it communicates

with the endolymphatic duct and connects the utricle to the saccule. As previously indicated, the three semicircular canals communicate with the utricle via openings formed by the union of the nondilated or nonampullary ends of the superior and posterior canals, termed the commun crus.

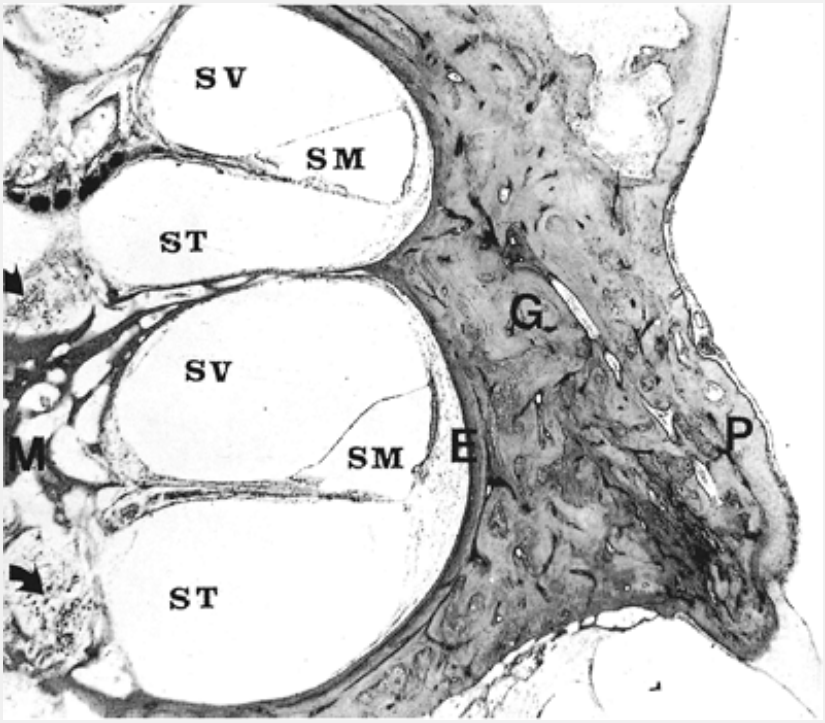

Figure 14.28 Cochlea, bony cochlea, and modiolus. (*Arrows,* spiral ganglion cells of basal and middle coils in modiolus; *E,* endosteal layer of bone; *G,* endochondral layer containing globuli interossei; *M,* modiolus; *P,* periosteal layer; *SM,* scala media; *ST,* scala tympani; *SV,* scala vestibuli)

Saccule

The saccule is located anteromedial to the upper (anterior) end of the utricle (Figure 14.29) and tends to be more round than the

utricle. The saccule and utricle are continuous via the utriculosaccular duct and with the cochlear duct by the ductus reuniens (also referred to as the canalis reuniens of Hensen) (1). The macule of the saccule contains

the sensory nerve endings of this portion of the inner ear and is an oval thickening on the lateral wall.

Figure 14.29 Ventricle of cat showing utricle (*U*) and saccule (*Sa*). (*St,* stapes)

Semicircular Canals

The semicircular ducts include the anterior or superior duct, the posterior duct, and the lateral ducts. The end of each semicircular duct is expanded to form the ampulla. The anterior duct is directed anterolaterally, the posterior duct is directed posterolaterally, and the lateral ducts form a laterally directed angle of approximately 90Â° between themselves. The osseous canals follow a similar direction. The three semicircular canals communicate with the utricle

via openings formed by the union of the nondilated or nonampullary ends of the superior and posterior canals (the common crus). From the common crus, the anterior duct curves upward, while the posterior duct curves backward and then downward. The other (membranous) ampullary ends of the semicircular canals contain the sensory endings of the ducts. At the ampullary ends, the anterior and posterior ducts empty into the utricle. The lateral semicircular duct lies in an approximate horizontal plane; both of its ends also connect to the utricle, with the anterior end being the ampulla.

Endolymphatic Duct and Sac

The endolymphatic duct traverses the medial portion of the petrous pyramid in its own bony canal, the vestibular aqueduct (7). The endolymphatic duct can be divided into segments. The first segment is the dilated portion referred to as the sinus, representing the common channel into which the utricular and saccular ducts open. The next segment of the duct is narrow and referred to as the isthmus. After the isthmus, the duct widens again to become the endolymphatic sac. The majority of the endolymphatic sac is located within the funnel-shaped cranial aperture of the cochlear duct, lying within a duplication of the posterior fossa dura and partially covered medially by a thin bony shelf referred to as the operculum. The endolymphatic sac ends in a terminal dilatation or fovea of the sac. Two portions of the endolymphatic sac are recognized: a proximal rugose portion with an irregular lumen caused by numerous folds of the epithelial lining and a distal portion with a smooth epithelial lining.

The membranous vestibular system contains the receptor organs for sense of motion and position. The neural structures of the inner ear, including the vestibulocochlear nerve and the facial nerve, enter the inner ear through the internal auditory canal.

Inner Ear Innervation

The nerve to the inner ear is cranial nerve VIII, variably referred to as the acoustic, auditory, or vestibulocochlear nerve. This nerve functionally consists of vestibular and cochlear divisions. In the internal auditory canal, these two parts are closely associated; but, at the lateral end of the canal, the nerve trunk divides into three parts, including two vestibular and one cochlear.

The vestibular nerve arises from the bipolar cells of the superior and inferior division of the (afferent) vestibular, or Scarpa's, ganglion located at the lateral end of the internal auditory canal. Peripherally, the vestibular nerve divides into two main divisions, the superior and inferior divisions. The superior part of the ganglion gives nerves to the ampullae of the lateral and anterior (superior) canals and to the saccular and utricle maculae. The inferior part of the ganglion gives rise to a posterior ampullary nerve and a nerve to the saccule. The inferior part also gives rise to a branch to the cochlear division.

The cells of origin for the cochlear nerve form the spiral ganglion, which represents the first of four neurons between the auditory end organ and the auditory cortex. The spiral ganglion is located in coils of the modiolus at the base of attachment of the osseous spiral lamina (see Figure 14.28). The osseous spiral lamina is a thin trabecula of bone surrounding afferent nerve fibers that run from the organ of Corti through the habenula perforata to the acoustic nerve and efferent fibers to the outer hair cells that arise from the olivocochlear system of Rasmussen. The efferent fibers make their exit from the brain with the vestibular part of the nerve and join the cochlear branch of cranial nerve VIII via the vestibulocochlear communicating branch, or nerve of Oort through the modiolus (1). Prior to reaching the modiolus, the nerve fibers are unmyelinated but are myelinated upon reaching the cochlear modiolus. The central fibers, or axons, of these bipolar neurons unite to form nerve bundles and pass from the cochlear modiolus through nerve channels in the osseous spiral foraminous tract into the internal auditory canal, where they form the cochlear nerve.

Within the internal auditory canal, the vestibulocochlear nerve is usually connected to the facial nerve. Together, the three nerves enter the posterior cranial fossa, transverse the cerebellopontine angle, and enter the brainstem at the posterior lower lateral aspect of the pons. The central auditory pathways consist of three additional neurons that form numerous connections with nuclei throughout the central nervous system as part of a complex auditory reflex system reaching the auditory cortex in the anterior transverse gyrus of the superior temporal lobe (7,8).

The facial nerve enters the temporal bone through the internal auditory meatus within the petrous portion of the temporal bone in company with (lying above) the vestibulocochlear nerve and the internal auditory artery. The facial nerve then passes Bill's bar, which represents a pointed bony projection separating the facial nerve from the superior division of the vestibular nerve. At the outer end of the canal, the facial nerve pierces arachnoid and dura to enter its own bony canal, the facial canal (fallopian

canal, or aqueduct of Fallopius). This canal continues for a short distance, and the facial nerve comes to lie just above the cochlea, where it bears the geniculate ganglion. The greater petrosal nerve comes off the geniculate ganglion and passes anteriorly and medially to enter the middle cranial fossa. Immediately beyond the geniculate ganglion, the facial nerve turns sharply (external genu; geniculum) laterally and posteriorly. As it runs backward in the bone of the lateral wall of the vestibule (which is the medial wall of the tympanic cavity), the facial nerve inclines downward and laterally where the bone surrounding it forms a bulge or projection, referred to as the prominence of the facial canal. This bulge or prominence is a normal finding, and it may be large enough to cover the oval window and base of the stapes. The facial nerve then makes a broad curve downward to run almost vertically through the mastoid process to the stylomastoid foramen, where the facial canal ends and the nerve exits from the skull.

Shortly before leaving the stylomastoid foramen, the facial nerve gives off the chorda tympani, which is composed of sensory and preganglionic motor fibers. Slightly above the stylomastoid foramen, the chorda tympani leaves the facial trunk and takes a recurrent course upward and forward in its canaliculus (â€œiter chordae posteriusâ€•) to enter the tympanic cavity through its posterior wall. Within the tympanic cavity, it passes between the malleus and incus and leaves the tympanic membrane through a canal in the pterygotympanic fissure (â€œiter chordae anteriusâ€•), where it joins the lingual nerve to be distributed to the anterior two-thirds of the tongue (taste buds) and to the submandibular ganglion, through which postganglionic fibers reach the submandibular and sublingual salivary glands.

Histology

Osseous Labyrinth

The cavity of osseous labyrinth (otic capsule) surrounds and replicates the outline of the membranous labyrinth lying within it. The osseous labyrinth is extremely dense and includes three layers: an outer periosteal layer; a middle layer in which there is persistence of much of the calcified cartilaginous matrix referred to as globuli interossei or globuli ossei (Figure 14.30); and an inner layer abutting the membranous labyrinth and lined by a thin layer of internal periosteum (also referred to as endosteum) (5). The density of the osseous labyrinth is necessary to insulate and safeguard the delicate vibrations of the fluids contained within it and is necessary in maintaining the integrity and functions of hearing and balance (5). As noted by Michaels (5) the bone of the adult osseous labyrinth is neither lamellar nor woven bone but â€œsomewhere in betweenâ€•; in contrast to other adult bone, the osseous labyrinth lacks the normal developmental process of removal and replacement of calcified cartilaginous matrix and of primitive bone (5).

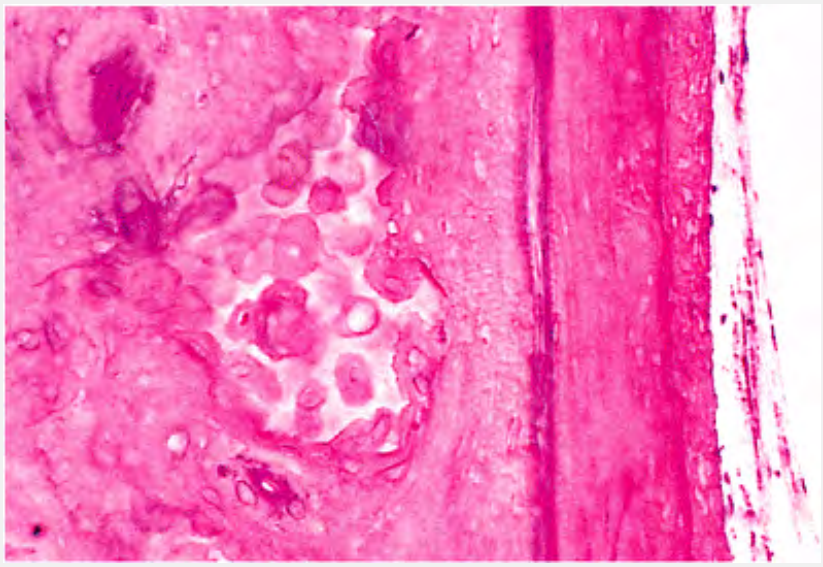

Figure 14.30 Globuli ossei (*left*) and endosteum (*right*) of cochlea.

Membranous Labyrinth

The membranous labyrinth consists of epithelium-lined channels surrounded by connective tissue. The three basic divisions of the membranous labyrinth (including the semicircular canals, the utricle and saccule, and the cochlear duct) have similar structure, consisting of a specialized thickened epithelium surrounded by and attached to a fibrogelatinous membrane. The specialized epithelium consists of supporting cells and neuroepithelium or hair cells. The neuroepithelium has processes (â€œhairsâ€•) that project from the free edge of the cells.

Cochlea

The organ of Corti consists of neurotransmitting hair cells that rest on the basilar membrane and is arranged in a spiral like the duct itself (Figure 14.31). The organ of Corti consists of supporting cells

and hair cells. The supporting, or pillar, cells are of several different types. Among the more important supporting cells are the phalangeal cells, which are arranged in two groups: an inner or single row of cells and an outer row of cells (cells of Deiters) formed from three to five rows of cells, depending on the level of the cochlea, with more rows of cells toward the apex and fewer rows of cells toward the base.

The inner row of phalangeal cells is associated with a single layer of hair cells; the outer row of phalangeal cells alternate with rows of hair cells. The phalangeal cells get their name from the shape of the stiff processes that project

from the cells contributing to the reticular membrane that covers the free surface of the organ (1). The hair cells have numerous (40 to 100 per cell) â€œhairsâ€• projecting from the reticular (cuticular) surface. The outer hair cells are more sensitive, are short and wedge-shaped between the apices of the phalangeal cells in order to reach the basilar membrane, and are believed to be responsible for the cochlear microphonics (1). The inner hair cells are long, are less susceptible to damage than the outer hair cells, and believed to be less sensitive to sound.

Figure 14.31 Scala media of cat. (*BM,* basilar membrane; *OC,* organ of Corti; *RM,* Reissner's membrane; *SL,* spiral limbus; *SP,* spiral prominence; *SV,* stria vascularis; *TM,* tectorial membrane)

Intercellular spaces among the cells of the organ of Corti are apparently filled with intercellular substance. The largest of these spaces runs the entire length of the organ of Corti between inner and outer rows of phalangeal and hair cells and is referred to as the tunnel, or canal, of Corti (Figure 14.32). The tunnel of Corti is bounded by special supporting cells, the inner and outer pillars (Corti's rods) (Figure 14.32). The tunnel and pillars together form Corti's arch.

The basilar membrane is fibrous tissue that supports the organ of Corti. The basilar membrane has the tectorial membrane attached to it. The basilar membrane has fibers that pass from the bony spiral lamina to the spiral crest of the spiral ligament. The basilar membrane increases in size from the base to the apex of the cochlea and is felt to have resonator action with deformation of the membrane by sound, beginning at its lower end and traveling toward the helicotrema. The tectorial membrane is a gelatinous structure with numerous fine fibers. Like the basilar membrane, the tectorial membrane increases in size from the base to the apex of the cochlea and is believed to have a vibratory effect on the hair cells.

Together, the organ of Corti and the basilar membrane form the spiral membrane, which is the floor or tympanic wall of the cochlear duct. The spiral ligament is a thickened, modified portion of periosteum of the osseous cochlea, which forms the outer or curved wall of the cochlear duct and adjacent parts of the scalae. The vestibular, or Reissner's, membrane is thin and consists of two layers of cells: an inner cell layer of ectodermal origin (consisting of epithelial-like clusters) and an outer layer of mesodermal origin (consisting of large, flat, and elongated cells) (5). This membrane forms the roof of the cochlear duct. In MÃ©niÃ¨re's disease (see below), the vestibular membrane bulges toward the scala vestibuli. In the outer (vertical) wall of the cochlear duct is the stria vascularis, which is supplied by 30 to 35 small arteries that originate from the modiolar region of the scala vestibuli and pass outward to the lateral wall of the osseous labyrinth (Figure 14.31) (22). It is believed to be the source of the endolymph (23). The tissue spaces of the spiral ligament serve as a site of absorption (24). The stria vascularis is altered in ototoxic conditions, as may occur secondary to use of cisplatin, diuretic agents, and other drugs (see below under Presbycusis and Other Hearing Loss) (5).

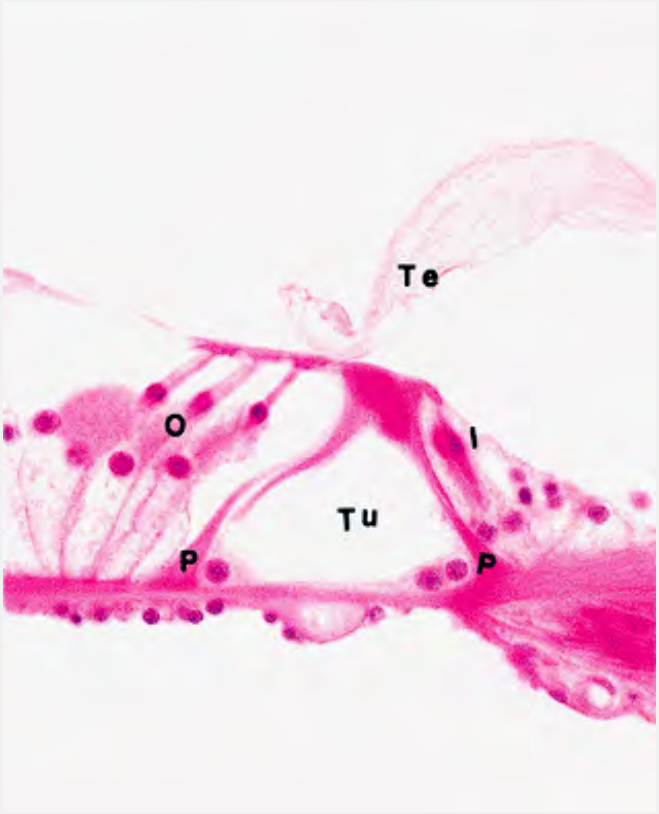

Figure 14.32 Higher power view of the organ of Corti (see Figure 14.31). (*I*, inner hair cells; *O*, outer hair cells; *P*, pillar cells (walls of tunnel); *Te*, tectorial membrane; *Tu*, tunnel of Corti)

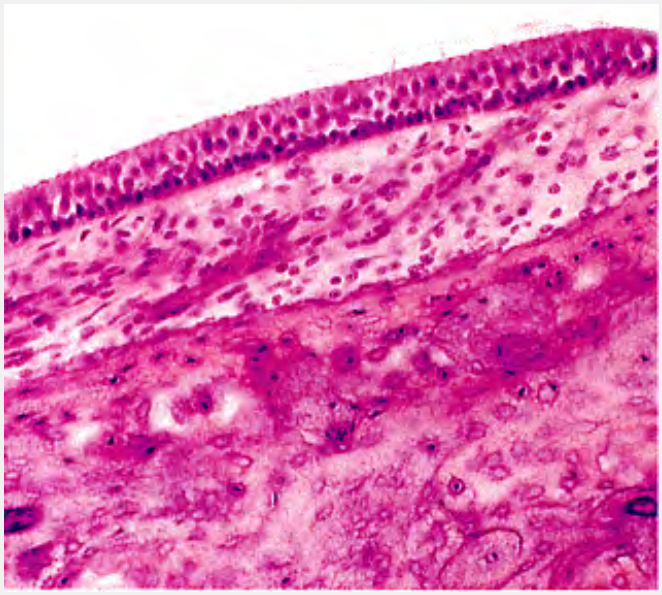

Figure 14.33 Higher power of a part of Figure 14.29, showing macula of the saccule.

Semicircular Canals, Utricle, and Saccule

The end of each semicircular duct is expanded to form an ampulla. The sensory endings in the ampullae of the ducts are the cristae. Each crista consists of thickened epithelium; above each crista rests a gelatinous formation of viscous protein polysaccharide called the cupola. The hairs of the neuroepitheial hair cells project into the base of the cupola. As a result of the gelatinous nature of the cupola, it may be bent by the pressure of the endolymph, which apparently stimulates the hair cells and, therefore, the nerve endings of the cristae.

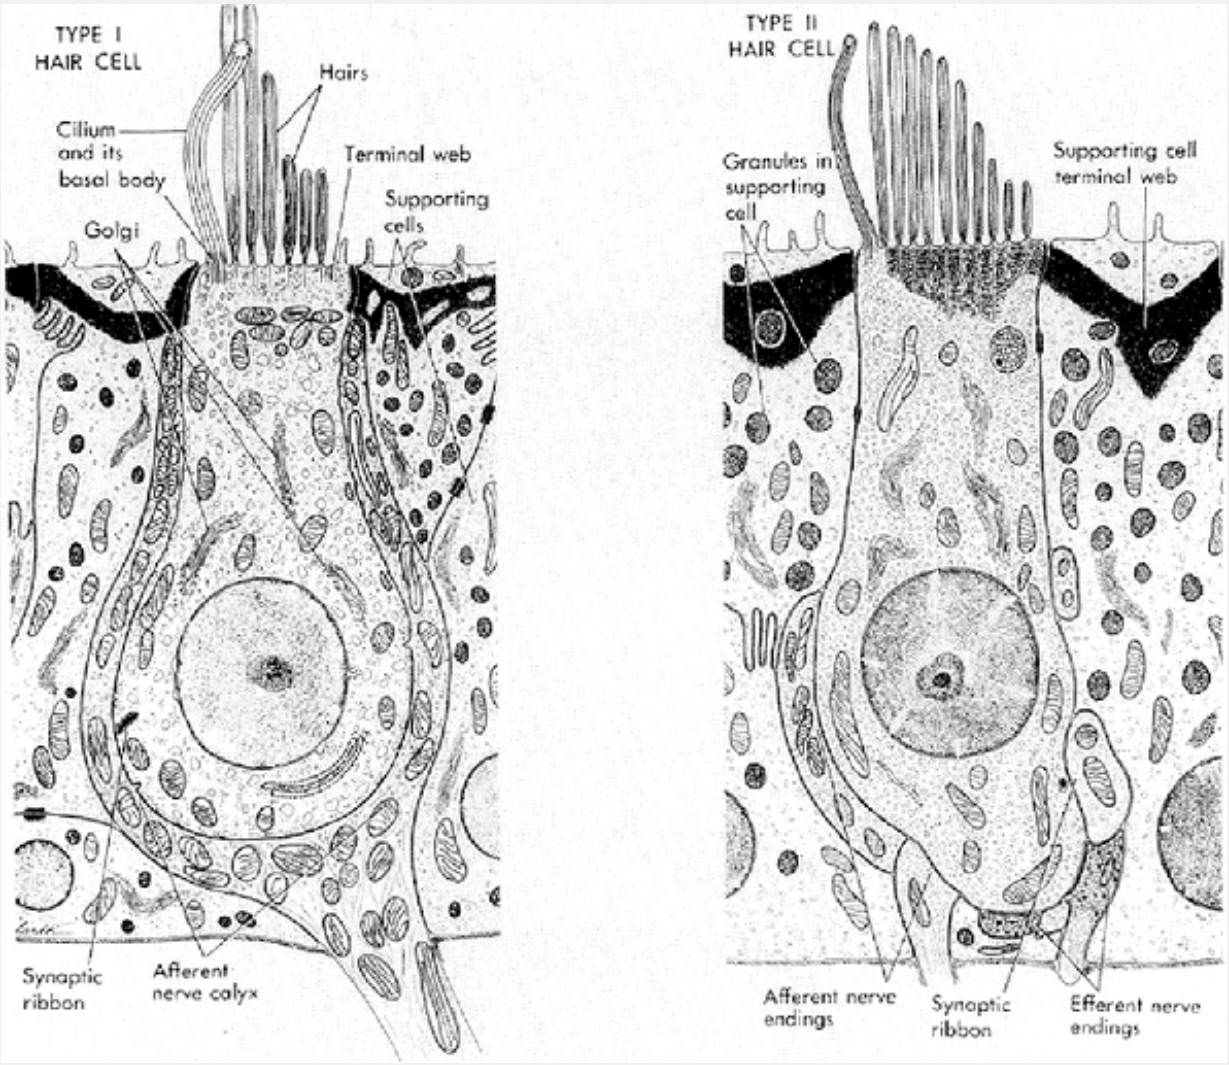

Figure 14.34 Schematic representation of the ultrastructure of vestibular hair cells showing the principal features of type I and type II hair cells and their supporting cells (Reprinted with permission from:
Nager GT. Anatomy of the membranous cochlea and vestibular labyrinth. In: Nager GT, ed. *Pathology of the Ear and Temporal Bone*. Baltimore: Williams & Wilkins; 1993:3â€“48
).

The utricle and saccule, representing the two main membranous structures of the vestibule, are lined by a sensory epithelium known as the macula (Figure 14.33). The maculae are identical to one another in structure and are similar to the cristae of the semicircular canals. By transmission electron microscopy, these sensory cells are of two types: type I cells are flask-shaped with a swollen basal portion; type II cell is cylindrical. Type I cells are attached to fibers of the sensory nerves by a wide chalicelike terminal, and the terminal of type II cells is connected by buttonlike attachments of the nerve (Figure 14.34) (5). The sensory epithelium consists of hair cells, which in turn have stiff, immotile projections embedded in the gelatinous otolithic membrane. Also embedded in the otolithic membrane are crystalline bodies, referred to as otoliths, that contain calcium carbonate and a protein suspended in a jellylike polysaccharide. It is only in the presence of otoliths that the maculae differ from the other sensory areas of the ear.

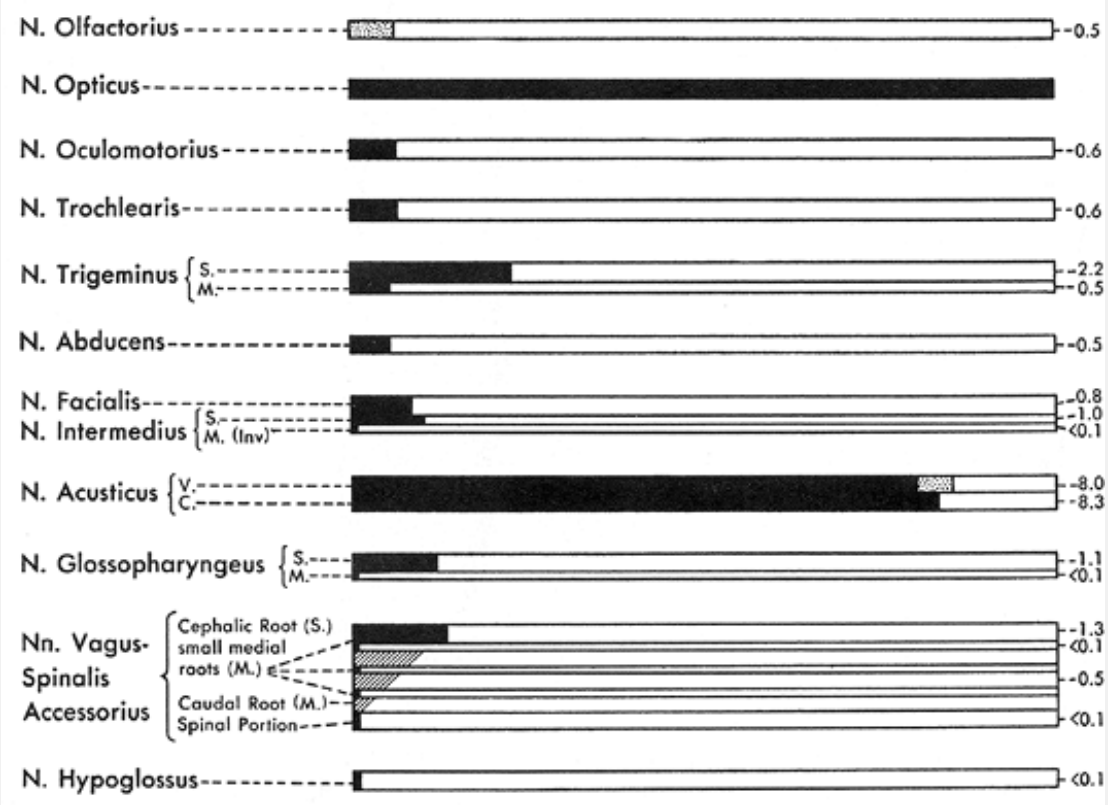

Figure 14.35 Schematic illustration of the cranial and spinal nerves showing that most of the nerves have glia extending for only a fraction of a millimeter beyond their external origins with the exceptions of the optic nerve, which is really a tract of brain (given the presence of neuroglia throughout its length), and the vestibulocochlear nerve (cranial nerve VIII). The vestibulocochlear nerve typically has glia extending from 6 to 8 mm along its course. (From:
Tarlov IM. Structure of the nerve root. II. Differentiation of sensory from motor roots: observations on identification of function in roots of mixed cranial nerves. *Arch Neurol Psychiatr* 1937;37:1338â€“1355
).

Nerves and Paraganglia

Most cranial and spinal nerves have glia extending only a fraction of a millimeter beyond their external origins (25,26). The optic nerve contains neuroglia throughout its length and, thereby, really is a tract of brain rather than a true nerve. The exception to the other cranial nerves is the eighth (vestibulocochlear) nerve, which typically has glia extending from 6 to 8 mm along its course (Figure 14.35). This distribution of glia along cranial nerve VIII helps explain the greater occurrence of glial tumors on this nerve as compared to the other cranial nerves (25). The vestibular and cochlear divisions are fused near the entrance to the internal auditory meatus; at this location, the nerve changes in appearance from pale staining proximally to dark staining distally. This change in appearance is the result of the abrupt transition of the coverings of the nerve fibers from the pale staining oligodendroglia to the darker staining Schwann cells (Figure 14.36). This glial-Schwann sheath junction of the cranial

nerve VIII is referred to as the Obersteiner-Redlich zone. Acoustic neuromas (also referred to as vestibular neuromas) may arise anywhere between this junction and the cribrosa area at the fundus of the canal (27).

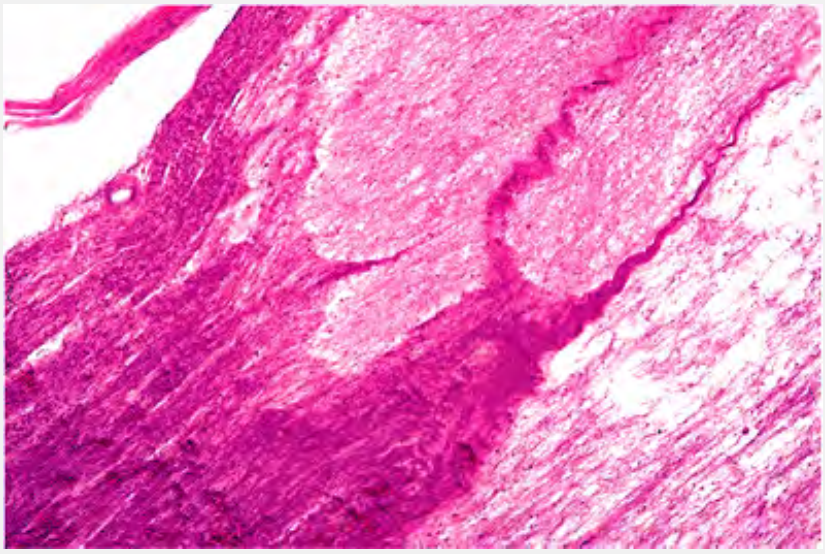

Figure 14.36 The vestibular and cochlear divisions of the vestibulocochlear nerve are fused near the entrance to the internal auditory meatus. At this location is the glial-Schwann sheath junction, also referred to as the Obersteiner-Redlich zone, where the nerve changes in appearance from pale staining proximally to dark staining distally as a result of the abrupt transition of the coverings of the nerve fibers from the pale staining oligodendroglia to the darker staining Schwann cells.

Paraganglia similar in structure to the carotid body are identified in the ear and may give rise to jugulotympanic paragangliomas. The majority of paraganglia are found in relation to the jugular bulb, and a minority are found under the mucosa of the medial side of the middle ear promontory (Figure 14.37).

Endolymphatic Sac and Duct

The lining epithelium of the endolymphatic duct is low cuboidal (Figure 14.38), and the epithelium of the endolymphatic sac is taller and has a papillary appearance (Figure 14.39). An aggressive neoplasm, termed the endolymphatic sac papillary tumor, is presumed to originate from the endolymphatic sac epithelium (28). This tumor, initially considered to represent a low-grade malignancy (i.e., adenocarcinoma), is potentially a locally destructive but not metastatic tumor characterized by variably appearing epithelium, including nondescript low-cuboidal to

papillary and glandular appearing neoplasm (28,29). Patients with this tumor often describe symptoms similar to those occurring in MÃ©niÃ¨re's disease, including vertigo and spinning of the room. This tumor has been found to be associated with von Hippel-Lindau (VHL) syndrome, including the identification of the VHL gene (30,31).

Figure 14.37 Normal tympanic paraganglion (arrow) under mucosa of medial side of middle ear over promontory. The tympanic membrane is on the right (Gomori's reticulin stain).

Composition and Circulation of the Perilymph and Endolymph

Perilymph, which is partly a filtration of cerebrospinal fluid (CSF) and partly a filtration from blood vessels of the ear, has a similar chemical composition as CSF, resembling extracellular fluid with low potassium and high sodium concentrations. The similarities of perilymph and CSF support the concept that perilymph is derived from CSF. The anatomic basis for this concept is based on the consideration that the cochlear aqueduct (perilymphatic duct) opens into both the subarachnoid and perilymphatic spaces (1). An increase in CSF pressure results in flow into the labyrinth.

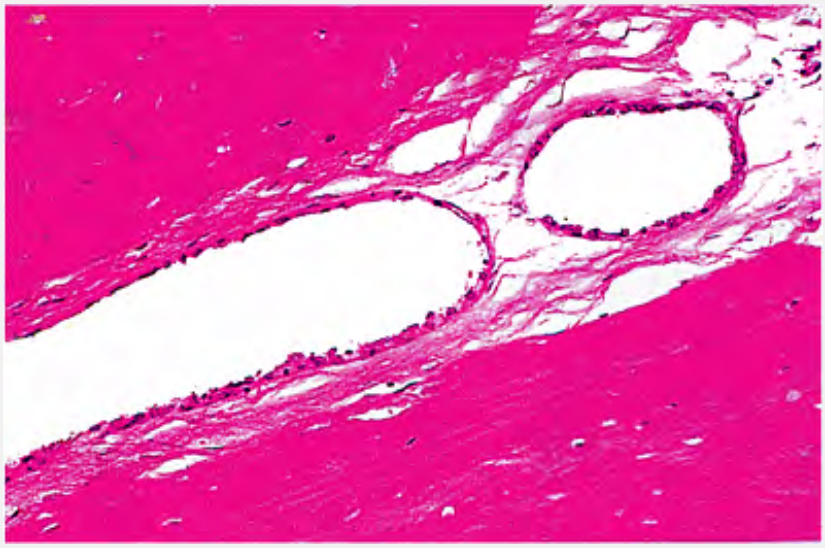

Figure 14.38 Endolymphatic duct within the vestibular aqueduct. The duct is lined by low cuboidal epithelium.

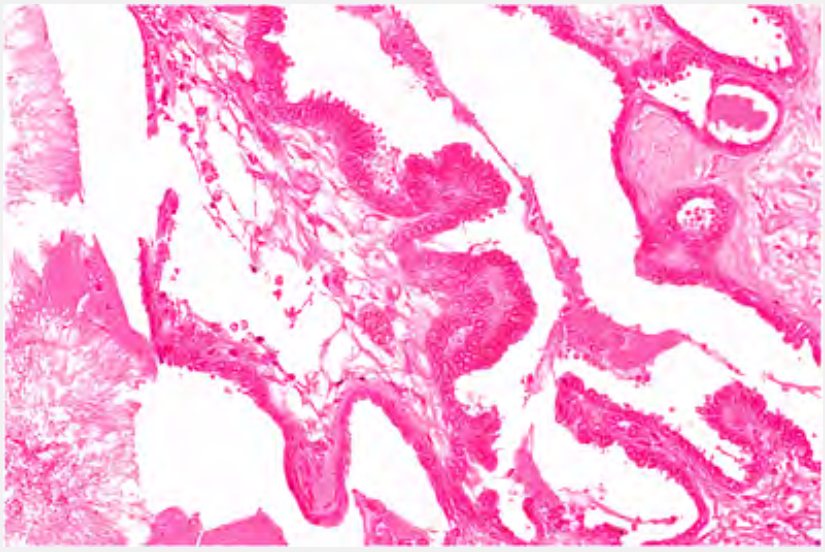

Figure 14.39 Endolymphatic sac, which is lined by tall columnar epithelium arranged on papillae.

The perilymphatic spaces of each osseous semicircular canal are continuous on both ends with the perilymphatic space of the vestibule, and this space is continuous with the scala vestibuli, which is continuous with the scala tympani at the helicotrema. All perilymphatic spaces open widely into each other. Due to areas of discontinuity or deficiency in the compact bone of the petrous portion of the temporal bone, foci of communication may exist between the perilymphatic space and other cavities. Such areas of potential communication include the middle and inner ear via the round and oval windows. In addition, the vestibular and cochlear aqueducts and the foramina for the nerves and blood vessels of the inner ear serve as potential channels between the inner ear and the cranial cavity.

Endolymph is an intracellular-like fluid containing high potassium and low sodium concentrations. Endolymph contains more than 30 times as much potassium as does perilymph or CSF but about one-tenth as much sodium (32). Endolymph has a low protein content; its protein

is entirely globulin instead of an admixture of globulin and albumin (1). It has a viscosity similar to the vitreous of the eye because of its high mucopolysaccharide content. The electrolyte concentration of the endolymph is critical for normal functioning of the sensory organs. It is generally believed that the main sources of endolymph are the stria vascularis, the epithelium of the ampullae of the semicircular ducts, and the epithelium of the maculae of the utricle and saccule.

Endolymph circulates through the cochlear duct (scala media) downward to the base of the cochlea, through the ductus reuniens into the saccule, and then into the endolymphatic sac and duct, where it is reabsorbed. The cochlear duct communicates with the vestibular endolymph-containing sacs through two canals so that the endolymphatic system is, like the perilymphatic system, a continuous one.

Conduction of Sound

Conduction of sound occurs via air and via bone. The pinna and external auditory canal conduct sound waves in air to the tympanic membrane. Conduction of sound by air is less efficient as compared with the ossicular route. The ossicular chain, including the malleus, incus, and stapes, enhances the sound energy transmission by conveying vibrations from the tympanic membrane to the footplate of the stapes and hence through the oval window of the vestibule to the perilymph. From the vestibular perilymph, vibrations derived from sound waves pass directly to the perilymphatic spaces of the cochlea, first via the scala vestibuli (upper compartment) ascending from the oval window, and then to the scala tympani (lower compartment) descending to the round window. The walls of the scala media (i.e., the cochlear duct, which contains endolymph) receive waves of vibrations from the adjacent perilymph (containing the scala vestibuli and scala tympani). Through the endolymph, the waves of vibrations

affect the sensory cells of the organ of Corti, the sensory organ of sound reception located in the scala media, from which it passes to the cochlear nerve with transmission via central pathways to the cerebral cortex.

Selected Abnormalities and Pathology

External Ear

Abnormalities of the external ear include those associated with first and second branchial arch syndromes. First and second branchial arch syndromes include otologic and nonotologic abnormalities. The otologic manifestations or abnormalities include malformed or absent external ears, atretic external auditory canal, and impaired hearing. The nonotologic abnormalities include asymmetric facies, abnormalities of the temporomandibular joint, neuromuscular abnormalities, and associated abnormalities of the cardiovascular, renal, and central nervous systems. Goldenhar's syndrome, also known as oculoauriculovertebral dysplasia, is a first and second branchial arch syndrome characterized by ear tags, preauricular pits and fissures, epidermoids, lipodermoids, and vertebral column abnormalities (33).

Ear abnormalities can also be seen in association with other abnormalities, including Down's syndrome (Figure 14.40). Cryptotia is a rare anomaly in which the superior portion of the auricle is buried in the scalp (Figure 14.41). Microtia represents gross hypoplasia of the pinna with a blind or absent external auditory canal. Microtia is typically bilateral although the degree of hypoplasia may differ on the two sides.

Accessory tragi (also referred to as accessory or supernumerary ears, accessory auricle, or polyotia) appear at birth and may be solitary or multiple, unilateral or bilateral, sessile or pedunculated, and soft or cartilaginous skin-covered nodules or papules. They are

located on the skin surface, often anterior to the auricle, and may be mistaken clinically for a papilloma. Histologically, accessory tragi recapitulate the normal external auricle and include skin, cutaneous adnexal structures, and a central core of cartilage. Accessory tragi are thought to be related to second branchial arch anomalies. They may occur independently of other congenital anomalies but also may occur in association with cleft palate or lip, mandibular hypoplasia, or other anomalies such as Goldenhar's syndrome (oculoauriculovertebral dysplasia) (33).

Figure 14.40 Individual with Down's syndrome. In comparison to non-Down's syndrome individuals, patients with Down's syndrome have external ears that are smaller, low set, and have an incompletely developed superior helix.

In adults, diagonal earlobe crease has been associated with coronary artery disease and has been referred to as Frank's sign (34). The crease runs diagonally backward and downward across the lateral

surface of the earlobe from the external meatus (Figure 14.42). Depending on the extent and depth of the crease, three grades have been assigned, with grade 1 being the least obvious appearing crease, grade 2 including a superficial crease across 100% of the earlobe or a deep crease across 50% of the earlobe, and grade 3 represented by a deep crease along 100% of the earlobe. Bilateral grades 2 and 3 creases are associated with a significantly higher risk of death from atherosclerosis and myocardial infarction (35).

Middle Ear

Otitis Media

Otitis media is either an acute or chronic infectious disease of the middle ear space. Otitis media is predominantly, but not exclusively, a childhood disease. The most common

microorganisms implicated in causing disease of the middle ear are *Streptococcus pneumoniae* and *Haemophilus influenzae* (36). Otoscopic examination reveals a hyperemic, opaque, bulging tympanic membrane with limited mobility; purulent otorrhea may be present. Bilateral involvement is not uncommon. The middle ear infection is felt to result from infection via the auditory tube at the time of or following a pharyngitis (bacterial or viral).

Figure 14.41 A. and B. Individual with cryptotia, a rare anomaly in which the superior portion of the auricle is buried in the scalp.

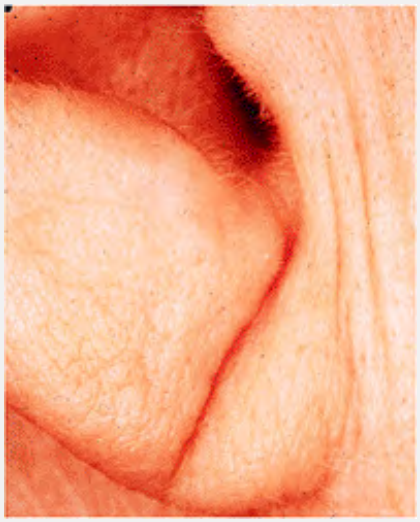

Figure 14.42 Individual with a grade 3 earlobe crease represented by a deep crease along 100% of the earlobe. This person had a similar earlobe crease of the opposite ear. Bilateral grades 2 and 3 creases are associated with a significantly higher risk of death from atherosclerosis and myocardial infarction.

In general, otitis media is managed medically. However, at times tissue is removed for histopathologic examination. The pathologic alterations are generally straightforward, but secondary changes such as glandular metaplasia of the surface epithelium (the result of chronic infection) may occur that might be confused with a true gland-forming neoplasm.

The histologic changes in chronic otitis media include a variable amount of chronic inflammatory cells, consisting of lymphocytes, histiocytes, plasma cells, and eosinophils. Multinucleated giant cells and foamy histiocytes may be present. The middle ear low cuboidal epithelium may or may not be seen. However, glandular metaplasia, a response of the middle ear epithelium to the infectious process, may be present (Figure 14.43). The glands tend to be more common in nonsuppurative otitis media than in suppurative otitis media. The metaplastic glands are unevenly distributed in the tissue specimens, are variably shaped, and are separated by abundant stromal tissue. The glands are lined by a columnar to cuboidal epithelium, with or without cilia or goblet cell metaplasia. Glandular secretions may or may not be present so that the glands may appear empty or contain varying

secretions, including thin (serous) or thick (mucoid) fluid content. The identification of cilia is confirmatory of middle ear glandular metaplasia and is a feature is not found in association with middle ear adenomas (36). Further, the haphazard arrangement of the glands in the background of changes of chronic otitis media should

allow for differentiating metaplastic from neoplastic glands. Acute inflammatory cells may be superimposed by chronic otitis media.

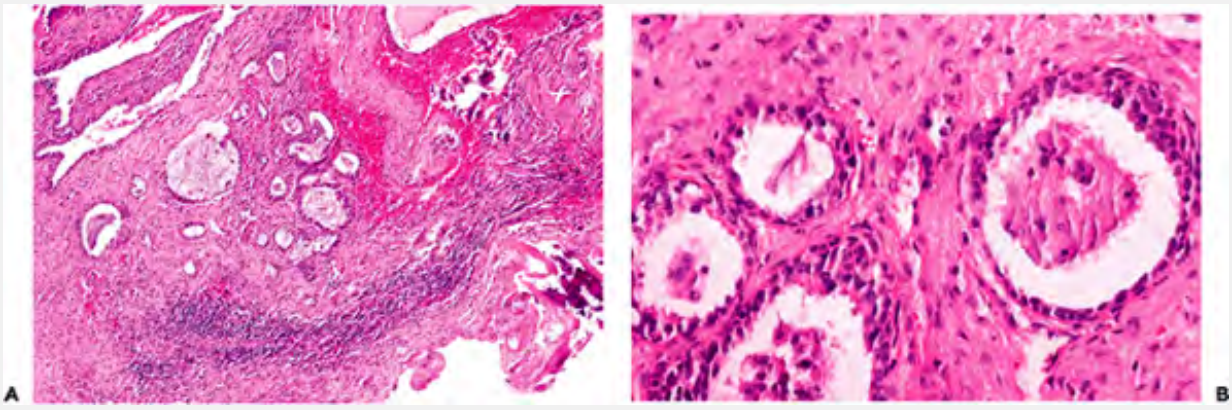

Figure 14.43 Under normal conditions, glands are not identified in the middle ear space; however, glandular metaplasia can be found in the setting of otitis media. A. Otitis media, showing chronic inflammation, fibrosis, glandular metaplasia, and foci of calcifications (*lower right*); residual normal cuboidal epithelium of the middle ear is seen in the upper left. B. Higher magnification showing glandular metaplasia is the setting of chronic otitis media.

In addition to the inflammatory cell infiltrate and glandular metaplasia, other histopathologic findings can be seen in association with chronic otitis media (or represent sequelae of chronic otitis media) and include fibrosis, granulation tissue, tympanosclerosis, cholesterol granulomas, and reactive bone formation. Due to the presence of scar tissue, the middle ear ossicles may be destroyed (partial or total) or may become immobilized. Perforation of the tympanic membrane pars tensa may occur with resulting ingrowth of squamous epithelium, potentially leading to the development of cholesteatoma (see below).

Tympanosclerosis represents dystrophic mineralization (calcification or ossification) of the tympanic membrane or middle ear that is associated with recurrent episodes of otitis media (37). The incidence of tympanosclerosis in otitis media varies from 3 to 33% (37). Tympanosclerosis of the tympanic membrane can be seen in children following myringotomy and tube insertion. In this setting, the tympanosclerotic foci may or may not be permanent. Tympanosclerosis of the middle ear typically affects older patients, represents irreversible accumulation of mineralized material, and is associated with conductive hearing loss (38,39).

On gross examination, tympanosclerotic foci may be localized or diffuse and appear as white nodules or plaques (Figure 14.44). Histologically, dense â€œclumpsâ€• of mineralized, calcified, or ossified material or debris can be seen within the stromal tissues or in the middle (connective tissue) aspect of the tympanic membrane (Figure 14.45). Tympanosclerosis may cause scarring and ossicular fixation.

Cholesterol granuloma is a histologic designation describing the presence of a foreign body granulomatous response to cholesterol crystals derived from the rupture of red blood cells with breakdown of the lipid layer of the erythrocyte cell membrane. Cholesterol granulomas arise in the middle ear and mastoid in any condition in which there is hemorrhage combined with interference in drainage and ventilation of the middle ear space (40). Cholesterol granuloma of the middle ear may present as idiopathic hemotympanum; patients may also complain of hearing loss and tinnitus. The majority of cholesterol granulomas in the middle ear and temporal bone have an indolent biologic behavior and cause no significant bone resorption (40).

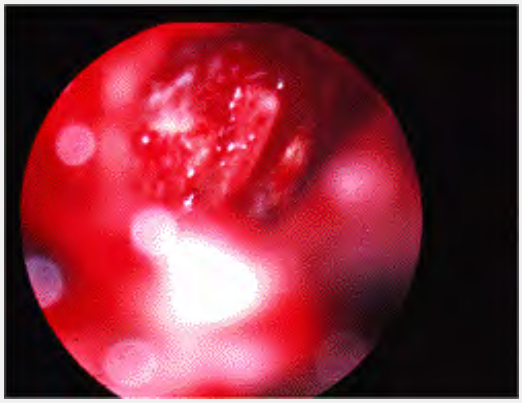

Figure 14.44 Tympanic membrane in tympanosclerosis showing calcified plaque on the tympanic membrane.

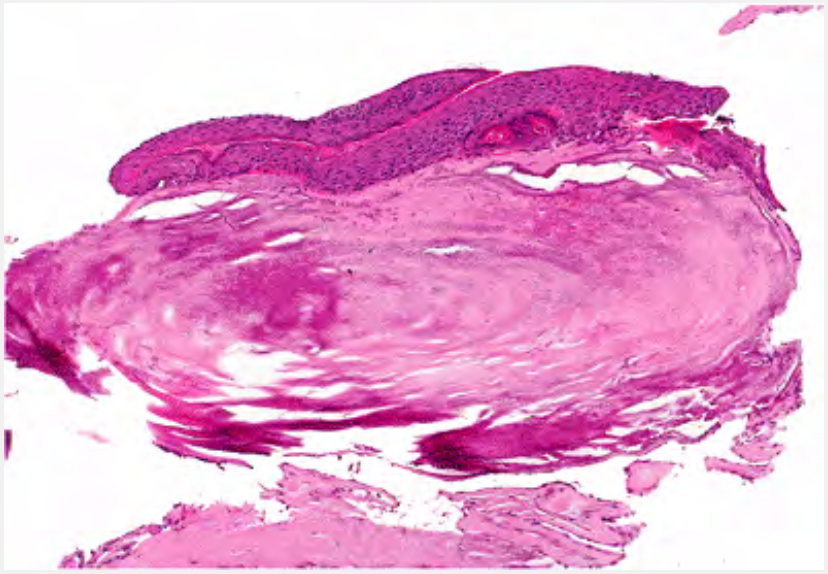

Figure 14.45 Tympanosclerosis. The tympanic membrane is thickened and calcified and is covered on its external (external auditory canal) aspect by keratinizing squamous epithelium (*top*) and on its internal (tympanic cavity) aspect by cuboidal epithelium (*bottom right*).

In contrast to cholesterol granulomas of the middle ear and temporal bone, cholesterol granulomas of the petrous apex may behave aggressively, producing a tumorlike mass with expansion of the cyst and erosion/destruction of adjacent structures. Depending on the direction of expansion, apical cholesterol granulomas may invade into the cochlea, cerebellopontine angle, jugular foramen, cranial nerves V to XI, brain stem, and cerebellum, producing life-threatening symptoms (41). Involvement of the petrous apex is more likely to be associated with sensorineural hearing loss; additional signs and symptoms may include headaches, cranial nerve deficits, and bone erosion with involvement of the posterior or middle cranial fossa (41,42). On axial computed tomography, apical cholesterol granulomas appear as round to ovoid to irregular-shaped cysts with smooth margins and evidence of bone remodeling.

The histology of cholesterol granulomas is the same irrespective of location and includes the presence of irregular-shaped clear-appearing spaces surrounded by histiocytes and/or multinucleated giant cells (foreign body granuloma) (Figure 14.46). Cholesterol granulomas are not related to cholesteatomas but may occur in association with or independent of a cholesteatoma.

Cholesteatoma (Keratoma)

Cholesteatoma is a pseudoneoplastic lesion of the middle ear characterized by the presence of stratified squamous epithelium that forms a saclike accumulation of keratin within the middle ear space (akin to an epidermal inclusion cyst). Despite their invasive growth, cholesteatomas are not considered to be true neoplasms. The term *cholesteatoma* is a misnomer in that it is not a neoplasm nor does it contain cholesterol. Perhaps the designation of *keratoma* would be more accurate, but the term cholesteatoma is entrenched in the literature. In the middle ear and inner ear, cholesteatomas take three forms: acquired cholesteatoma, congenital cholesteatoma, and

cholesteatoma of the petrous apex. Depending on the site of origin in the tympanic membrane, each of these cholesteatomas may be subdivided into pars flaccida (Schrapnell's membrane) and pars tensa cholesteatomas.

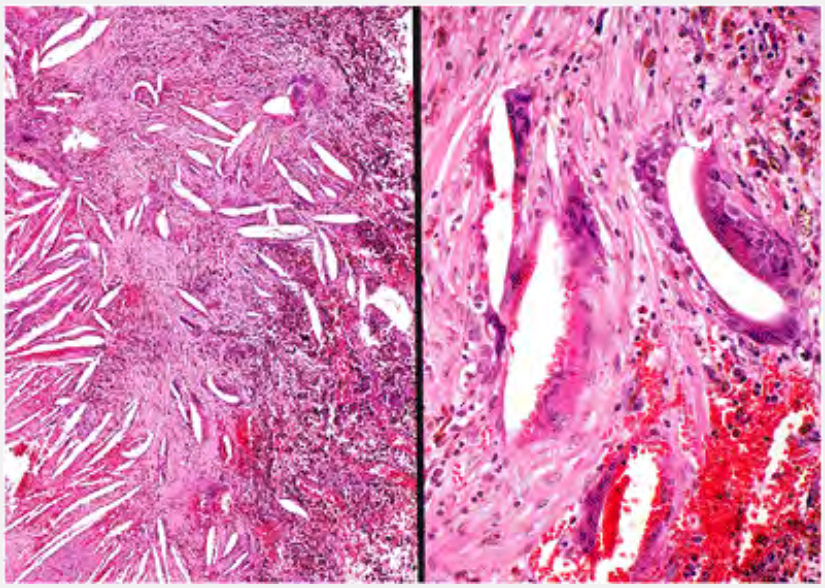

Figure 14.46 Cholesterol granuloma appears as empty, irregularly shaped clefts or spaces surrounded by histiocytes and multinucleated giant cells. Fresh hemorrhage and hemosiderin pigment are readily apparent.

Acquired Cholesteatoma

Acquired cholesteatoma is the most common type of cholesteatoma. It tends to be more common in men than in women and occur in older children and young adults. Acquired cholesteatoma is derived from entry of external ear canal epidermis into the middle ear. The latter may occur in one of several ways: via perforation of the tympanic membrane, following localized retraction of the tympanic membrane with epithelial invagination or ingrowth of a band of

stratified squamous epithelium into the middle ear; via entrapment of squamous epithelium following surgery and/or trauma; or via squamous metaplasia of the middle ear mucosa (43). A decrease in middle ear pressure can induce retraction of certain regions of the tympanic membrane in the pars flaccida, pars tensa, or both (43). Retraction pockets are felt to represent the precursors for the development of cholesteatoma (Figure 14.47) (44,45). Dysfunction of the auditory tube leading to chronic (recurrent) otitis media is felt to represent a causative factor (43).

The upper posterior part of the middle ear space is the most common site of acquired cholesteatoma. Initially,

cholesteatomas may remain clinically silent until extensive invasion of the middle ear space and mastoid occurs. Symptoms include hearing loss, malodorous discharge, and pain and may be associated with a polyp arising in the attic of the middle ear or perforation of the tympanic membrane. Otoscopic examination may reveal the presence of white debris within the middle ear, which is considered diagnostic.

Figure 14.47 Section of malleus from an adult ear with a retraction pocket of the tympanic membrane at autopsy. There is a thin layer of stratified squamous epithelium between the bone and middle ear epithelium. This was found on serial section to be an ingrowth of the stratified squamous epithelium from the outer epithelial covering of the retraction pocket.

Congenital Cholesteatoma

Congenital cholesteatoma is a cholesteatoma of the middle ear that exists in the presence of an intact tympanic membrane, presumably occurring in the absence of chronic otitis media that may result in perforation or retraction of the tympanic membrane. Congenital cholesteatomas are found in infants and young children. Small colonies of epidermoid cells, referred to as epidermoid formations, are found on the lateral anterior superior surface of the middle ear in temporal bones after 15 weeks gestation (43). During the first postpartum year, the epidermoid colonies disappear; however, if the epidermoid cells do not disappear but continue to grow, they will become a congenital cholesteatoma. The latter have also been referred to as epidermoid cysts (46). In the majority of cases, congenital cholesteatomas are found in the anterosuperior part of the middle ear. Early lesions show no symptoms and are discovered by otoscopic examination. In later lesions, the signs and symptoms may be the same as acquired cholesteatoma.

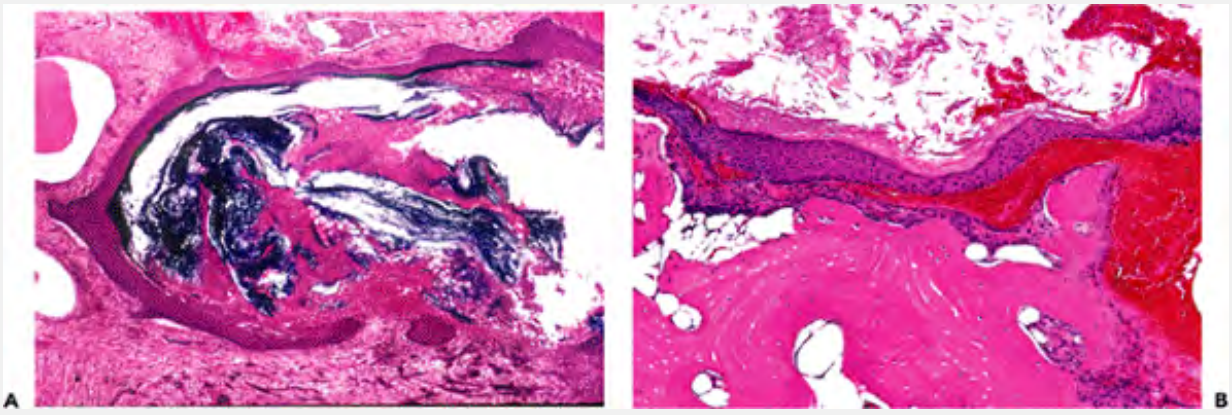

Figure 14.48 Cholesteatoma of the middle ear. A. The histologic diagnosis of cholesteatoma is based on the presence of finding keratinizing squamous epithelium within the middle ear space. B. Osseous involvement.

Cholesteatoma of the Petrous Apex

Cholesteatoma of the petrous apex is an epidermoid cyst of this location and bears no relation to cholesteatoma of the middle ear. It is likely of congenital origin, but no cell rests have been discovered that may explain the origin of these lesions. Symptoms usually relate to involvement of the cranial nerves VII and VIII in the cerebellopontine angle (46).

Pathology

Cholesteatomas appear as cystic, white to pearly appearing masses of varying size that contain creamy or waxy granular material. The histologic diagnosis of cholesteatoma is made in the presence of a stratified keratinizing squamous epithelium, subepithelial fibroconnective or granulation tissue, and keratin debris (Figure 14.48). The essential diagnostic feature is the keratinizing squamous

epithelium, and the presence of keratin debris alone is not diagnostic of a cholesteatoma. The keratinizing squamous epithelium is

cytologically bland and shows cellular maturation without evidence of dysplasia. In spite of its benign histology, cholesteatomas are â€œinvasiveâ€• and have widespread destructive capabilities.

The destructive properties of cholesteatomas result from a combination of interrelated reasons, including mass effect with pressure erosion of surrounding structures from the cholesteatoma, the production of collagenase (which has osteodestructive capabilities by its resorption of bony structures), and bone resorption (20). Collagenase is produced by both the squamous epithelial and the fibrous tissue components of the cholesteatoma. This local aggressive behavior is the result of the continuing accumulation of the cholesteatomatous material with progressive erosion of surrounding structures. Depending on the location and extent of the cholesteatoma, erosion may include the lateral wall of the attic, the middle ear ossicles, the tegmental bone over the attic and antrum, and the mastoid cortex (43). Less frequent progression includes erosion of the lateral sinus and jugular bulb, the vestibular and cochlear capsules, the facial canal, the dura of the middle and posterior cranial fossa, the semicircular canals, and the facial nerve (43). Sequelae of such erosions may include semicircular canal fistulas, exposed tympanic facial nerve, or brain herniation through the tegmen.

The histologic diagnosis of cholesteatomas is relatively straightforward in the presence of keratinizing squamous epithelium. In contrast to cholesteatomas, squamous cell carcinoma shows dysplastic or overtly malignant cytologic features with a prominent desmoplastic stromal response to its infiltrative growth. Cholesteatomas do not transform into squamous cell carcinomas. In an attempt to determine whether cholesteatomas were low-grade squamous carcinomas, Desloge et al. (47) performed DNA analysis on human cholesteatomas to determine whether ploidy abnormalities

were present. In ten cases with interpretable data, nine were euploid and one was aneuploid. These authors concluded that, due to a lack of overt genetic instability, cholesteatomas could not be considered to be malignant neoplasms. Cholesterol granuloma is not synonymous with cholesteatoma. These entities are distinctly different pathologic entities and should not be confused with one another.

Otosclerosis

Otosclerosis is a disorder of the bony labyrinth and stapedial footplate that exclusively occurs in humans and is of unknown etiology. Otosclerosis means hardening of the ear and is derived from Greek (*ous*, ear; *skleros*, hard; *osis*, condition); osseous ankylosis (from the Greek *ankoulon*, to stiffen); chronic metaplastic ostitis; progressive otospongiosis. Otosclerosis primarily causes conductive hearing loss that usually begins in the second and third decades of life and is slowly progressive. The extent of the hearing loss directly correlates with the degree of stapedial footplate fixation. It is not uncommon for patients with otosclerosis also to have vestibular disturbances (48,49). Otosclerosis usually involves both ears; however, unilateral disease can occur in up to 15% of cases (50).

Although many theories regarding the etiology of otosclerosis appear in the literature, there is no consensus. Hereditary factors are often cited as among the causes. Surgical management of the conductive hearing loss caused by stapes fixation (stapedectomy) is the treatment of choice, with replacement of the fixed stapes by a prosthesis. The resected bone may include the entire stapes (with the footplate) or only the superstructure that includes the head and crura (without the footplate).

Histologically, the initial alterations include resorption of bone around blood vessels. The cellular fibrovascular tissue replaces the resorbed bone, resulting in softening of the bone (otospongiosis).

Immature bone is laid down with continuous active resorption and remodeling. The new bone is rich in ground substance and deficient in collagen; but, over time, more mature bone with increased collagen and less ground substance is produced, resulting in densely sclerotic bone. This process most often begins from the adjacent temporal bone (anterior to the oval window) and eventually involves the footplate of the stapes moving across the annulus fibrosus or stapediovestibular joint (Figure 14.49). Stapedial involvement causes fixation of the stapes, with inability to transmit sound waves resulting in conductive hearing loss. While the otosclerotic changes can be seen in the resected stapedial footplate, even when the footplate is removed intact it may be free of otosclerotic changes as fixation results via pressure on the nonotosclerotic footplate from swelling of the otosclerotic process in the adjacent temporal bone (7).

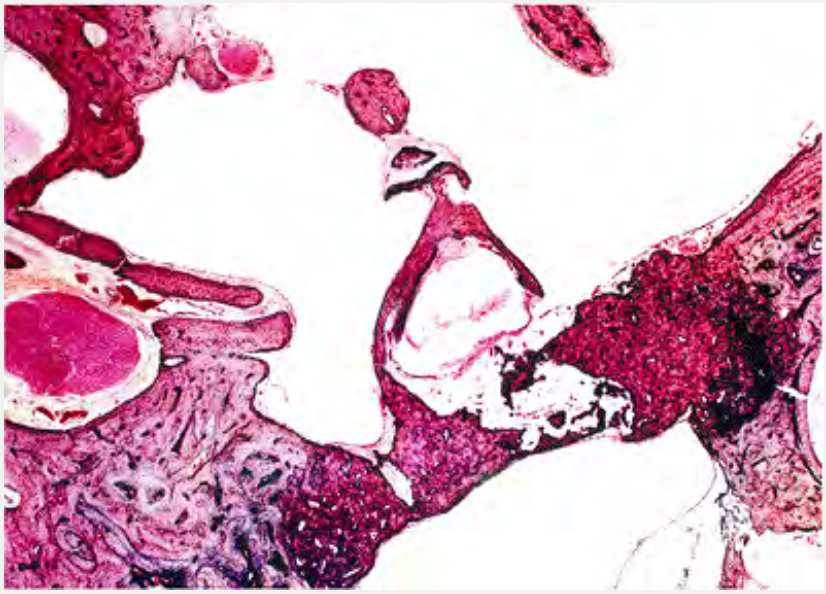

Figure 14.49 Otosclerosis of the temporal bone (anterior to the oval window) involving the footplate of the stapes moving across the annulus fibrosus or stapediovestibular joint. Stapedial involvement causes fixation of the stapes, with inability to

transmit sound waves resulting in conductive hearing loss.

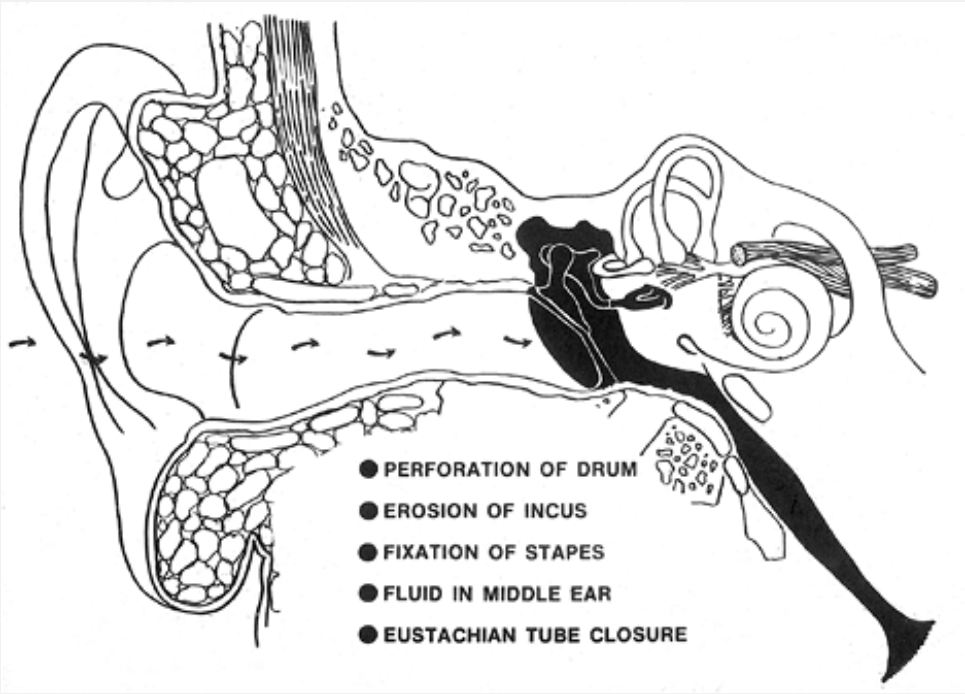

Figure 14.50 Causes of conductive hearing loss.

Inner Ear

Presbycusis and Other Hearing Loss

Hearing loss may include conductive hearing loss and sensorineural hearing loss. There are many causes for conductive and sensorineural hearing loss, respectively (Figures 14.50,14.51). Hearing loss that occurs with increasing age is referred to as presbycusis. There is still controversy as to the underlying electrophysiologic and histopathologic alterations associated with the

development of presbycusis. Degenerative alterations within various microanatomic structures of the cochlea, including the hair cells, spiral ganglion cells, stria vascularis, and basilar membrane, have been invoked as the cause of presbycusis (51). Alternatively, damage to the outer hair cells alone has been invoked as the cause of presbycusis (52,53). As Soucek and colleagues have shown in their studies of aged ears (52,53), the histopathologic changes include scanty to absent outer hair cells of the third row (Figure 14.52), with complete loss of both inner and outer hair cells of all rows at the extreme lower end of the basal coil. In contrast to these aforementioned sites, Soucek and colleagues found that the inner hair cells sustained minimal loss, the first row of outer hair cells had

greater loss, and the second row more loss but not to the extent seen in the third row of outer hair cells or at the extreme lower end of the basal coil (54,55). In addition, these authors also found the presence of enormously lengthened and thickened sterocilia and giant stereocilia, which they felt contributing to the development of presbycusis.

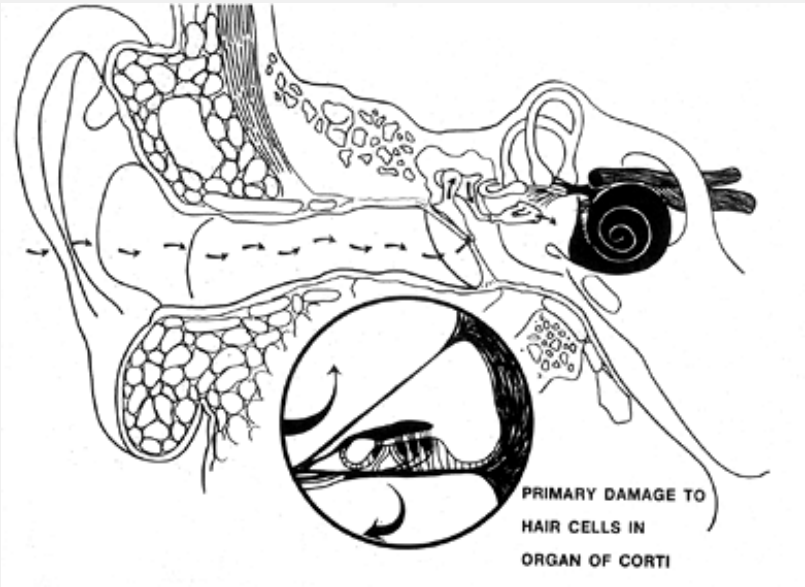

Figure 14.51 Cause of sensorineural hearing loss.

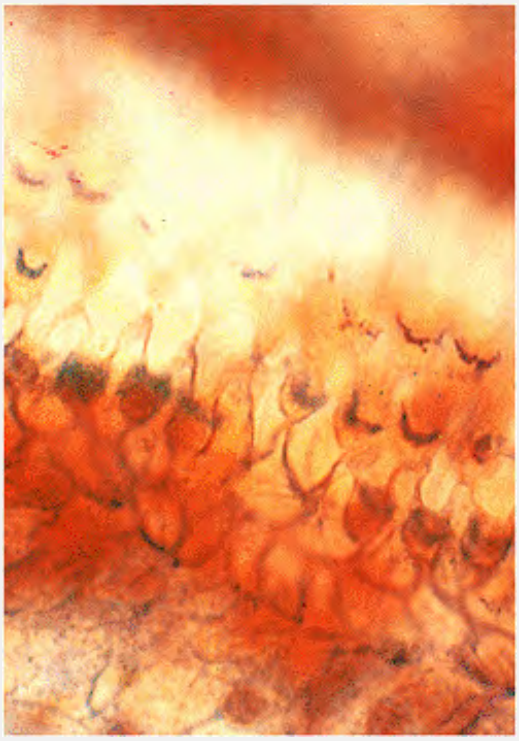

Figure 14.52 Surface preparation of outer hair cells from basal coil of cochlea of an elderly man. There are many gaps among the hair cells of the first two rows. (*P,* pillar cells) (Osmic acid, Alcian blue, and phloxine eosin, oil immersion.)

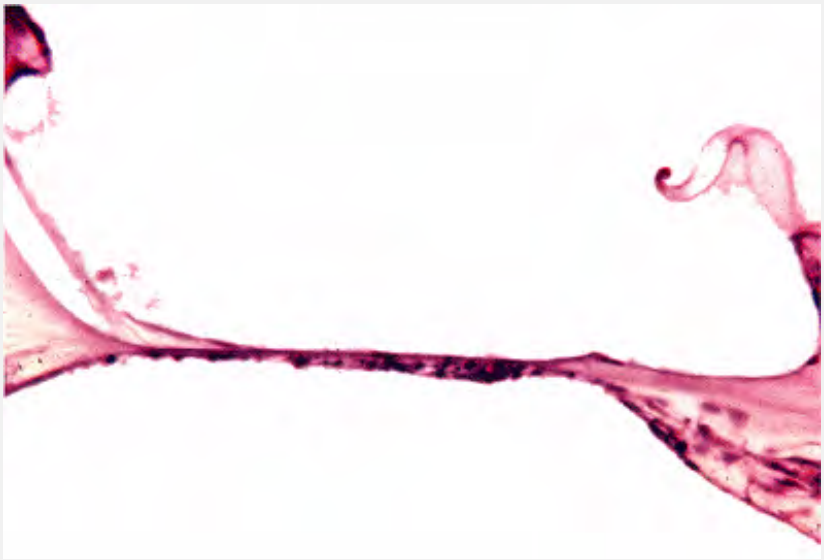

Figure 14.53 Viral labyrinthitis- (end stage) related hearing loss with total degeneration of the organ of Corti.

Degenerative alterations within various microanatomic structures of the membranous labyrinth resulting in sensorineural hearing loss may occur secondary to infectious disease (Figure 14.53), metabolic abnormalities (Figure 14.54), trauma (Figure 14.55), sensory presbycusis (Figure 14.56), and use of certain medications, including cisplatin, diuretic agents, and other drugs (Figures 14.57,14.58).

MÃ©niÃ¨re's Disease

MÃ©niÃ¨re's disease is an idiopathic disorder of the inner ear associated with a symptom complex of spontaneous,

episodic attacks of vertigo, sensorineural hearing loss, tinnitus, and a sensation of aural fullness. The onset of vertigo is frequently sudden, reaching maximum intensity within a few minutes, lasting from an hour or more, and either subsiding completely or continuing as a sensation of unsteadiness for hours to days.

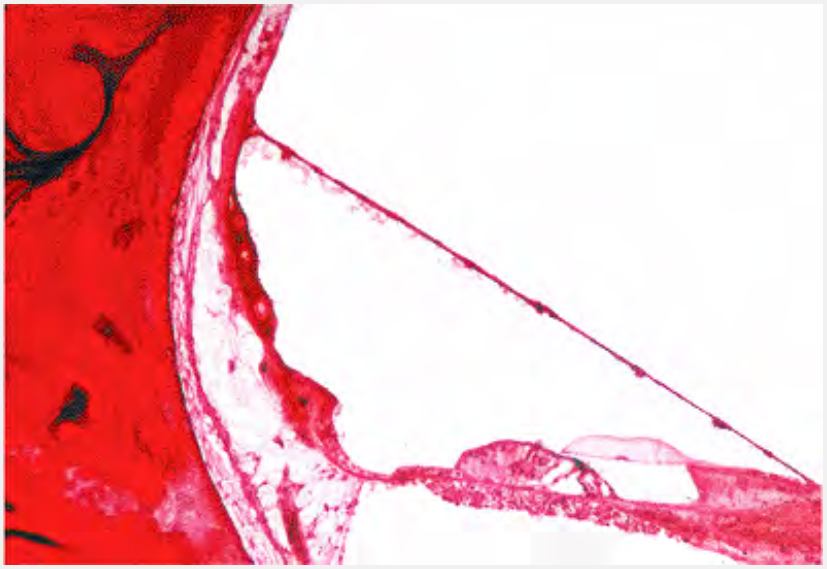

Figure 14.54 Metabolic-related hearing loss in a patient with diabetes is characterized by the presence of hyalinized vasculature structures in the stria vascularis.

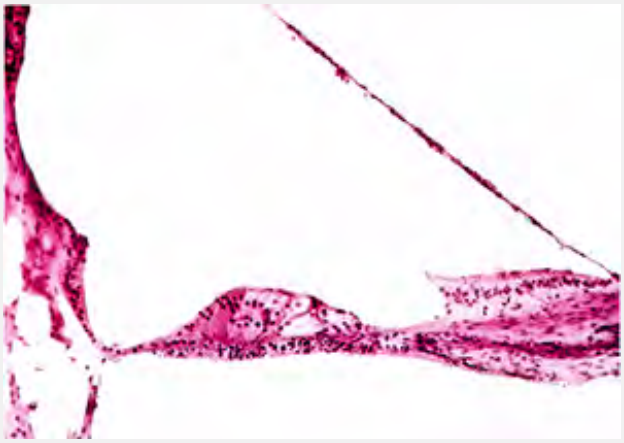

Figure 14.55 Posttraumatic hearing loss with focal avulsion of the organ of Corti.

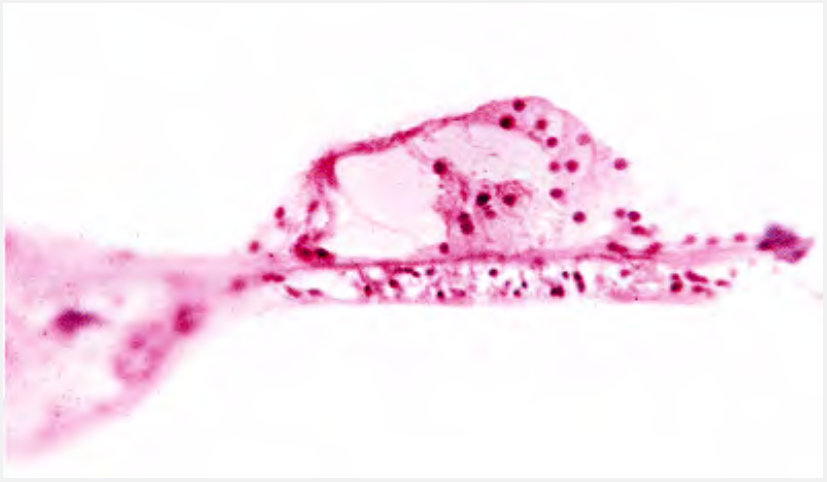

Figure 14.56 Sensory presbycusis characterized by the loss of hair cells in the organ of Corti.

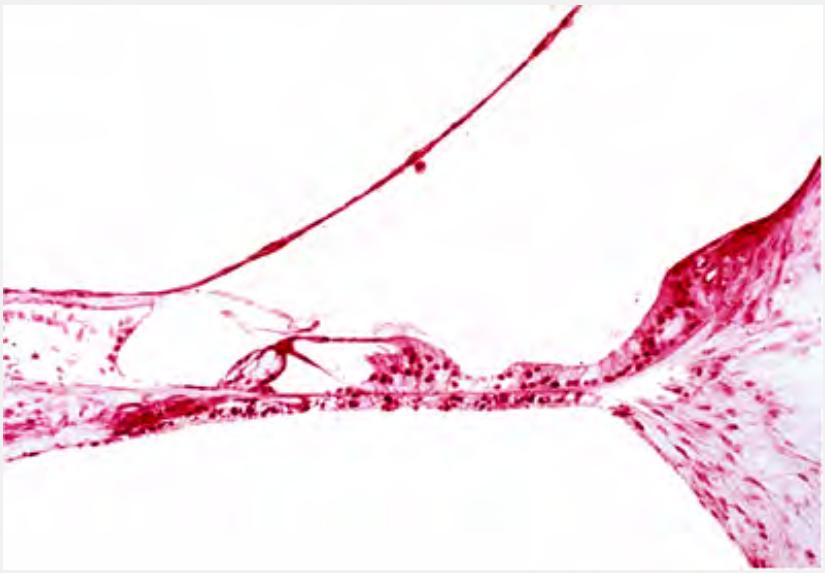

Figure 14.58 Kanamycin ototoxic effects on the organ of Corti, including loss of hair cells.

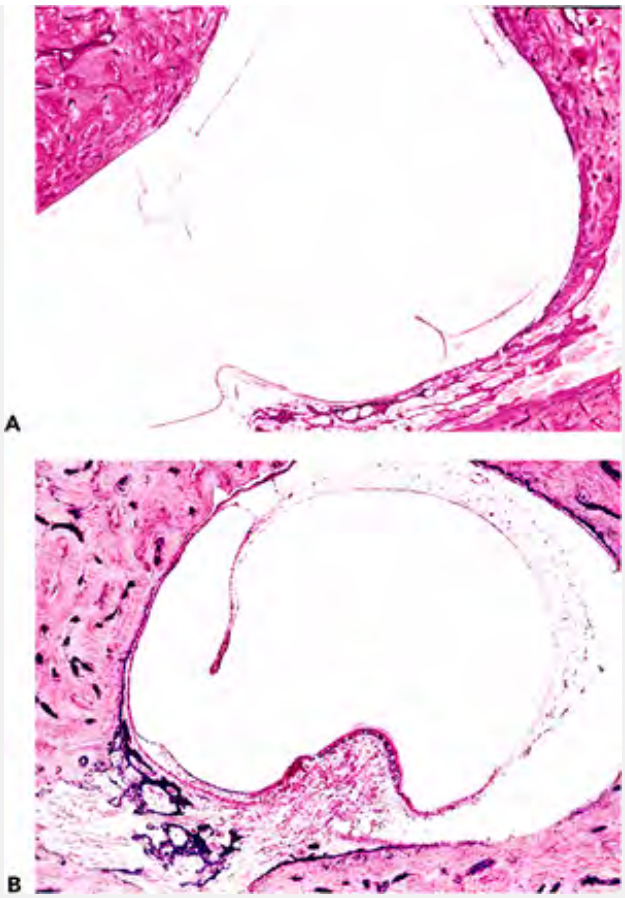

Figure 14.59 MÃ©niÃ¨re's disease showing dilatation (A) and rupture of the membranous labyrinth (B).

The pathogenesis of MÃ©niÃ¨re's disease is distortion of the membranous labyrinth, defined as changes in the microanatomy of the membranous labyrinth as a consequence of the over-accumulation of endolymph (endolymphatic hydrops) and at the expense of the perilymphatic space (54,55). Endolymph, which is produced by the stria vascularis in the cochlea and by cells in the vestibular labyrinth, circulates in a radial and longitudinal fashion. In patients with MÃ©niÃ¨re's disease, it is believed that there is inadequate absorption of endolymph by the endolymphatic sac (55).

In the early stages of the disease, endolymphatic hydrops primarily

involves the cochlear duct and saccule, but in the later stages the entire endolymphatic system is involved. Alterations of the membranous labyrinth include dilatation, outpouching, rupture, and collapse (Figure 14.59). Fistulae (unhealed ruptures) may occur. Severe cytoarchitectural and atrophic changes may occur in the sense organs with loss of neurons in the cochlea.

Temporal Bone Dissection

For a detailed discussion of proper postmortem removal, sectioning, and processing for microscopic evaluation of the temporal bone, the reader is referred to other texts (7,56).

Embryology and Prenatal Changes

The development of this highly specialized part of the head is restricted t
to the surgical pathologist. For details, the reader is referred to other sou

The oral region develops from an ectodermal depression, the stomodeum.
formed by the forward growth of structures about the margins of the stor
superficial parts of the face and jaws, as well as the walls of the oral cav
prominence is surrounded bilaterally by the maxillary and mandibular proc
unpaired frontal prominence. The upper lip, maxilla, and nose are derivec
surrounding the stomodeum. The caudal boundary of the oral cavity is for
mandibular processes, which, during the second year of life, fuse in the m
mandible. The paired maxillary processes likewise meet in the midline, cr
to ultimately form the maxilla and, by fusion in the midline, the palate. Tl
change with the rapid growth of the nose and jaws (2). The nose is form
frontonasal elevation by an invagination of ectoderm into the mesoderm to
gradually converge toward the midline, where they merge with each othe
mesenchyme develops into bone, cartilage, and skeletal muscle.

At the end of the second month of fetal life, the formation of the bony st
maxilla is one of the first bones to calcify. Simultaneously, the nasal pits

deeper and extend downward toward the oral cavity. Later, elevations app the right and left nasal cavity that will become the scroll-like nasal turbir cavities communicate with chambers in the adjacent bones known as para the bones in which they lie, they comprise the frontal, maxillary, sphenoi The paranasal sinuses can be first identified around the fourth month of fe expansion occurs after birth, and they attain full size many years later. T cavities invaginates into the surrounding bone, thereby lining the expandi has been taking shape from the roof of the mouth, the tongue has been f posterior part of the tongue (behind the sulcus terminalis)

is derived from the midventral areas of branchial arches II, III, and IV.

The tonsils first develop as endodermal epithelial buds that arise from the oronasal cavity and grow into the subjacent mesenchyme to eventually giv crypts. Crypt formation may be simple, as in the lingual tonsil, or more c tonsils. Lymphoid tissue begins to accumulate and organize around the cry when secondary budding of the crypts takes place. This development occu with mucous glands, which explains the close anatomic proximity of such

Tooth development (odontogenesis) is of considerable importance to an u pathogenesis of odontogenic tumors and cysts. Odontogenesis is a highly process that relies upon several genes, growth factors, structural protein tuftelin, predentin, cementum, enamelin), and extracellular matrix molecu temporal- and space-specific patterns (3). The teeth begin to develop ins and lower jaw (Figure 15.1). Such regulatory interactions occur during th morphogenesis, particularly when the dental epithelium induces the cond cells around the epithelial bud. Teeth pass through three stages of devel mineralization, and eruption. The growth period is further subdivided into stages.

Initially, the oral epithelium shows definite thickening and begins to grow mesenchyme around the entire arc of each jaw. The free margin of this e two invaginating processes. The outer process (vestibular lamina) will forı demarcates the cheeks and lips. From the inner horseshoe-shaped proces buds (bud stage) arise at the site of each future tooth. Thus, the primord deciduous (primary) teeth are formed. Shortly afterward, the primordia o

(permanent) teeth develop in the same way. The permanent tooth germs l alveolar sockets on the lingual side of the deciduous teeth. The developin tooth takes the shape of a goblet with the dental lamina as its stem. As t disintegrates, the inner lining cells (inner enamel epithelium) of the enan become columnar epithelial cells called ameloblasts, whereas the outer lay epithelium) flatten into a layer of closely packed cells. Between the amelo enamel epithelium is the loosely arranged epithelium of the stellate reticu shaped enamel organ, the mesenchymal cells proliferate to form a dense papilla (cap stage).

Figure 15.1 Coronal section of head of a human fetus about 30 weeks of length). The bell-shaped enamel organs are present in each quadrant. Th large. The paranasal sinuses are not yet discernible at this stage of fetal

The dental papilla will form the dentin, cementum, and pulp. The dentin is tooth, the cementum is the bony tissue covering the root of the tooth, and part of the tooth. More peripherally, the condensing mesenchymal cells ex organ as the dental follicle. The cells of the dental follicle eventually proc collagen fibers of the periodontium. In the final

(bell) stage of growth, the epithelium of the cap will form the enamel. Du and inner enamel epithelium meet at their apical ends, where they prolife

Gross Anatomy

In this chapter we will consider only those features that are important fo

Jawbone

The mandible is a horseshoe-shaped bone; its horizontal part forms the b with the vertical parts of the two sides, the rami. The bone of the body ha compact shell contains plates of cancellous bone arranged along the traje the body is hollowed into sockets that carry eight teeth on each side. Eacl vertical, flattened, oblong plate of bone surmounted by two processes. T process ends in the condyle, articulating with the articular disk of the te anterior (coronoid) process serves for the insertion of the temporal musc

The right and left maxillae jointly form the upper jaw; they participate in cavities: the roof of the mouth, the floor and lateral wall of the nose, the sinus, and the floor of the orbit. The alveolar processes of the maxillae t arch.

Nose

The external nose and nasal septum are partly composed of hyaline cartila orifices of the external nose, the nares (nostrils), are separated from each vertical soft tissue columella. The columella is attached posteriorly to the forms the medial wall of the two approximately symmetrical chambers, th cavities. The nasal cavity extends from the nares anteriorly to the choan the nares, the nasal cavity widens to form the vestibule. A ridge (limen n wall separates the vestibule from the rest of the nasal cavity proper. In e olfactory region that occupies the superior part of the nasal cavity. The re consists of the respiratory region. On the lateral wall of each nasal fossa

and inferior turbinates. A fourth supreme turbinate may be present at the lateral nasal wall. The scroll-shaped turbinates hang over the correspond passages, or meatuses, into which the various paranasal sinuses open. Th continuity with the mucosa of these sinuses through their corresponding mucous membrane is most vascular and thickest over the turbinates and the nasal septum.

Paranasal Sinuses

The air-filled paranasal cavities (sinuses) are located in the bones around maxillary and frontal sinuses open into the middle meatus of the nose. T into the sphenoethmoidal recess above the superior turbinate. There are sinuses that form small communicating cavities, also called ethmoid air c The ethmoid air cells have thin bony walls. According to their location, th divided into three groups: the anterior and middle ethmoidal sinuses, whi meatus, and the posterior ethmoidal sinus, which opens into the superior are many variations in size, shape, and location of all paranasal sinuses. C even be underdeveloped or absent.

Blood Vessels

The nasal cavity has an extraordinarily rich blood supply. The anterior ar branches of the ophthalmic artery supply the frontal and ethmoidal sinuses the nasal cavity. The sphenopalatine branch of the maxillary artery supplie turbinates, meatuses, and the nasal septum. The mucosa of the maxillary branches of the maxillary artery and the sphenoidal sinus by the pharyng all these vessels form a plexiform network in and below the mucous mem nasal mucosa are well developed, particularly in the inferior turbinate and the nasal fossa, where they form a cavernous plexus. The veins of the low inferior central vein into the pterygoid plexus. Blood from the upper jaw in two directions: the more anterior parts into the anterior facial vein and into the pterygoid plexus. The pterygoid plexus drains the teeth, soft pal These anatomic relationships are particularly important because infections mouth, nose, and paranasal sinuses can reach the intracranial cavernous emissary vein of Vesalius or by way of veins communicating with the infe

veins. The latter veins drain the structures of the anterior face, such as l nose, as well as the mucosa of the frontal sinuses, ethmoidal cells, and u cavernous sinus also receives venous blood from the mucosa of the sphe

Nerves

The regions discussed here have a rich and complex innervation, the desc the scope of this

chapter. However, many nerves of the head lie in close proximity to the r the upper aerodigestive tract and are therefore prone to early invasion b

Lymph Nodes

Lymph nodes of the head and neck are abundant and can be divided into mastoid, parotid, facial, sublingual, submaxillary, submental, retropharyn and lateral cervical nodes. Only those lymph nodes related to the regions are discussed here. There are three principal parotid lymph node groups: preauricular) nodes; subfascial (extraglandular) nodes contained in the pa intraglandular nodes. The parotid lymph nodes drain the parotid gland, e facial region, eyelids, upper lip, root of the nose, floor of the nasal cavity mucosa. Their efferents pass into the superior deep cervical nodes.

The small superficial group of facial nodes include, from rostral to caudal (nasolabial) nodes situated in the nasolabial fold, the buccal nodes placed muscle and its fascia, and the mandibular nodes located external to the r receive afferent lymphatics from the eyelids, nose, cheek, upper lip, and empty into the submaxillary nodes. There are also deep facial nodes situat the mandible near the maxillary artery. Heterotopic buccal nodes may ra immediately beneath the buccal mucosa near the orifice of Stensen's duct impression of a neoplasm (15 ,16). The sublingual (or lingual) nodes are course of the collecting lymph trunks of the tongue. The submaxillary (s situated in the space lodging the submaxillary salivary gland, are located fascial sheath of this gland. They receive lymph vessels from the chin, lip the anterior nasal cavity), gums, teeth, floor of the mouth, hard palate, t

nodes. The submental nodes receive lymphatics from similar regions. The partly with the submaxillary and internal jugular nodes. The retropharyng between the posterior wall of the pharynx and prevertebral fascia, may p soft palate and therefore may be mistaken for palatine tonsils. The more nodes atrophy with age. These nodes drain the nasal cavities, palate, mi orophrynx. They send efferent vessels to the internal jugular chain of no

Lymphatics

For a detailed description of the lympahtic system draining the head and referred to the compendium by Tobias, which is a translation of the origin). Lymphatics arising from the upper lip terminate in the parotid, submer lymph nodes. Central lymphatics from the lower lip drain into the submer originating more laterally empty into the submaxillary nodes. Lymphatics of the cheeks traverse the buccinator muscle to eventually terminate in t Their course may be interupted by the buccinator nodes. Cutaneous lymph the submaxillary, submental, and parotid nodes. The lymphatic network of into a superficial and deep (muscular) set. They drain to the linguinal and end mainly in the deep cervical lymph nodes. The node at the bifurcation artery is considered to be the principal lymph node of the tongue (17). L the tongue may cross the midline to reach nodes of the opposite side. Th superficial and deep anastomosing lymphatic network that drains into the submaxillary, internal jugular, and occasionally the retropharyngeal nodes exit from the dental pulp of the teeth are in direct communication with th Lymphatics from the floor of the mouth are continuous with those from th Afferent lymphatics from the floor of the mouth drain into the sublingual, cervical nodes, while those from the posterolateral region terminate in th cervical nodes. The draining lymphatics of the palate, which are continuou and palatine tonsils, reach the submaxillary, retropharyngeal, and deep no

The cutaneous lymphatics of the nose terminate in the submaxillary lymph nasal vestibule goes to the parotid and submaxillary nodes. Lymphatics o anterior nasal cavities drain to the submental nodes, while those from the the retropharyngeal and deep superior cervical nodes. turbinate, along with lymphatics from the middle turbinate, drain into the
internal jugular lymph nodes. The superior turbinates drain to the retroph
cervical nodes. Lymphatics from the frontal and maxillary sinuses, along v
medial group of ethmoidal sinuses, drain to the submaxillary nodes. The
and sphenoidal sinuses drain lymph into the retropharyngeal nodes.

Tonsils

Nonencapsulated lymphoid tissue present in the oropharynx is normally c
covered lymphoid aggregates termed *tonsils* . Tonsils are typically softer
palpation because they lack a fibrous capsule or trabeculae. The word *ton*
refer to the palatine tonsils. Waldeyer's ring, described by the nineteenth
Wilhelm von Waldeyer, refers to the circular collection of submucosal lym
the opening into the upper aerodigestive tract (18). Waldeyer's ring is c
pharyngeal, tubal, and lingual tonsils, as well as the lateral pharyngeal ly
intervening isolated lymphoid follicles (pharyngeal granulations) (19 ,20
are located on the posterolateral wall of the oropharynx, just behind the
The oval shaped palatine (faucial) tonsils are situated laterally in the oro
triangular tonsillar fossa, which is bound by the palatoglossal arch anteri
arch posteriorly. Their tonsillar crypts usually become occupied with des
debris, and microorganisms that are grossly visible on the surface as whi
crypt plugs may calcify. The palatine tonsils are the only tonsils with a pa
formed by compressed connective tissue on their attached side. This caps
from the underlying musculature of the pharyngeal wall. The tonsils are l
after about four years of age, they begin to gradually atrophy. Following
become increasingly fibrotic. The pharyngeal tonsil (adenoid, or tonsil of l

Oral Mucosa and Submucosa

The oral mucosa consists of an epithelial layer and an underlying layer of lamina propria (Figure 15.9). The mucosa of the oral cavity shows regio structure and cytokeratin expression that correspond to functional requir squamous epithelium of the oral mucosa has three functional types: the mucosa, and specialized mucosa (28). Most of the oral mucosa is lined epithelium, representing the lining mucosa. The palate, gingiva, and dorsu exposed to the forces of mastication and are covered by keratinized epith mucosa type. The mucosa of the palate is orthokeratinized, whereas the e often parakeratinized. Details of the specialized mucosa are described wit the oral cavity the epithelium is worn off by mastication and speaking; h cells are a normal constituent of the saliva and are frequently encountere sputum or as â€œcontaminantsâ€• in bronchoscopic specimens. Squamou mucosa have also been a convenient source for the microscopic demonstra chromosome (Barr body) (Figure 15.10). The shed epithelial cells are re which divide then migrate to the surface and are themselves eventually w

the oral mucosa takes about 12 days (29). As the name implies, the squ mucosa is kept moist and glistening by mucus that is secreted by the nur major salivary glands. This thin film of mucus covers and protects all int the teeth, which are bathed by saliva. Saliva rinses away bacteria, provic phosphate and bicarbonate) that neutralize acids created by bacteria that contains antibacterial agents, and minerals required for tooth remineraliz promotes tooth decay

The submucosa under the lining mucosa is composed of fairly loosely arr which contains larger blood vessels, lymphatics, nerves, adipose tissue, a salivary glands. Where the mucosa is in close proximity to the underlying palate), there is no submucosa and the fibers of the lamina propria are c to bone. In these areas, the mucosa, lamina propria, and periosteum are membrane and are generally referred to as a mucoperiosteum.

Palate and Uvula

The roof of the oral cavity is formed by the palate; the anterior two-thirds palate, and the posterior one-third is comprised of the soft palate. The pa and nasal cavities. Anteriorly and laterally, the palate is bounded by the posteriorly, it is continuous with the soft palate. The hard palate is cover which has a series of ridges (palatal rugae) running across, but not cross ridges are easily seen and palpated and can be felt with the tongue. The connective tissue fibers of these ridges pass directly from the papillary lay into the underlying bone. In the anterior lateral regions of the hard palat fat tissue, whereas more posteriorly its lateral regions contain minor sali glands), which are pure mucous glands (Figure 15.13).

The soft palate is the mobile portion. With no bony support, it is suspend border of the hard palate like a curtain. Its oral surface is covered by lini surface, which is continuous with the floor of the nasal cavity, is mostly epithelium. The soft palate contains fibers of striated muscle, blood vesse 15.14). Larger mucous glands underlie the oral epithelium of the soft pa groups of mixed glands are present on the nasal surface under the respir middle of the posterior border of the soft palate hangs a small, conical pr uvula. The uvula is microscopically similar to the

soft palate (Figure 15.15). It contains predominantly mucous glands and more sparse from the proximal to the distal end. The musculus uvulae mu mucosa of the uvula. Mast cells, usually located around blood vessels, are

Floor of the Mouth

The mucous membrane of the floor of the mouth is thin and loosely attac structures. The rete ridges are short. The submucosa contains some adip minor salivary glands (sublingual mucous glands).

Tonsils

The tonsils are organized aggregates of lymphoid tissue covered on their mucous membrane. The close proximity of lymphocytes to the surface ep direct internal transport of foreign material from the exterior. Epithelial-li further aid in trapping foreign material. Tonsils normally lack a prominent contrast to lymph nodes, which have a capsule and subcapsular sinus tha

delivery through afferent lymphatics. The mucosa lining the palatine and stratified squamous epithelium, whereas the mucosa overlying the pharyn pseudostratified ciliated respiratory type epithelium that contains occasion epithelium lining the crypts or folds represents an extension of the regio However, the epithelial lining of some crypts in the palatine tonsil may o respiratory mucosa. The palatine tonsil contains 10 to 30 crypts that may juxtacapsular region. In the lingual tonsil (Figure 15.16) and pharyngeal epithelium forms only shallow folds 0.5 to 1.0 cm deep. Sulfur granules c and other *Actinomyces* -like oral flora are a frequent finding within tonsill nodes, the lymphoid component may contain lymphoid follicles, some wit Intraepithelial lymphocytes within the surface and crypt-lining epithelium is commonly observed (Figures 15.17 ,15.18) and merely reflects the nc lymphocytes. Sometimes the epithelium is so heavily infiltrated by lympho

distinguishable. Intraepithelial lymphocyte trafficking primarily overlies s follicles (Figures 15.19 ,15.20), resembling Peyer's patches of the small Intraepithelial lymphocytes of the surface mucosa are predominantly T ce and CD8+), whereas those present within the crypt epithelium include both The epithelial cells of lymphoepithelium (known as M cells) exhibit numer microfolds. At the ultrastructural level, intraepithelial lymphocytes have be within intracytoplasmic compartments that communicate with each other network of channels (37).

Table 15.2 Minor Salivary Glands of the Mouth, Nose, and Parana

Minor Salivary Glands

Numerous small salivary glands are scattered throughout the submucosa o and paranasal sinuses, as well as adjacent to the palatine and pharyngeal not encapsulated and are named by their location. They can be classified mixed seromucinous types (Table 15.2). These glands produce secretions major salivary glands, which empty onto the mucosal surface through nu ducts. The secretory activity of these glands appears to be continuous, al to specific local chemical or physical stimuli.

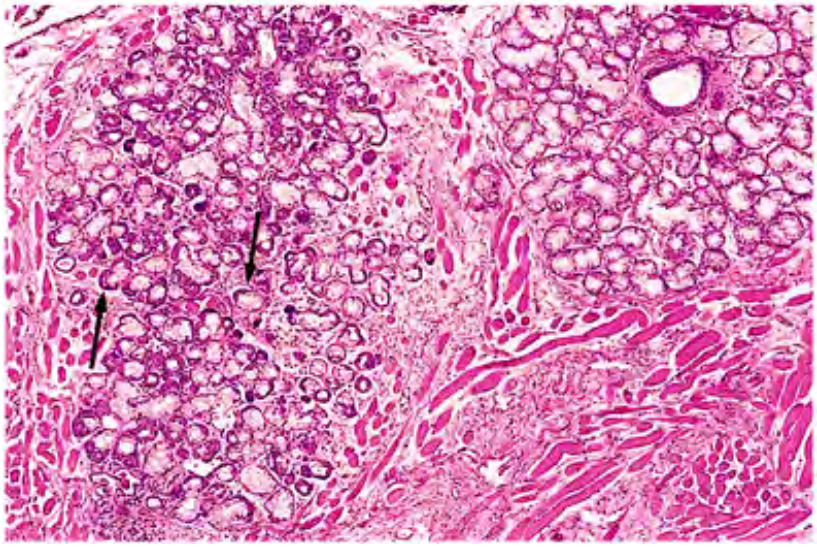

Figure 15.22 Minor salivary glands in the uvula are surrounded by cross gland with the distinct duct is of the pure mucous type. The other gland serous cells forming darker staining crescents (*arrows*).

Structurally, the minor salivary glands are compound tubular or tubuloaci portions are the acini that are designated according to their secretion as Within mixed acini, the mucous cells are nearest to the excretory duct, w at the cul-de-sac of the acini and appear as crescents, called the demilun 15.22 ,15.23). The mucous acini are more tubular than those of the sero are also larger,

and their flattened nuclei are present at the cell bases. The mucous cells cytoplasm in H&E-stained sections (Figure 15.13) and will also stain witl Schiff (PAS), or mucicarmine (39 ,40). The smaller serous cells have mo and have an eosinophilic cytoplasm that contains zymogen granules. Cor

are wrapped around the acinus and assist by squeezing the secretion from excretory ducts (41). The myoepithelial cells of the minor salivary glands immunoreactive with antibodies to cytokeratin (CK5, CK14, and CK17), to (smooth muscle actin, h-caldesmon, calponin), p63 (nuclear immunoreacti 100 protein (42). It should be noted that melanocytes may be found in of minor salivary glands (43).

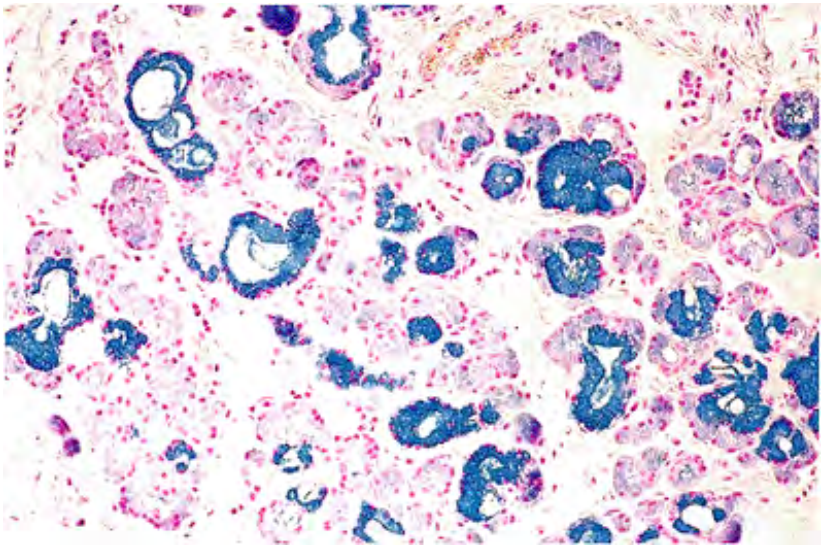

Figure 15.23 Mixed minor salivary gland of the uvula. Acid mucopolysac are stained turquoise (Alcian blue at pH 2.6).

It is important to note that the minor salivary glands, wherever they occu paranasal sinuses, can become involved by the same pathologic processes glands. This is especially true for neoplasms, which arise from various ce minor salivary glands.

The surgical pathologist must be well aware of the fact that squamous me excretory ducts and acini of minor salivary glands. For instance, epithelia of various types may lead to squamous metaplasia that can mimic squam example of this is seen in necrotizing sialometaplasia or in irradiated saliv case, the diagnostic dilemma is usually compounded by the possibility of squamous cell carcinoma. Oncocytic cells may be found in minor salivary and distribution patterns (Figure 15.24). Oncocytes (â€œswollen cellsâ€• columnar epithelial cells with a finely granular eosinophilic cytoplasm that

many exocrine or endocrine glands (44). Up to 60% of their cytoplasm is mitochondria that can be visualized after long-term (48 hours) staining v hematoxylin on fresh-frozen sections incubated for the histochemical dem mitochondrial enzyme activity, by means of immunohistochemistry (e.g., antibody), or by electron microscopy. Oncocytes are benign cells that occ frequency in older persons. They develop due to metaplasia of ductal and However, the etiology and functional significance of oncocytic metaplasia is salivary glands, oncocytes can be seen in nodular or diffuse oncocytosis, even oncocytic carcinomas (47).

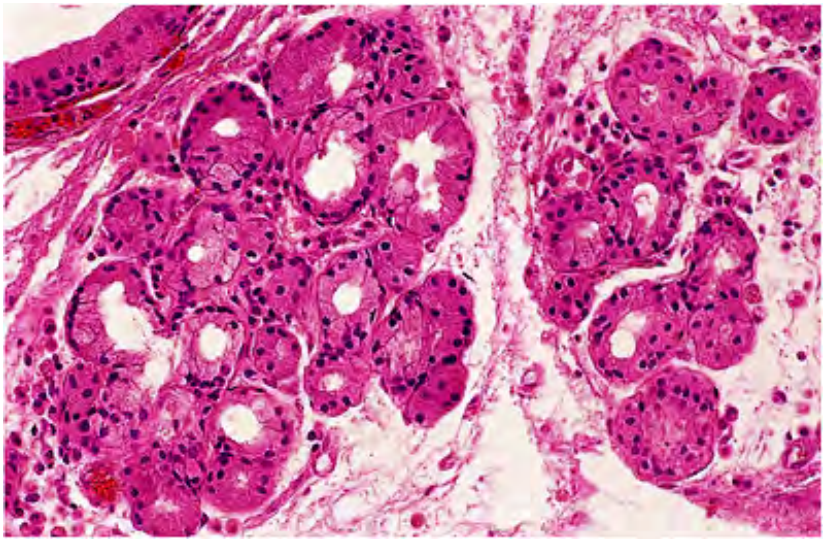

Figure 15.24 Oncocytes in minor salivary gland appear as cuboidal swolle granular oxyphilic cytoplasm.

Cheeks

The skin of the cheek is part of the facial skin. The inner surface of the c squamous lining mucosa. The submucosa contains some fat cells and man the mixed type, embedded in loose connective tissue. The mucosa and su underlying buccal musculature by connective tissue fibers.

Juxtaoral Organ of Chievitz

Deep in the wall of the cheeks overlying the angle of the mandible sits a

small fusiform structure, the juxtaoral organ (JOO) of Chievitz, which is r buccotemporal space (48 ,49). In adults, it measures 0.7 to 1.7 cm in ler diameter and persists throughout life. It is multilobulated, has a dense fi of round or elongate nests of nonkeratinizing squamouslike epithelial cells organized connective tissue stroma that is rich in small nerves and senso two to four branches of the buccal nerve (50). The connective tissue env inner stratum fibrosum internum, middle stratum nervosum, and outer s These nests of epithelial cells appear in a cluster on histologic sections, l them to be small sprouts and folds in continuity with a mass of epithelium sections through different portions of the JOO can show considerable varia of epithelial sprouts (Figure 15.25). The larger nests of epithelium are co clear PAS-positive cytoplasm and round or oval nuclei, forming â€œlight bridges can be seen toward the center of the cell nests. The cells in the s whorl-like or concentric arrangement. Occasionally, a glandlike lumen or a colloidlike mucin-negative material is encountered. Melanin pigmentation h JOO (51). The central epithelial cells of the JOO appear to be immunore whereas the outer

more basaloid cells are usually keratin negative. The cell nests are also p epithelial membrane antigen (EMA) but are negative for S-100 protein, g (GFAP), neurospecific enolase (NSE), synaptophysin, and chromogranin (5

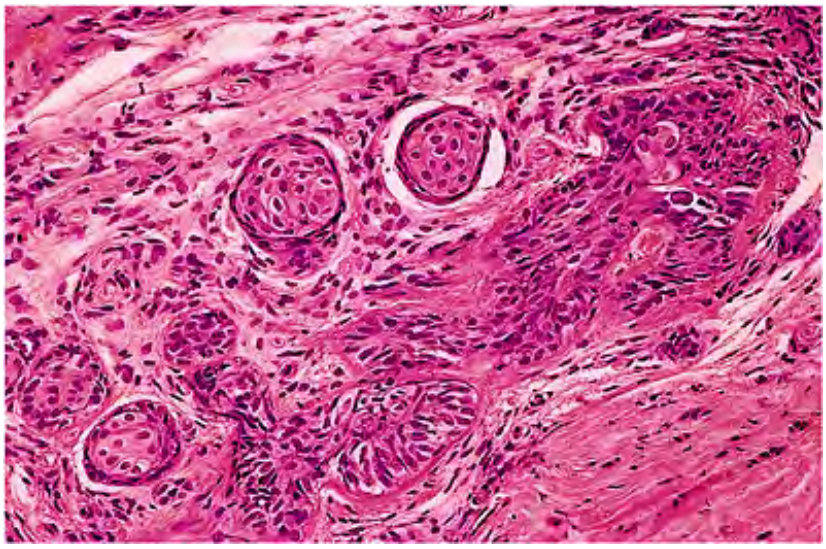

Figure 15.25 Juxtaoral organ of Chievitz. Small nests of nonkeratinized

are delineated by basement membrane. The elongated cells outside the e fibroblasts and Schwann cells. Nerve is seen below and to the right.

The seemingly esoteric and minute JOO has considerable importance for because the presence of squamous epithelial nests intimately admixed wi may be misinterpreted as perineural invasion by squamous cell carcinoma astute pathologists aware of this pitfall have, in a case of a mucoepiderm lymphatic spread in the retromolar region, correctly recognized the epithe organ (55). Such cases unequivocally demonstrate the importance of awa organ. Cases of clinically enlarged (56) and hyperplastic JOOs have been far no carcinoma originating from it has been reported. The function of th Johan Henrik Chievitz, a Danish anatomist, described this structure in 188 embryo (58), it has been widely believed that the organ of Chievitz is a representing an abortive salivary gland anlage. More recently, the possibi and receptor function of the organ has been raised (59). The JOO has be pacinian corpuscles (60), supporting its mechanosensory function. For a literature, the reader is referred to the small monograph by Zenker (49) Pantanowitz and Balogh (59). Finally, we would like to alert our readers benign epithelial islands may reside within peripheral nerves in the maxilla).

Tongue

Situated in the floor of the mouth, the tongue is an organized mass of c invested by mucous membrane. Its muscles are partly extrinsic (i.e., have tongue) and partly intrinsic, being contained entirely within it. The bundl are embedded in connective tissue with some adipocytes and are arrang tongue is well-supplied with blood vessels that form numerous anastomos endowed with myelinated and nonmyelinated nerves containing motor, se nerve fibers, some with ganglion cells. The ventral (under) surface of the smooth lining mucosa that has short, blunt rete ridges (Figure 15.26). I the connective tissue that intersects with the ventral muscle bundles of t

The dorsal (upper) surface of the tongue is divided into an anterior and p shaped shallow groove, the sulcus terminalis. The anterior two-thirds of th

lined by specialized mucosa, which is bound by connective tissue fibers t muscle of the tongue. This specialized mucosa is modified keratinized sq with small projections (papillae) that are visible to the naked eye. The pa of these papillae so as not to mistake them for papillary epithelial hyperp hairy leukoplakia. According to their shape, the papillae can be filiform, f circumvallate. The great majority are filiform papillae, conical projections epithelium (Figure 15.27). Among these are scattered the fungiform pap elevations above the surface of the tongue; their surface is not keratinize Clinically, fungiform papillae appear as small red nodules because the thi mask the underlying vascular connective tissue. Microscopically, fungiform misinterpreted as denture-induced fibrous hyperplasia or small traumatic papillae are located posteriorly along the sides of the tongue. At

the junction of the anterior two-thirds and the posterior one-third of the circumvallate papillae. These are the largest papillae, measuring 0.1 to 0.2 arranged in a V-shape immediately anterior to the sulcus terminalis. The number 6 to 12. A small, ring-shaped furrow surrounds each circumvallat from a circular, palisade-like mucosal elevation (vallum), which is the outc circumvallate papilla (Figure 15.29).

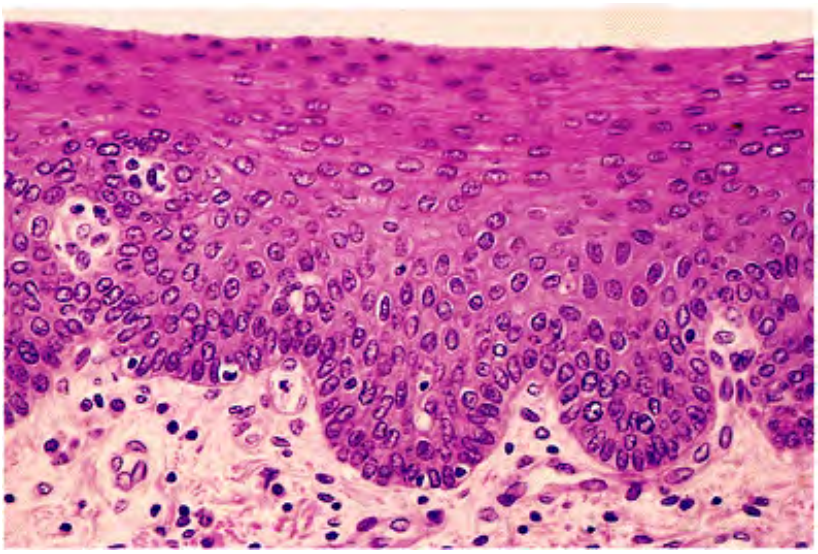

Figure 15.26 Ventral surface of tongue. The stratified nonkeratinized squ lining mucosa has a slightly wavy interface with the lamina propria. A fe are seen in the lamina propria and in the epithelium.

Figure 15.27 Dorsal surface of tongue. Filiform papillae have a connectiv secondary papillae with pointed ends. The superficial squamous cells are slender, pointed rete ridges.

Taste buds are present in large numbers on the side of the circumvallate numbers on the fungiform and foliate papillae, as well as elsewhere on th aspects of the tongue. These small epithelial organs stain lighter than th Like other simple epithelia, taste buds express low-molecular weight kerat accordingly, they are immunoreactive with the antibody CAM5.2 (Figure 1 serous glands (Ebner's glands) are located under the circumvallate papilla glands empty their secretion into the small furrow around each papilla; t out the furrows, thus facilitating perception of new tastes (Figure 15.29) barrel-shaped intramucosal sensory receptors that occupy the full thicknes communicate with the surface through a small opening, the gustatory pore taste buds are composed of three types of cells: (a) gustatory or taste ce sustentacular, cells, and (c) basal cells. The taste cells are crescent-shap

cytoplasm, and possess numerous

fine microvilli that protrude through the taste pore as gustatory hairs. The cells has intimate contact with many fine nerve terminals that leave throu membrane and become myelinated outside the taste bud. The supporting crescentic, extending between the basement membrane and the surface; t taste bud and are also scattered between the gustatory cells. The support cytoplasm and possess microvilli that also protrude through the taste pore situated between the bases of the other cells, give rise to the other cells

The apex of the V-shaped sulcus terminalis projects backward and is mark foramen cecum, which is an embryologic remnant indicating the upper en Correspondingly, ectopic thyroid tissue can occur at the base of the tongu anywhere along the tract of the thyroglossal duct caudally (Figure 15.32 thyroid resembles normal thyroid tissue. However, the surgical pathologist presence of thyroid glands within muscle may mimic carcinoma. Ectopic t all the physiologic and pathologic changes of the thyroid gland proper.

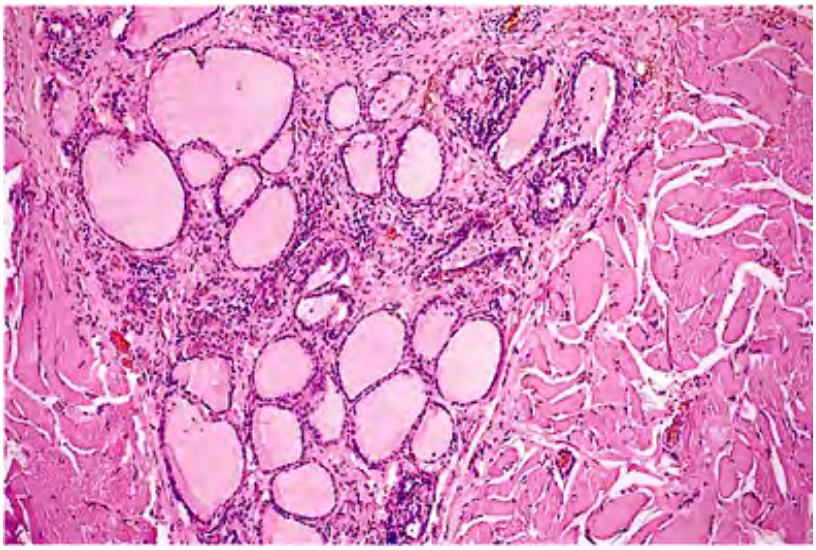

Figure 15.32 Lingual thyroid. The glandular parenchyma is embedded in thyroid tissue is not encapsulated, and care should be taken to avoid mis growth.

Gingiva

The gingiva (gum) is that portion of the oral mucosa that surrounds the n collar. Masticatory mucosa (i.e., parakeratinized or keratinized stratified covers the gum. There is no submucosal layer. Instead, the connective tis contains collagenous fibers that bind the epithelium tightly to the underl and bone. The gingival epithelium interdigitates with the underlying conn interconnected rete ridges that are separated by connective tissue plates 15.33 ,15.34). The gingival epithelium is divided anatomically into oral junctional epithelia. The cytokeratin expression profile of gingival epitheliu anatomical division (Table 15.1).

Oral gingival epithelium that extends onto the oral surface of the gum be of masticatory mucosa. The short portion of gingiva apposed to the tooth from the rest of gingival epithelium in that it is thinner, lacks the charact not keratinizing (65 ,66).

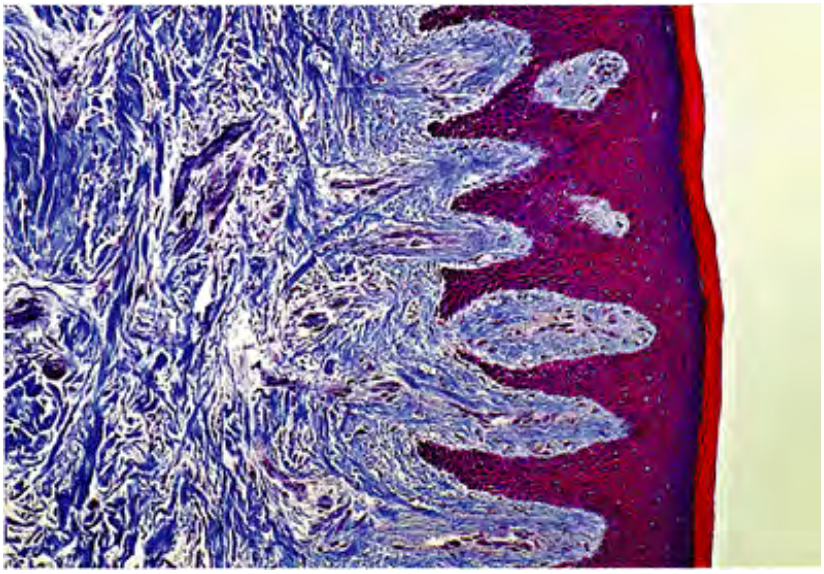

Figure 15.33 Gingiva (gum). The masticatory mucosa has tall rete ridges collagen fibers (blue) tightly anchors the epithelium to the underlying bon layer (orange band) on the surface of the epithelium imparts further strer trichrome).

The gingiva is highly vascular; its vessels originate in the periodontium ar propria, forming well-organized capillary loops. Occasionally random biopsi performed to support the diagnosis of systemic diseases (e.g., amyloidos

Intraepithelial Nonkeratinocytes

Four different nonepithelial cell types normally occur in the oral mucosa: Langerhans cells, and lymphocytes.

Melanocytes are found mainly in a basal location in the oral mucosa; they people with darker complexions (67 ,68). Small areas of melanin pigmen mm in diameter, may occur. They are most common on the gingiva but ar palate, and buccal mucosa and are called mucosal melanosis (melanotic r 15.35). Melanin pigment formed by melanocytes in the basal layer is tra epithelial cells. Such changes can sometimes occur after inflammatory rea Peutz-Jeghers syndrome and Addison's disease, or secondary to drugs ar virus (HIV) infection. Melanocytic hyperplasia (lentigo) and pigmented nevi oral mucosa but less commonly than on the skin (70 ,71 ,72 ,73). Histolo increased melanin pigmentation in the basal cell layer without an increase melanocytes. Intramucosal nevi, similar to intradermal nevi, are the most Other types of nevi, such as compound nevi, junctional nevi, blue nevi, ar observed on the vermilion border, cheek mucosa, gingiva, palate, and to primary malignant melanomas can arise anywhere from the oral mucosa (

Merkel cells also occur in the basal layer of the oral epithelium, either inc). Clusters are preferentially located in masticatory mucosa in close conta supports the notion that they have a mechanoreceptor function. On routi their cytoplasm appears lighter than that of the surrounding basal cells. are morphologically and functionally identical to those in the skin. They a antibodies to S-100 protein, chromogranin, CK20, and villin. Their ultrast many intracytoplasmic dense-core, membrane-bound granules, 80 to 100 15.36).

Langerhans cells, mostly located suprabasally, are microscopically similar cannot be distinguished with certainty in routine H&E-stained sections. In Langerhans cells are structurally and functionally similar to those in the s

cytoplasm appears clear, and their small indented (â€œcoffee beanâ€•) hematoxylin. Their dendritic processes, spread among the cells of the stra seen well with the immunohistochemical stain for S-100 protein (Figure 1 the MHC class II

molecules (e.g., HLA-DR), and various adhesion molecules (78). Electron characteristic Birbeck granules in their cytoplasm and a lack of tonofilame frequency of oral mucosal Langerhans cells varies inversely with the degr are quantitatively lowest in the floor of the mouth and do not occur only the taste buds and in epithelium lining periodontal pockets.

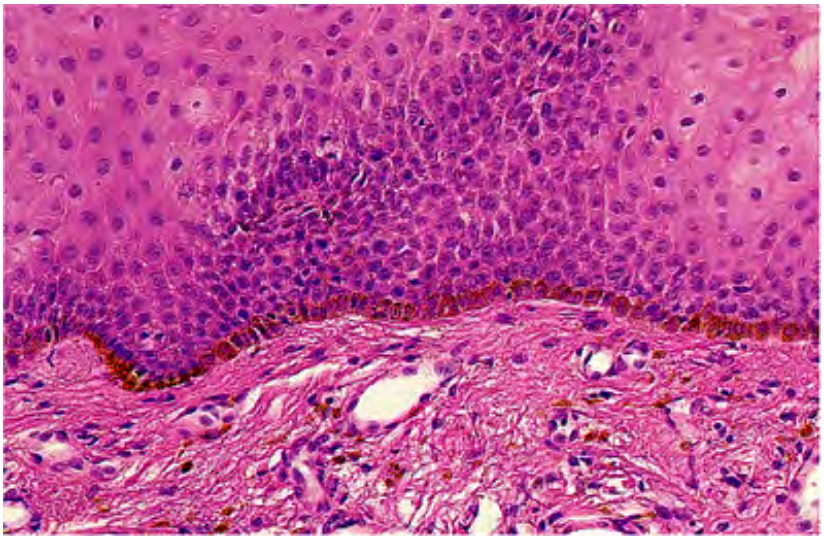

Figure 15.35 Mucosal melanosis of the lip. Numerous melanocytes above as a brown ribbon.

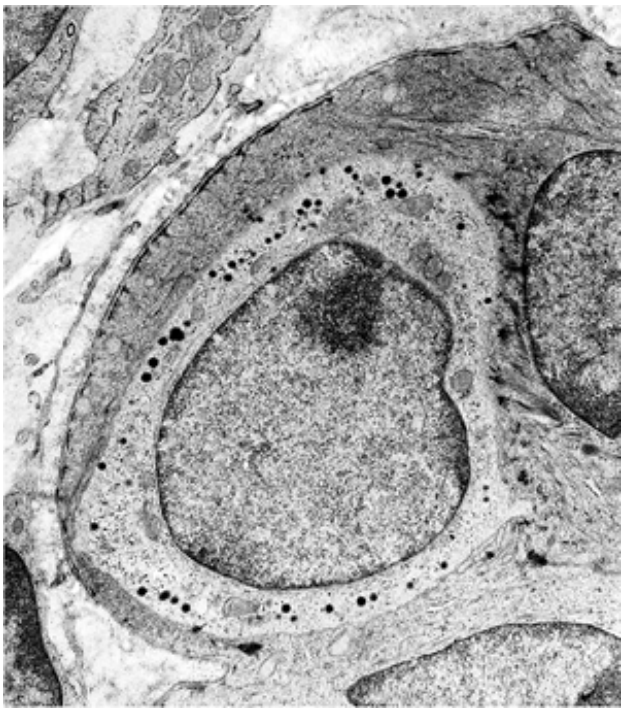

Figure 15.36 Merkel cell surrounded by keratinocytes in the basal layer micrograph shows the lighter-staining cytoplasm with characteristic and membrane-bound, dense-core granules. The nucleus has no fibrous lamin adjacent dermis contains fibroblasts. (Original magnification Ã—11,500.)

Langerhans cells play an important role in the immune response, being ir and presentation of antigens to subjacent lymphocytes. An increased num seen in biopsy samples of the oral mucosa in oral lichen planus, associate tobacco and alcohol consumption, and in tumor epithelium of invasive ora carcinoma.

Teeth and Supporting Structures

The deciduous and permanent teeth have a similar microscopic appearance bony sockets on the alveolar processes of the maxillae and the mandible. lies within the socket is called the root; there may be multiple roots. The the apex. The alveolar processes are covered by the gum, and the crowns above the gums. The roots of the teeth are held securely in their sockets fibers called the periodontal ligament (periodontal membrane) (12 ,66). the tissues investing and supporting the teeth: the cementum, periodonta

bone, and gingiva (Figures 15.38 ,15.39). The center of each tooth has a

pulp chamber, or pulp cavity, that is filled with dental pulp containing lo nerves, blood vessels, and lymphatics (79) (Figure 15.40). The pulp ch root and becomes the root canal. The vessels and postganglionic sympath fibers enter and leave the root canal through a small opening, the apical chamber of the growing tooth is lined by a single continuous layer of odo columnar cells with oval nuclei. An elongated cell process, also known as each odontoblast into the extracellular matrix secreted by them (Figure 1 the odontoblastic process eventually mineralizes, so that Tomes' fiber com tubule (80 ,81). Besides the odontoblastic process, the tubules also cont unmyelinated nerve fibers, which account for the well-known sensitivity of arranged in the shape of tubules running from the pulp chamber toward tubules and the meshwork of collagen between them are embedded in hy weight basis, 80% of dentin consists of inorganic calcium salts and 20% o harder than bone but softer than enamel. Dentin makes up most of the wa mature tooth, many odontoblasts become inactive, but some continue pro reduced rate throughout the life of the tooth. In response to physiologic odontoblasts can upregulate their protein synthetic activity.

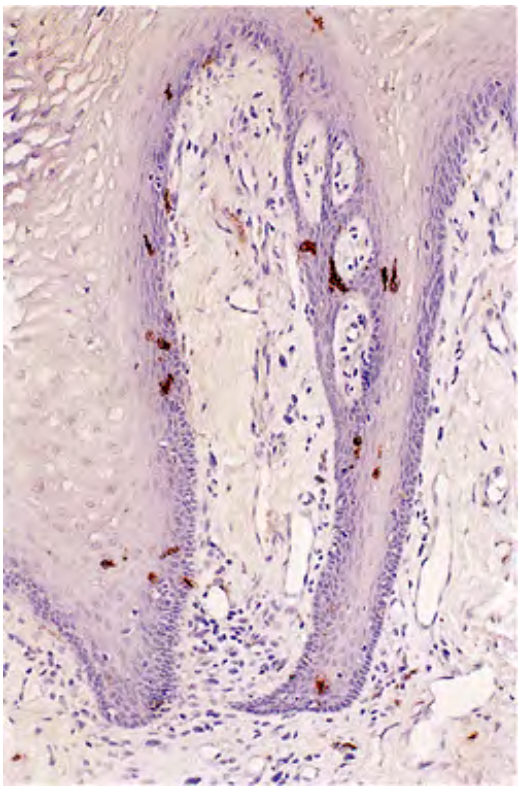

Figure 15.37 Langerhans cells in mucosa of tongue. Dendritic cells in th demonstrate immunoreactivity for S-100 protein.

As the dental pulp ages, the number of fibroblasts decreases and, concon size of collagen fibers increases. Pulp stones (denticles) are commonly ob of aging individuals. True denticles contain dentinal tubules within a mine surrounded by odontoblasts. False denticles are composed of a mineralize concentric lamellae. Most denticles are asymptomatic.

Enamel covers the crown of the tooth. It is the hardest material found in 99.5% apatite crystals (82). Mature enamel is made up of long thin rods decalcification and are therefore not seen on conventional histologic sect junction lies at the former interface between the inner enamel epithelium Coronal dentin is covered with enamel, and radicular dentin is covered w cementum covers the root of the tooth. A slight indentation (cervical line) marks the junction of the crown with the root.

The cementum joins the enamel at this junction (cementoenamel junction)

structure and composition to bone but has fewer cells, called cementocyte (10 ,11). It is composed of 55% organic material (mainly calcium) and 4 Cementum is attached by the periodontal ligament to the surrounding bon persons, many cementocytes die, and only the surface layer appears viab phenomenon are cementicles, which are small round calcified bodies on or the periodontal ligament. Cementicles are of no clinical significance.

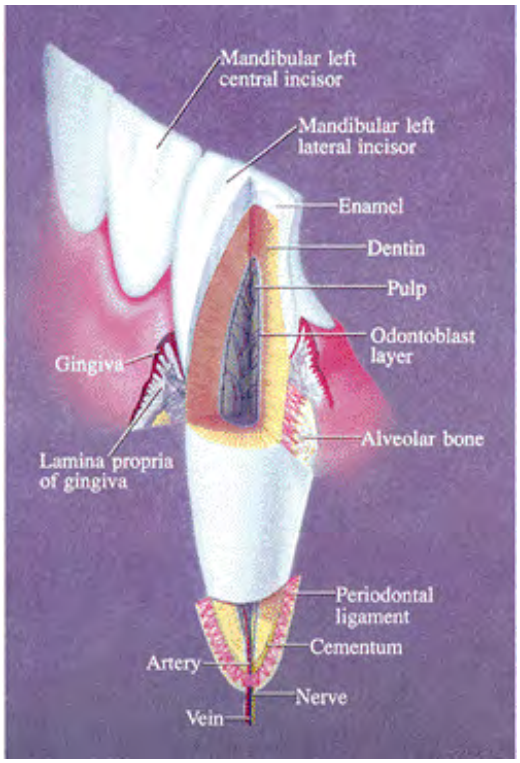

Figure 15.38 Schematic drawing depicts the periodontium including the periodontal ligament, and cementum.

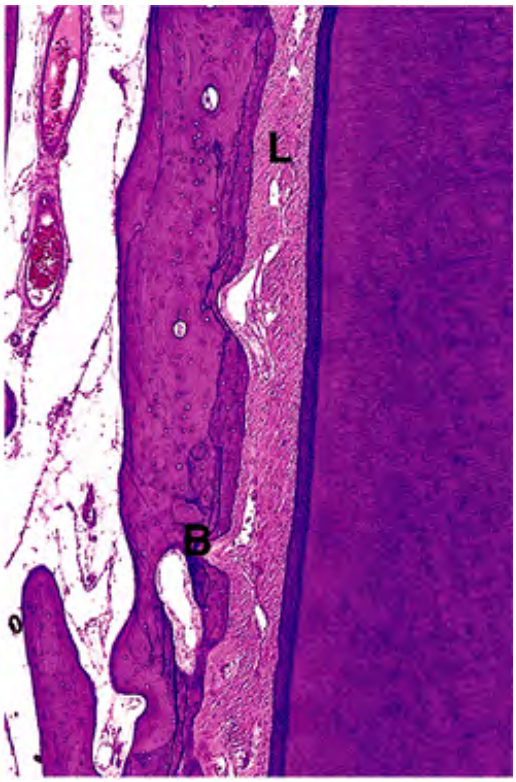

Figure 15.39 Root of tooth and supporting structures, perpendicular sect a thin layer of cementum (appearing as a blue band). The periodontal liga in the bony socket of the alveolar process (*B*).

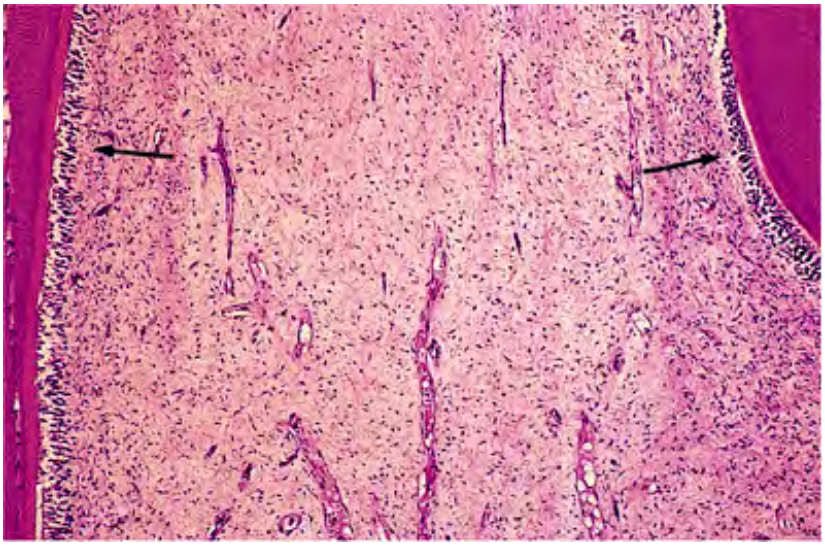

Figure 15.40 Pulp of developing tooth. Odontoblasts (*arrows*) line denti of loosely arranged fibroblasts. Note the delicate wall of blood vessels.

From the pathologist's point of view, it is noteworthy that examination of neoplastic growth in most cases shows tumor invading the periodontal lig bone, destroying these structures. The roots of the teeth may remain inta resorption. However, the dental pulp is rarely invaded by neoplasm.

Odontogenic epithelium changes over time. Before tooth eruption, it consi epithelium, inner enamel epithelium, stellate reticulum, Hertwig's epithelia lamina; after complete tooth formation, it comprises the epithelial rests c odontogenic epithelia express cytokeratins 5, 8 and 19 (83). In addition, epithelium and stellate reticulum also express cytokeratins 7, 13, 14, 17, epithelium, cytokeratins 14 and 18; dental lamina, cytokeratins 7, 13, an of Malassez, cytokeratins 14 and 19. During odontogenesis, CK14 express gradually replaced by CK19. Odontogenic epithelium is the source of odor neoplasms, which explains why CK19 is present in almost all epithelial ce

Pathologic Correlates of the Rests of Serres an Malassez

Developmental remnants of the dental lamina, called the rests of Serres, gum as small nests of squamous epithelium (10 ,14) (Figures 15.2 , 15.4 islands may proliferate and undergo cystic degeneration, which leads to t cysts. Similarly, epithelial remnants of Hertwig's root sheath, called the r universally present in the periodontal membrane and, exceptionally, even i alveolar ridge. When dental caries cause a bacterial infection and necrosis usually spreads toward the apical foramen, and a periapical granuloma ma the inflammatory stimulus, the nearby epithelium of the rests of Malassez forms an epithelial lining in these apical granulomas (Figure 15.41). It is rests of Serres and the rests of Malassez are potential sources of amelob cysts.

Nose and Paranasal Sinuses

External Nose and Nasal Vestibule

The external nose is covered by skin that is rich in sebaceous glands, sw
The anterior skin of the nares and widened nasal vestibule, lined by skin

continuous with the integument of the nose, similarly contains many hair and sweat glands. The squamous epithelium of the vestibule merges with which covers the respiratory portion of the nasal cavity and all of the pa

Larynx

Definition and Boundaries

The larynx is a complex organ with numerous connective tissue elements and a variety of epithelia. The superior border of the larynx is the tip of the epiglottis and the aryepiglottic folds. The inferior limit is the inferior rim of the cricoid cartilage. The anterior boundary is composed of the lingual surface of the epiglottis, the thyroid cartilage, the anterior arch of the cricoid cartilage, the thyrohyoid membrane, and the cricothyroid membrane. The posterior boundary is the cricoid cartilage and the arytenoid region. The piriform fossa is frequently, and erroneously, considered to be a part of the larynx. In reality, it is a pouch of the hypopharynx that passes on each side of the larynx. It is, thus, a conduit for food and water, not air.

Although not part of the larynx per se, the pre-epiglottic space is an important area for the spread of carcinoma. This more or less triangular space is filled with fat and loose connective tissue. It is bounded posteriorly by the epiglottis, anteriorly by the thyroid

cartilage and thyrohyoid membrane, and superiorly by the hyoepiglottic ligament.

Embryology

The supraglottic portion of the larynx is derived from the third and fourth branchial arches and is, therefore, related to the development of the oral cavity and oropharynx. The glottis and subglottis arise from the sixth branchial arch, which also give rise to the trachea and lungs. Bocca et al. (1) have demonstrated that the larynx virtually consists of two hemilarynges (superior and inferior), each of them with its own different derivation and its own largely independent lymphatic circulation. These authors also discuss the importance of this embryologic derivation with respect to the origin and spread of laryngeal carcinoma. Each of these hemilarynges may become invaded by cancer independent of one another. The extension of cancer is often limited within the boundaries of this embryologic demarcation (1).

The first embryologic appearance of the respiratory apparatus occurs at approximately 21 days in the 3-mm embryo. At this time, an evagination, or groove, forms adjacent to the superior portion of the foregut, above the fourth branchial arch. The inferior portion of this evagination is the pulmonary anlage. The first portion of the larynx to develop is the epiglottis, but this does not appear as a definitively formed structure until approximately the fifth week of intrauterine development.

The outline of the larynx is recognizable in the 6-mm embryo. At this time, the respiratory groove described previously begins to close; this closure is completed with the formation of the arytenoid cartilages. By 60 to 70 days, at the stage of the 30-mm embryo, the vocal cords begin to differentiate. The embryonic development of the larynx is complex, and it is not surprising that at least 30 different congenital malformations have been described (2).

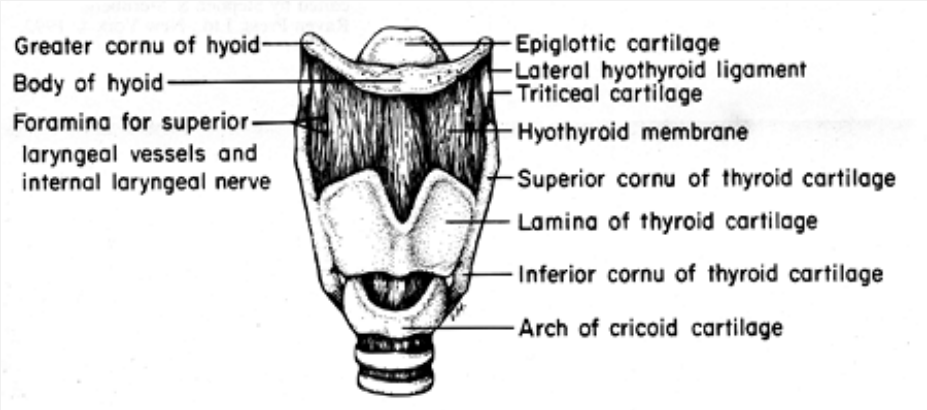

Figure 16.1 Anterior view of an unopened larynx shows the lamina of thyroid cartilage, the arch of the cricoid cartilage, and the hyothyroid membrane as the major structures that define the anterior external surface of the larynx. (From: Mills SE, Fechner RE. Pathology of the larynx. *Atlas of Head and Neck Pathology Series.* Chicago: American Society of Clinical Pathologists Press; 1985.
)

Gross and Functional Anatomy

The larynx is composed of an elastic cone, cartilages, intrinsic and extrinsic muscles, submucosa, and an overlying mucous membrane (Figures 16.1,16.2,16.3). The elastic cone provides most of the structural strength to support the true vocal cords. The elastic tissue is thickened just under the mucosa of the free edge of the cord. This portion of the elastic cone is referred to as the vocal ligament. It is visible grossly as a white band beneath the mucous membrane (Figure 16.3). The vocal ligament inserts on the thyroid cartilage anteriorly and the vocal process of the arytenoid cartilage posteriorly (Figure 16.4).

The major cartilages of the larynx are the cricoid, thyroid, and the paired arytenoid cartilages (Figure 16.5). These major structural cartilages are all of hyalin type. The epiglottis, in contrast, is composed of elastic cartilage containing numerous fenestrations. Calcification of the thyroid and cricoid cartilages begins during the second decade of life in males and somewhat later in females. In older individuals, the thyroid cartilage is frequently ossified, replete with fibrofatty and hematopoietic bone marrow elements. The ossification of the thyroid cartilage is important in regard to the spread of laryngeal carcinoma. This cartilage is involved by continuous or metastatic carcinoma only when ossified. Hyalin cartilage, perhaps because of its elaboration of angiogenesis inhibiting factors, is remarkably resistant to the spread of neoplasia.

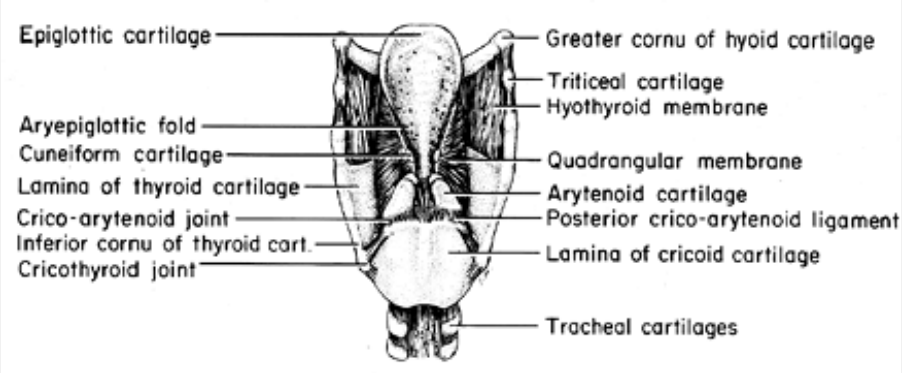

Figure 16.2 Posterior view of an unopened larynx emphasizes the position of the arytenoid cartilages. Major support and posterior definition of the larynx are provided by the lamina of the cricoid cartilage. (From:
Mills SE, Fechner RE. Pathology of the larynx. *Atlas of Head and Neck Pathology Series.* Chicago: American Society of Clinical Pathologists Press; 1985.
)

The cricoid and thyroid cartilages articulate with one another, but their motion is limited by several dense ligaments that anchor the cartilages together. The arytenoid cartilages articulate with the cricoid cartilage. Both the cricothyroid and cricoarytenoid joints are diarthrodial and lined by flattened synovial cells. These tiny joints are susceptible to conditions that more commonly affect larger synovial-lined spaces, such as gout and rheumatoid arthritis.

Each arytenoid cartilage attaches to the thyroarytenoid muscle and has a protrusion, the vocal process, that is the posterior point of insertion of the vocal ligament. The position of the arytenoid cartilage determines the tension of the vocal ligament. During adduction of the cords, the arytenoid cartilages move medially along the facets of the cricoid cartilage; they also pivot or rock (Figure 16.4). The rocking motion causes the vocal processes to move downward and toward the midline to complete the adduction of the vocal cords.

The muscles of the larynx can be divided into two groups. The extrinsic muscles originate from neighboring structures outside the larynx and insert on the thyroid, cricoid, or hyoid cartilages. These muscles include the omohyoid, sternohyoid, sternothyroid, and thyrohyoid muscles; they act as a whole upon the larynx during swallowing.

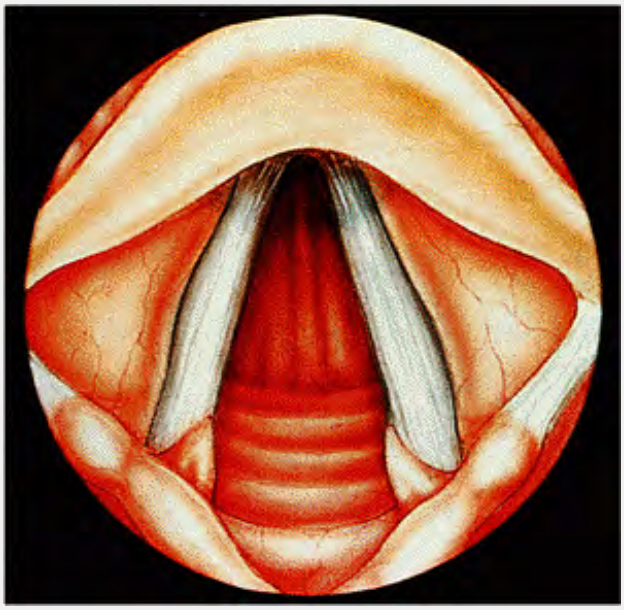

Figure 16.3 Larynx as viewed endoscopically from above. The elastic cone is visible through the mucosa of the true cord as a gray-to-white zone. False cords are loose folds of mucosa without further distinguishing features.

The principle intrinsic muscles of the larynx are the cricothyroid, posterior cricoarytenoid, lateral cricoarytenoid, and thyroarytenoid. There are also small strands of muscle that are in continuity with the thyroarytenoid muscle and insert along the length of the vocal ligaments. This is frequently referred to as the vocalis muscle. It should be remembered that the vocalis muscle is actually a component of the thyroarytenoid muscle, and some authors use these names interchangeably.

The lateral cricoarytenoid muscle adducts the vocal cord, and the posterior cricoarytenoid muscle abducts the cord. During phonation, the thyroarytenoid muscle slightly moves the thyroid cartilage. The degree of contraction of the thyroarytenoid muscle

determines the length and tension of the vocal cord.

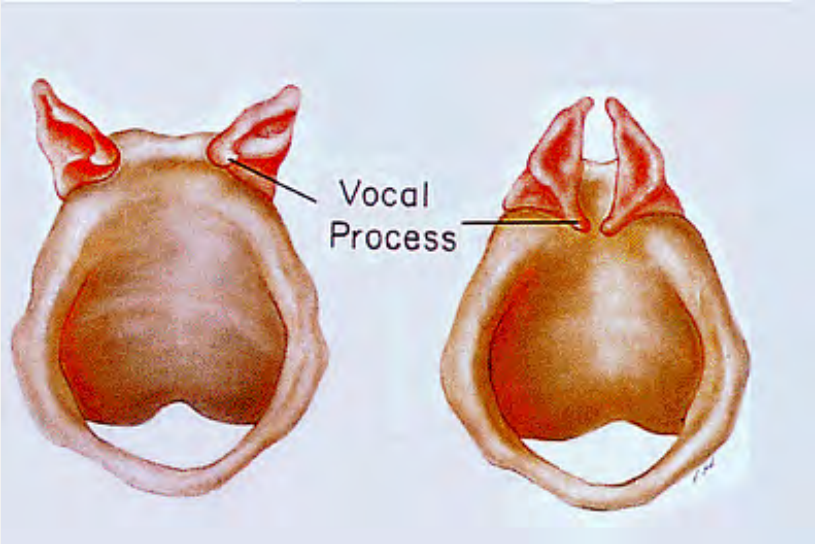

Figure 16.4 The arytenoid cartilage articulates with the posterior lamina of the cricoid cartilage. When the arytenoid cartilages are abducted, they are widely separated and the airway is open (*left*). When adducted, the arytenoid cartilages pivot, as well as move medially, thus bringing the vocal cords together (*right*). (From:
Mills SE, Fechner RE. Pathology of the larynx. *Atlas of Head and Neck Pathology Series.* Chicago: American Society of Clinical Pathologists Press; 1985.
)

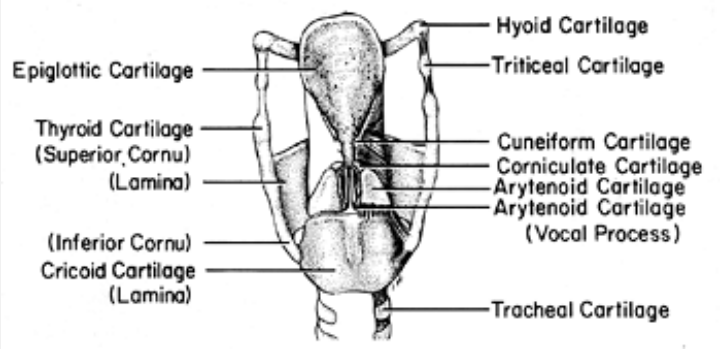

Figure 16.5 The major cartilages of the larynx are better seen in this drawing that deletes the associated soft tissues. (From: Mills SE, Fechner RE. Pathology of the larynx. *Atlas of Head and Neck Pathology Series.* Chicago: American Society of Clinical Pathologists Press; 1985.
)

The larynx can be divided into three major compartments (supraglottic, glottic, subglottic) for purposes of discussing its submucosal and mucosal components. The supraglottic larynx extends from the tip of the epiglottis to the true cord (3). This portion of the larynx also includes the aryepiglottic (arytenoepiglottic) folds, false vocal cords, and ventricles. The arytenoepiglottic folds run posteriorly from the base of the epiglottis to the region of the arytenoid cartilages. The false vocal cords are soft, rounded protrusions of the mucous membrane that lie superior to the true cords. The ventricles form the lower boundary of the false cords and separate them from the inferiorly located true cords. The ventricles extend upward behind the false cords as elliptical pouches. The greatest extension of the ventricles is slightly forward, where they end as dilated, blind pouches called the saccules. Involvement of the ventricle is a

frequent route of superior spread by glottic carcinoma, and this spread may be difficult to detect clinically.

The glottic compartment consists of the true vocal cords and the narrow band of mucous membrane called the anterior commissure, which bridges the vocal cords anteriorly (4,5). The subglottic compartment is the area between the lower border of the true vocal cords, where the squamous epithelium normally ends, and the first tracheal cartilage (6).

Microscopic Anatomy

Studies of larynges from newborns have shown that, except for the true vocal cords, the larynx initially is lined by ciliated epithelium (7) (Figures 16.6,16.7). Squamous epithelium begins to appear on the false vocal cords by about 6 months of age but does not necessarily completely replace the ciliated respiratory mucosa (8,9). The lingual, or anterior, surface of the epiglottis is invariably covered by stratified squamous epithelium. The posterior, or laryngeal, surface of the epiglottis is covered by stratified squamous epithelium in its upper portion, but this merges with

respiratory-type epithelium inferiorly (10). About one-half of nonsmoking adults have patches of squamous epithelium intermixed with ciliated epithelium, both in the supraglottic and infraglottic regions. In smokers, the ciliated, respiratory epithelium of the larynx often is totally replaced by squamous epithelium.

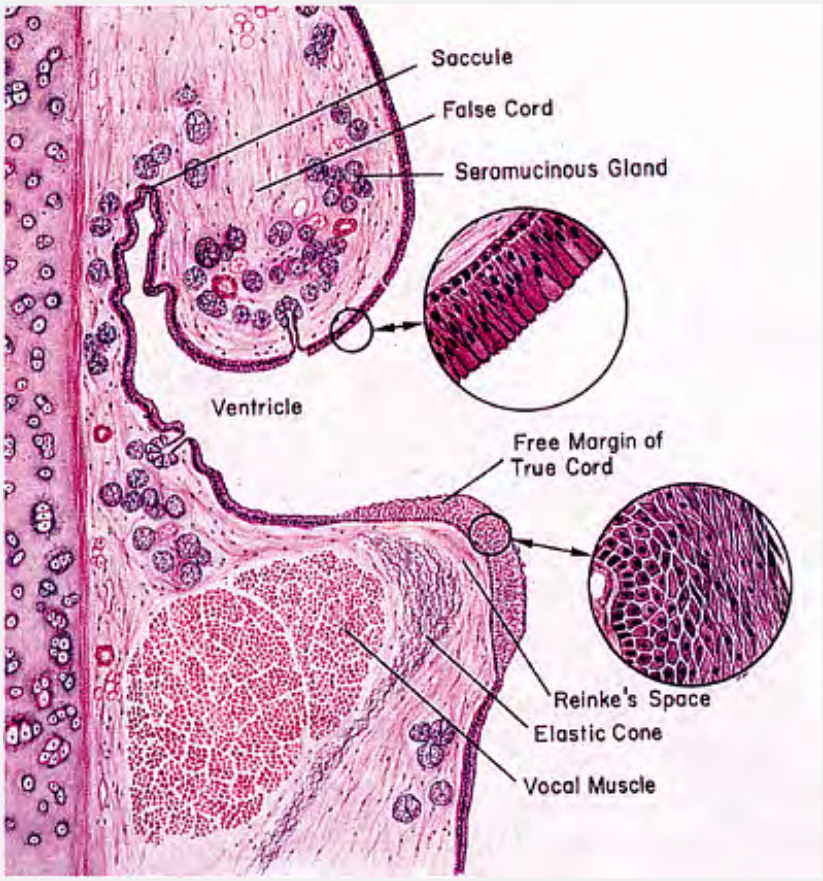

Figure 16.6 Drawing of the normal microscopic anatomy of the larynx. Seromucinous glands are prominent in the false cord, and this cord is lined by ciliated columnar epithelium at birth. The vocalis muscle, elastic cone, and Reinke's space are also visualized in the true cord. (From:
Mills SE, Fechner RE. Pathology of the larynx. *Atlas of Head and Neck Pathology Series.* Chicago: American Society of Clinical Pathologists Press; 1985.
)

The normal ciliated epithelium of the larynx has an innermost layer of small, round cellsâ€”the basal, or reserve, cell layer. This single cell layer of basal cells is overlaid by a second row of

ciliated columnar cells. Variation in the position of the nuclei within the columnar cell layer imparts a pseudostratified appearance to the epithelium. The ciliated layer may vary considerably in thickness (Figure 16.8). Mucus-secreting cells may be numerous or rare. When there is abundant mucin, the cells assume a goblet configuration and may be located either within the middle portion of the epithelium or near the surface (Figure 16.9). Other mucus-secreting cells are barely recognizable and have only a few faintly discernible vacuoles within otherwise eosinophilic columnar cells.

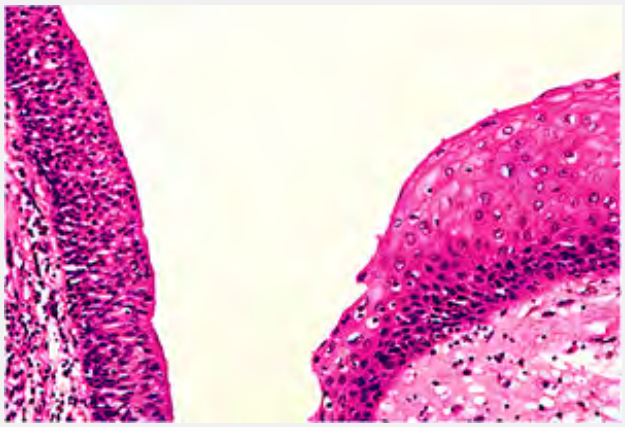

Figure 16.7 Section through ventricle discloses ciliated columnar to intermediate epithelium lining false cord (*right*) and squamous epithelium lining true cord (*left*).

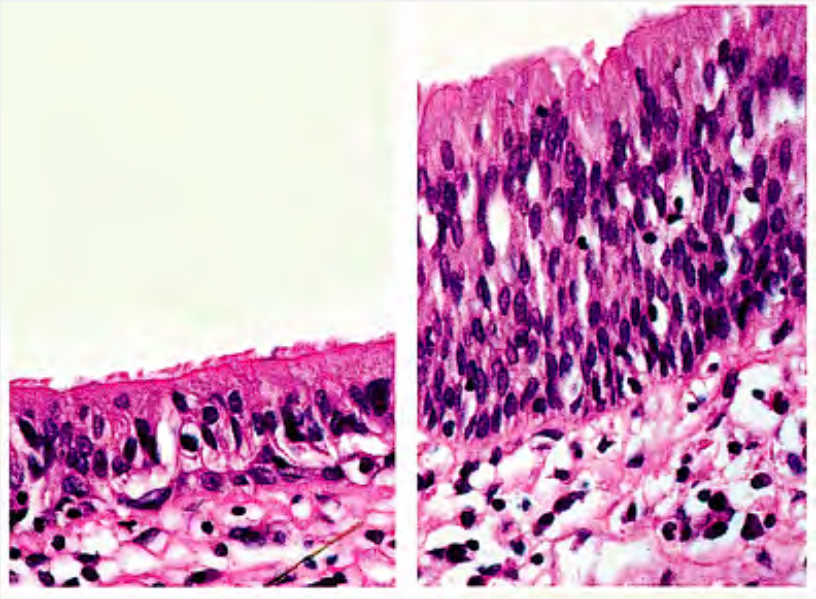

Figure 16.8 The ciliated columnar epithelium of the larynx may be only a few cells in thickness (*left*), or it may form a considerably thicker layer (*right*). (From: Mills SE, Fechner RE. Pathology of the larynx. *Atlas of Head and Neck Pathology Series.* Chicago: American Society of Clinical Pathologists Press; 1985.)

The squamous epithelium of the larynx has a basal layer of small cells with scant cytoplasm and ovoid nuclei that are typically oriented perpendicular to the surface. Mitotic figures are normally confined to this layer. Dendritic melanocytes may be present in the basal layer, especially in African Americans (11,12). The frequency with which this

melanocytic change is observed, and whether it represents a congenital or acquired process, remain unclear. Rare laryngeal malignant melanomas presumably arise in such foci.

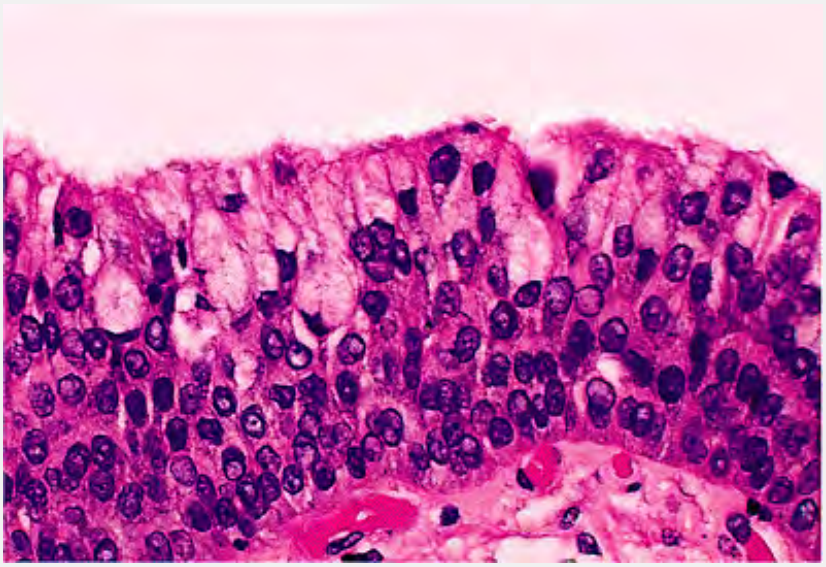

Figure 16.9 Goblet cells and columnar mucinous cells may be present in variable numbers within the nonsquamous epithelium of the larynx.

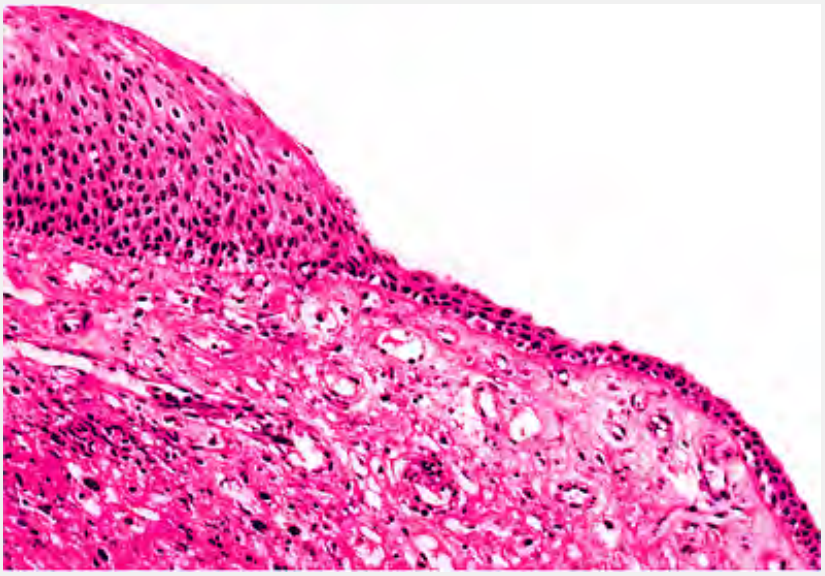

Figure 16.10 The squamous epithelium of the larynx can vary

from approximately 5 cells to over 25 cells in total thickness, even within the same larynx.

As the squamous cells in laryngeal mucosa mature and migrate toward the lumen, the nuclei enlarge, assume a more spherical shape, and have more vesicular chromatin. The eosinophilic cytoplasm becomes abundant, and slight cell shrinkage during fixation produces numerous, thin strands of cytoplasm from adjacent cells that remain attached by desmosomes. Because of these thin cytoplasmic strands between cells, the term *prickle cell layer* (malpighian layer) has been applied to this zone. This is the broadest component of the squamous epithelium. The superficial layer is composed of one to three flattened cells with small, condensed nuclei. The squamous epithelium of the larynx can vary from about 5 cells in total thickness to over 25 cells (Figure 16.10). Normally, the larynx lacks a layer of parakeratotic surface cells. Continued exposure to irritants, such as cigarette smoke, may lead to foci of parakeratosis that may also be associated with orthokeratin formation.

The lamina propria of the true vocal cord is loose or dense connective tissue that lies between the vocal ligament and the squamous epithelium (Reinke's space) (Figure 16.11). Reinke's space contains a few capillaries but lacks lymphatics and only rarely has sparse seromucinous glands. As a result of this limited vascular access, carcinomas confined to the true vocal cords tend to remain localized and are amenable to curative radiation or surgical therapy. The poor lymphatic drainage of Reinke's space also probably contributes to the development of vocal cord nodules and polyps when abnormal amounts of edemalike fluid collect in this region. Likewise, vocal abuse or upper respiratory tract infections frequently produce edema in this region and manifest clinically as hoarseness or dysphonia. The anterior commissure, unlike the true cords, contains more abundant capillaries,

lymphatics, and seromucinous glands.

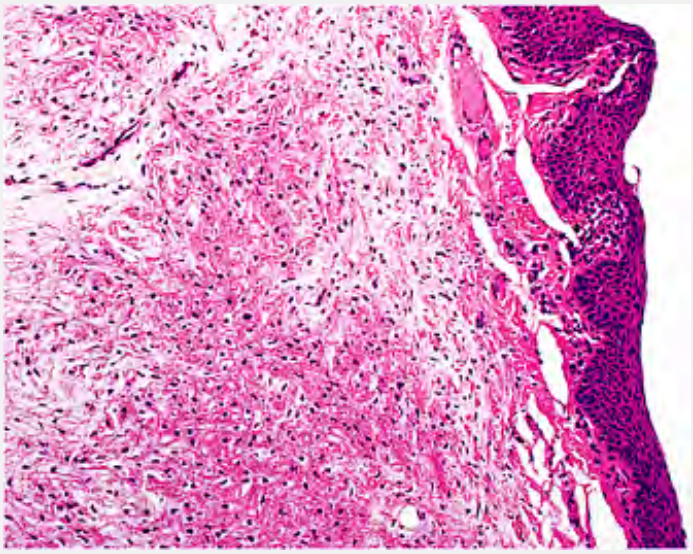

Figure 16.11 The true vocal cord is lined by squamous epithelium. A narrow, sparsely vascular zone (Reinke's space) lies between the squamous epithelium and the underlying vocal ligament.

The junction between the ciliated columnar epithelium, inferior and superior to the squamous epithelium of the true vocal cords, may be abrupt, but usually there is a transitional zone that varies from several cells to a width of 1 to 2 mm. The transitional zone consists of columnar cells that are gradually replaced by small, basaloid or immature squamous cells (Figure 16.12). In effect, this is a zone of immature squamous metaplasia in which the cells become progressively larger until they reach the size of the fully mature squamous epithelium that lines the true vocal cord.

The transitional zone often has a microscopically disorganized appearance when compared to the adjacent squamous and ciliated epithelium (Figure 16.12). Furthermore, the epithelium in this zone may be thickened and consist predominantly of basaloid cells.

cells have uniform nuclei with mitotic figures confined to the basal-most cell layer. This normal pattern can easily be confused with dysplasia or so-called carcinoma in situ, particularly in frozen sections or otherwise suboptimal preparations. Awareness of this transitional zone and attention to cytologic detail will avoid confusion.

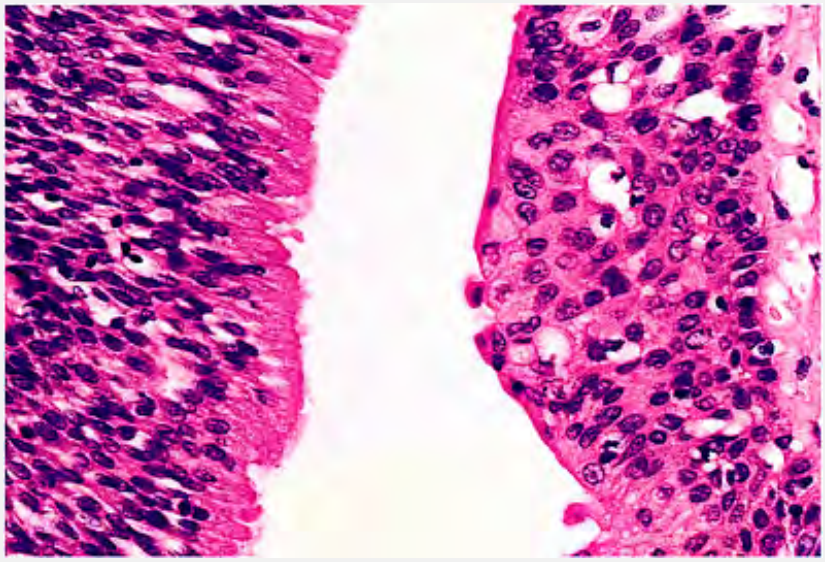

Figure 16.12 Ciliated columnar epithelium lines the false cord (*left*). A transitional zone is seen on the true cord (*right*). This zone of immature squamous metaplasia has a disorganized appearance that should not be confused with dysplasia. (From: Mills SE, Fechner RE. Pathology of the larynx. *Atlas of Head and Neck Pathology Series.* Chicago: American Society of Clinical Pathologists Press; 1985.
)

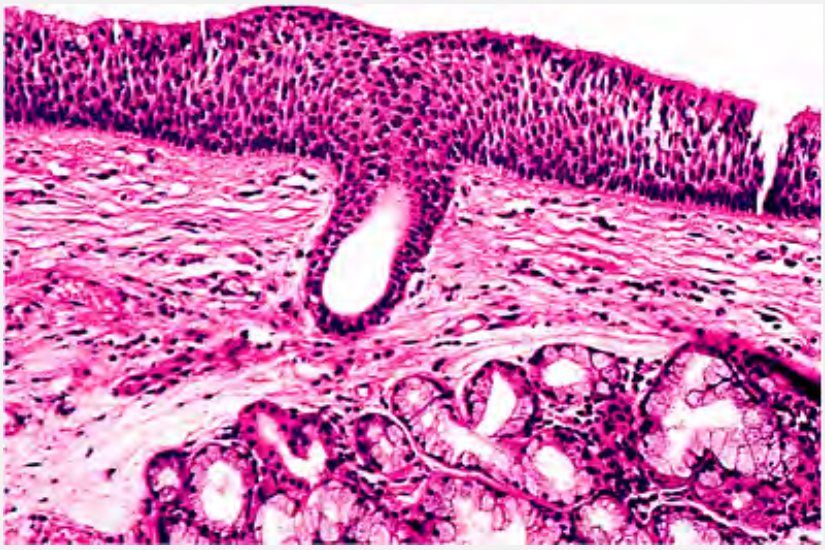

Figure 16.13 Seromucinous glands in the false cord drain into a duct that enters the overlying ciliated columnar epithelium. (From:
Mills SE, Fechner RE. Pathology of the larynx. *Atlas of Head and Neck Pathology Series.* Chicago: American Society of Clinical Pathologists Press; 1985.
)

Human papillomavirus (HPV) subtypes have been implicated in the pathogenesis of a variety of squamous proliferations in the larynx and elsewhere in the head and neck. Using sensitive polymerase chain reaction (PCR) techniques, studies are beginning to document some HPV subtypes, such as type 11 in approximately 25% of light microscopically normal laryngeal specimens (13). Thus, the finding of this HPV subtype adjacent to a laryngeal carcinoma cannot be assumed to represent a causative assocation. HPV subtypes more commonly associated with malignancy (HPV-16, HPV-18) have not yet been demonstrated in light-microscopically normal laryngeal mucosa.

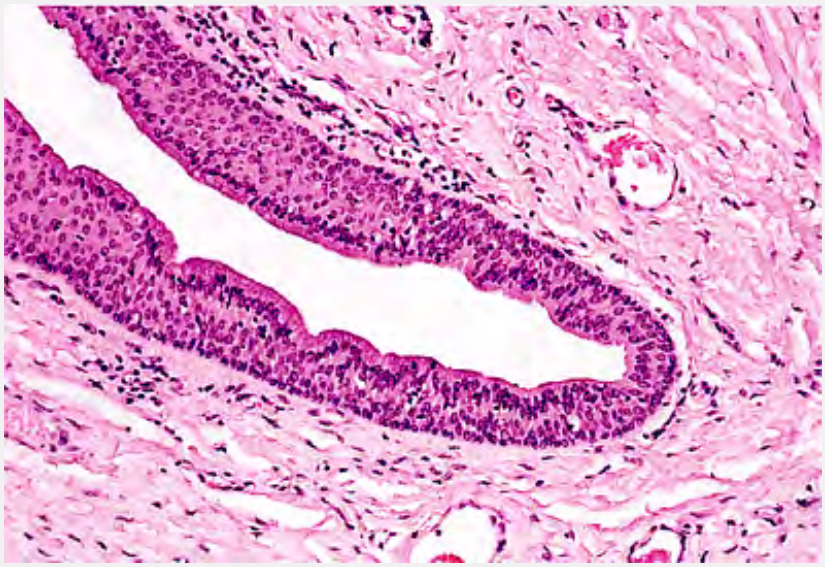

Figure 16.14 Ducts from seromucinous glands may be lined by squamous cells, ciliated columnar epithelium, or a mixture of the two.

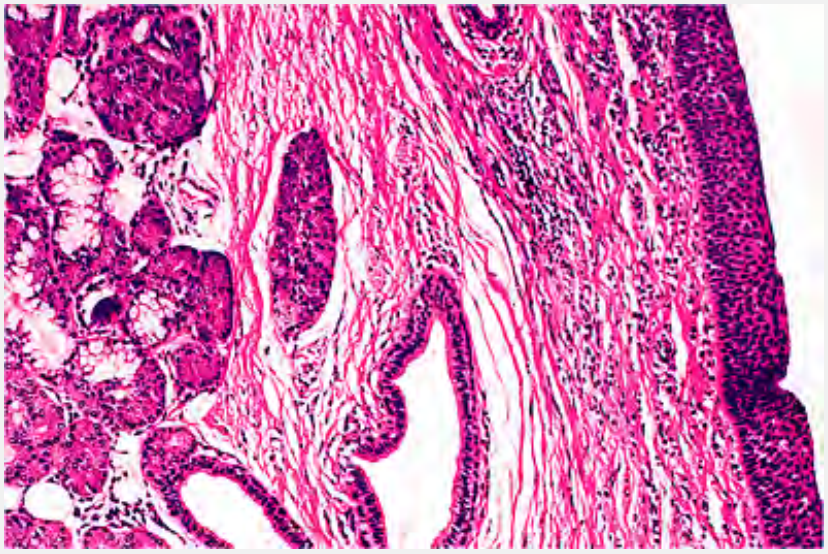

Figure 16.15 Seromucinous glands and their ducts are most prominent in the false cord.

Seromucinous glands are present throughout most of the larynx and communicate with the surface epithelium by ducts that are lined either by squamous cells, columnar epithelium (Figures 16.13 and 16.14), or a mixture of the two (14). The columnar epithelial component may or may not be ciliated. The glands are most abundant in the false cords (Figure 16.15), and there is also an extensive group of seromucinous glands just below the anterior commissure. Just superior to the anterior commissure is a narrow zone that is devoid of glands. In most cases, no glands are found beneath the squamous epithelium lining the free edge of the true vocal cords. Glands are present, however, beginning immediately at the squamocolumnar junction, both above and below the squamous epithelium of the true cords. Occasionally, there are glands in the stroma of the true vocal cord, and glands may be present in the underlying vocalis muscle (Figure 16.16).

The fenestration in the elastic cartilage of the epiglottis are filled with abundant seromucinous glands. These glands penetrate completely through the cartilage and afford a ready path for the spread of supraglottic carcinoma.

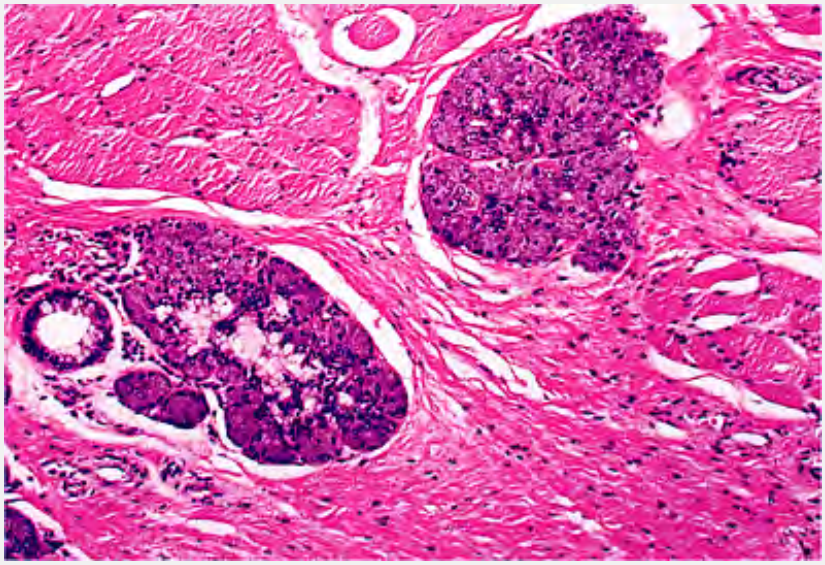

Figure 16.16 Seromucinous glands are occasionally located deep within the vocalis muscle.

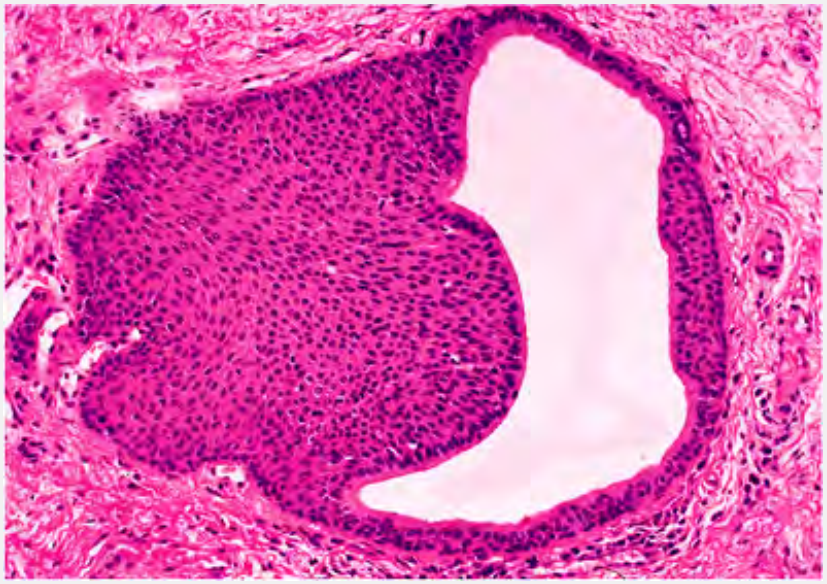

Figure 16.17 This seromucinous gland duct is associated with a large aggregate of metaplastic, nonkeratinizing squamous

cells.

Laryngeal biopsies, particularly from the region of the false cords, will often contain seromucinous gland ducts lined by squamous epithelium and located deep beneath the surface mucosa (Figure 16.17). Because of tangential sectioning, these ducts may appear as seemingly isolated squamous nests. Distinction from infiltrating carcinoma should not be a problem in adequately prepared sections. However, changes of basal cell hyperplasia or dysplasia also can involve these ducts. Fortuitous sections of such ducts may then result in seemingly isolated nests of basaloid or overtly dysplastic epithelium that are much more likely to be mistaken for invasive carcinoma (Figure 16.18).

Oncocytic metaplasia of ductal and acinar cells in the seromucinous glands of the larynx is a common, age-related change. Oncocytes are not seen in the seromucinous glands of individuals younger than 18 years of age, but oncocytes are present in these glands in approximately 80% of people over the age of 50 (15,16). Uncomplicated oncocytic metaplasia is asymptomatic; but, occasionally, oncocytic metaplasia may become cystic (Figure 16.19) and, if sufficiently large, produce symptoms.

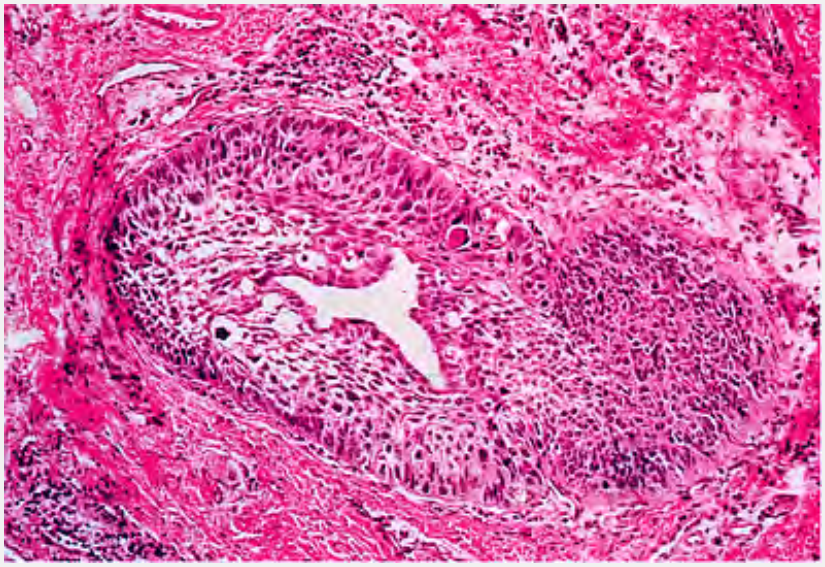

Figure 16.18 When ducts are involved with cytologically atypical squamous epithelium resembling surface dysplastic changes, they should not be misinterpreted as invasive carcinoma. In this example, the inner columnar cell lining is retained.

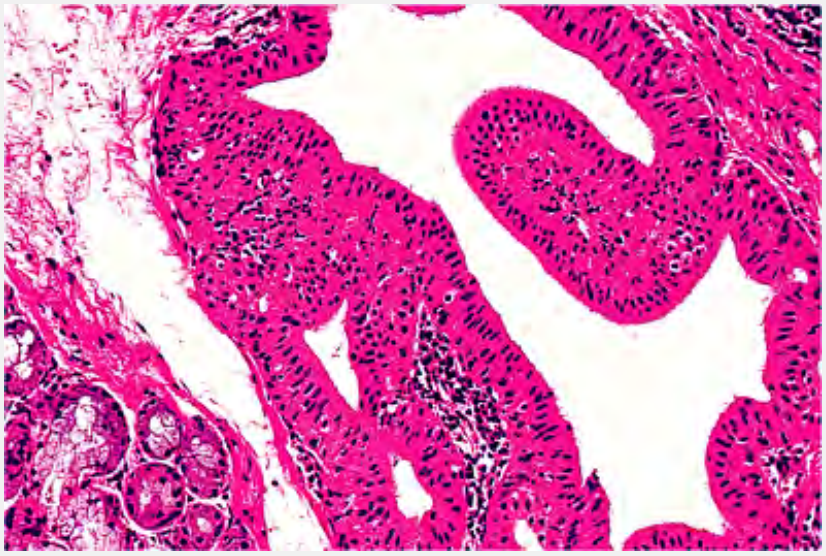

Figure 16.19 Oncocytic transformation of seromucinous epithelium can result in cystic structures.

The seromucinous glands of the larynx may also undergo infarction and associated squamous metaplasia (Figures 16.20,16.21). The resultant process, termed necrotizing sialometaplasia, is much more common in the oral cavity and probably results from a traumatic or spontaneous ischemic event (17). The islands of metaplastic cells may be mitotically active and exhibit mild-to-moderate nuclear atypia. Confusion with mucoepidermoid or squamous cell carcinoma is common, particularly in frozen section specimens. At low-power magnification, the preservation of the acinar pattern, in association with infarction, inflammation, and extravasation of mucin, will aid in the correct diagnosis.

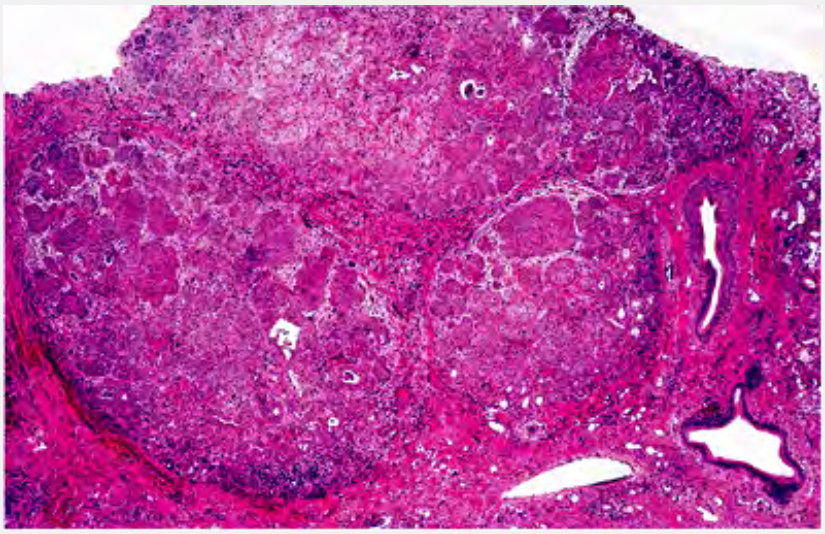

Figure 16.20 This low-power example of necrotizing sialometaplasia shows preservation of the pre-existing lobular architecture of the seromucinous glands.

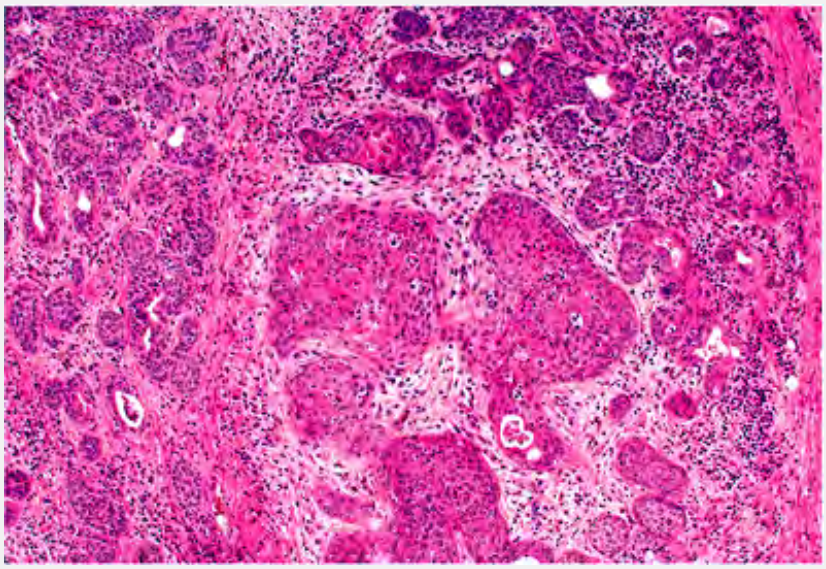

Figure 16.21 Higher magnification of necrotizing sialometaplasia shows replacement of the seromucinous lobules by aggregates of squamous cells with associated inflammation.

If the external surface of the larynx is carefully sampled, it is not unusual to find microscopic islands of normal thyroid tissue within the fibrous capsule of the larynx and trachea, just external to the cricothyroid membrane (18). The thyroid follicles are small and appear normal, with well-formed colloid. Continuity with the main thyroid gland is not usually demonstrable (19). Less commonly, microscopic foci of thyroid tissue will be encountered internal to the cartilage of the larynx and trachea, usually at the junction of the cricoid cartilage and the first tracheal ring (18,20). These isolated foci of extrathyroidal thyroid tissue probably lose their connection to the main portion of the thyroid gland during embryologic development (18). Awareness of this phenomenon and attention to the microscopic features will avoid confusion with

invasive or metastatic thyroid carcinoma.

The normal larynx contains at least two pairs of paraganglia. The superior, supraglottic paraganglia are sharply localized to the upper, anterior third of the false cords, in close approximation to the margin of the thyroid cartilage and the internal branch of the superior laryngeal nerves (21,22). The paired inferior paraganglia are more variably situated and may be found between the thyroid and cricoid cartilages or just below the cricoid cartilage (21,22). They are closely associated with the inferior laryngeal nerves. Aberrant or ectopic paraganglia have been described in various sites throughout the larynx. Laryngeal paraganglia are minute, neuroendocrine structures (0.1â€“0.4 mm) of unknown physiologic activity. Their close association with neurovascular bundles suggests chemoreceptor function, but this has not been proved. Laryngeal paraganglia presumably give rise to the rare paragangliomas of the larynx.

The vocal process of the arytenoid cartilage is a normal structure that is occasionally encountered in biopsy specimens from the posterior portion of the true cord. It is a sharply circumscribed nodule of uniformly mature, elastic-type cartilage (Figure 16.22). Its elastic nature, demonstrable with appropriate elastin stains, allows distinction from cartilaginous neoplasms of the larynx, all of which are composed of hyalin-type cartilage. The sharp circumscription of the cartilaginous arytenoid process allows it to be differentiated from chondroid metaplasia of the vocal ligament. Chondroid metaplasia of the vocal cord is a common, usually asymptomatic, finding that typically affects the mid- and posterior portions of the vocal cord (23,24). The margins of the cartilage are blurred, and there is a peripheral zone of connective tissue that is rich in acid mucopolysaccharides (Figure 16.23) (24). The metaplastic nodules contain dense aggregates of elastic fibers throughout the lesion. The multilobular pattern, typical of cartilaginous neoplasms, is absent. Chondroid metaplasia can occur

in other soft tissues of the larynx, particularly in the region of the false cord. In one study, foci of chondroid metaplasia were found in 1 to 2% of larynges at autopsy (23).

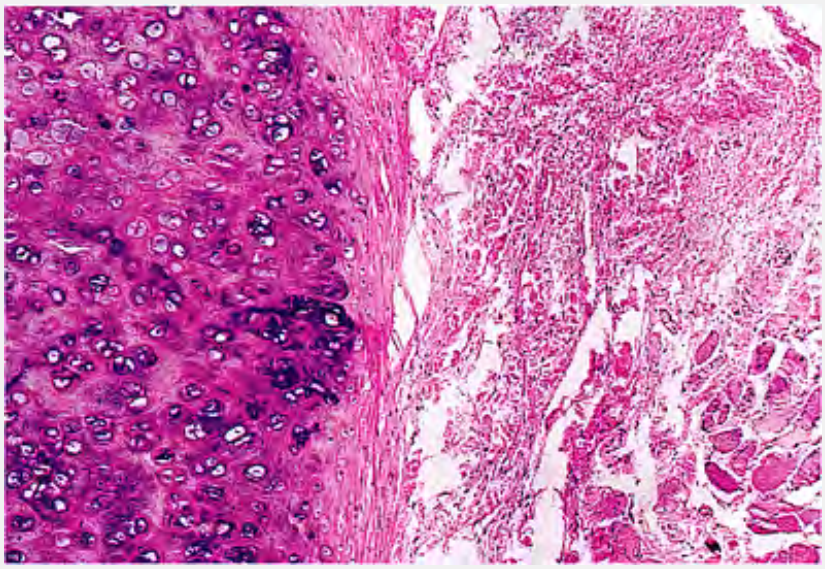

Figure 16.22 The vocal process of the arytenoid cartilage is a sharply circumscribed nodule of elastic-type cartilage. (From: Mills SE, Fechner RE. Pathology of the larynx. *Atlas of Head and Neck Pathology Series.* Chicago: American Society of Clinical Pathologists Press; 1985.

)

Neural, Vascular, and Lymphatic Components

The intrinsic laryngeal muscles are innervated by branches of the vagus nerve. The cricothyroid muscle is supplied by the superior laryngeal branch of the vagus, and the remainder of the intrinsic musculature has been conventionally viewed as being innervated by the recurrent laryngeal branch of the vagus nerve. The terminal portion of the recurrent laryngeal nerve is referred to as the inferior laryngeal nerve (25). More recently, it has been shown that branches of the superior and recurrent laryngeal nerves form anastomoses, most commonly within the interarytenoid muscle but

less consistently in the piriform sinus. Branches from the superior laryngeal nerve, referred to as the communicating nerve, may pass through the cricothyroid muscle to partially innervate the vocalis muscle (26,27). It has been suggested that the communicating nerve may be the nerve of the elusive fifth branchial arch (27).

The lower portions of the larynx are supplied with blood from the inferior laryngeal artery, a small branch of the inferior thyroid artery that accompanies the inferior laryngeal nerve. The inferior laryngeal artery has anastomoses with the larger superior laryngeal artery, derived from the superior thyroid artery. The laryngeal arteries are accompanied by similarly named veins. The superior laryngeal vein joins the superior thyroid vein and drains into the internal jugular vein (25). The inferior laryngeal vein joins the inferior thyroid vein. Numerous anastomoses across the front of the trachea between the left and right inferior laryngeal veins may lead to contralateral venous return (25).

The lymphatics of the larynx tend to drain along with the vasculature. Therefore, supraglottic lymphatics drain superiorly, and subglottic lymphatics drain inferiorly (1,25). As discussed earlier, lymphatics are scarce in the glottis. Some of the laryngeal lymphatics end in very small lymph nodes on the thyrohyoid membrane, cricotracheal ligament, or superior trachea (25). These nodes, however, drain into the deep cervical nodes (25). Lymphatics in the supraglottic larynx are prominent and, typically, terminate in the anterior jugular chain (28). Subglottic lymphatics terminate in the midline pretracheal nodes or, less commonly, in the lower cervical lymph nodes (28).

Pharynx

Definition and Boundaries

The pharynx has three functionally and structurally dispersed subpartsâ€”the nasopharynx, oropharynx, and hypopharynx (Figure 16.24). The nasopharynx is the portion of the pharynx that lies above the soft palate. It has anterior, posterior, and lateral walls. The anterior wall is perforated by the posterior nares (choanae). The posterior wall is an arch that includes the roof of the nasopharynx, as well as the posterior portion against the base of the skull. The posterior wall extends inferiorly and, at the level of the horizontal projection of the soft palate, continues inferiorly as the posterior wall of the oropharynx. The anterior and posterior walls are connected by the lateral walls into which the eustachian (pharygotympanic, or auditory) tubes empty.

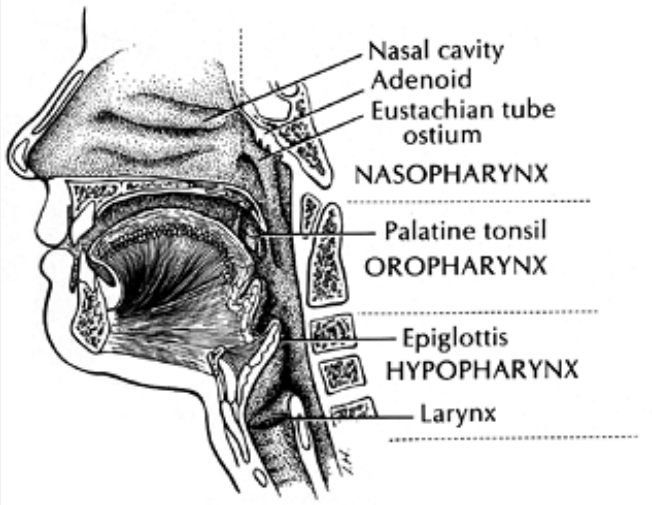

Figure 16.24 This sagittal section delineates the boundaries of the nasopharynx, oropharynx, and hypopharynx.

The oropharynx lies between the soft palate and the tip of the epiglottis. By definition, its superior boundary is a horizontal projection of the soft palate. Anteriorly, it is bounded by the fauces or opening from the mouth and, below this, the posterior aspect of the dorsum of the tongue. The inferior margin of the

anterior portion of the oropharynx is marked by the opening of the piriform recess at the level of the tip of the epiglottis. A horizontal projection posteriorly from this point, marks the posterior aspect of the inferior margin, which is continuous with the hypopharynx.

The hypopharynx is the portion of the pharynx below the tip of the epiglottis and extending downward to the beginning of the esophagus. The hypopharynx is wide superiorly, but rapidly narrows as it approaches the level of the cricoid cartilage and becomes continuous with the esophagus. The hypopharynx partially surrounds the larynx laterally and is separated from it by the aryepiglottic folds. The latter extend from the upper posterior border of the larynx to the side of the epiglottis. The lateral extensions of the hypopharynx are called the piriform recesses or sinuses (25) (Figure 16.25).

Embryology

The embryologic pharynx is of endodermal derivation and, at its cephalic end, is in direct continuity with the ectoderm forming the stomodeum. Recent observations have

suggested that the development of the roof of the pharynx is highly dependent on the closely adjacent notochord (29). The stomodeum and pharynx are separated by the buccopharyngeal membrane, which is lined on its external surface by ectoderm and internally by endoderm. At the end of the third week of embryologic development, the buccopharyngeal membrane ruptures, establishing contact between the stomodeum and the primitive pharyngeal portion of the foregut (29,30). Superiorly, the buccopharyngeal membrane corresponds to approximately the level of the nasal choanae. In the subsequent fifth through seventh weeks of gestation, the primitive nasal cavity forms and enlarges, with formation and later rupture of the bucconasal membrane, establishing the final connection between the nasal

cavity and pharynx (29). In the eighth through the tenth gestational weeks, the secondary palate develops behind the primary palate, ending the formation of the basic pharyngeal structures. At this point, however, the pharynx is proportionally quite small; and, after the tenth week of gestation, remarkable growth in this region occurs with enlargement of the pharynx and downward movement of the palate and tongue (29).

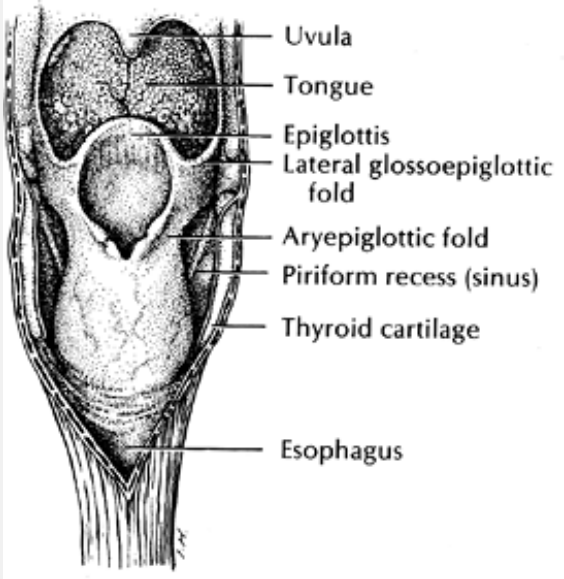

Figure 16.25 The piriform sinuses are a conduit between the oropharynx and the opening of the esophagus. They surround the larynx laterally.

Thus, the lining of the nasal cavity and paranasal sinuses is of ectodermal origin and constitutes the so-called schneiderian membrane. The nasopharynx, oropharynx, and hypopharynx are, at least in large part, of endodermal origin. The sharp demarcation between endoderm and ectoderm at the level of the nasal cavity is of considerable practical importance. Certain neoplasms, such as angiofibromas and lymphoepitheliomas, are virtually confined to

the endodermally derived nasopharynx. In contrast, schneiderian papillomas and intestinal-type adenocarcinomas arise from the ectodermally derived lining of the nasal cavity and paranasal sinuses; they do not occur in the nasopharynx.

Gross Anatomy

By nature of their boundaries and lack of resectability, the nasopharynx and oropharynx are practically never encountered as gross specimens. The roof of the nasopharynx is composed of mucosa overlying the basal portions of the sphenoid and occipital bones (25). The lateral and posterior walls of the nasopharynx are composed of the superior constrictor muscles and the pharyngobasilar fascia. The soft palate is the floor of the anterior portion of the nasopharynx: the only truly mobile portion of the nasopharynx (25). Although the opening between the nasopharynx and oropharynx is normally patent, the soft palate can be moved posteriorly and superiorly to completely separate the nasal and oral segments. This is important as a component of proper speech and to keep food and water out of the nasal region during eating and drinking.

The most important gross features of the nasopharynx encountered by pathologists are the pharyngeal tonsil, pharyngeal recess, and the eustachian tube openings. The pharyngeal tonsil, or adenoids, is a prominent, convoluted mass in the roof of the nasopharynx in children. (It typically atrophies in adults.) The pharyngeal recess, or RosenmÃ¼ller's fossa, is a mucosal-lined depression in the posterolateral portion of the nasopharynx. Just anterior to the recess, located in the lateral wall, is the ostium of the eustachian tube. This opening is surrounded on its superior and posterior aspects by mucosa-covered cartilage, the tubal torus, from the eustachian tube wall (25).

The superior portion of the anterior oropharynx is bounded by the fauces, or opening of the mouth into the oropharynx. The lateral

walls of the fauces are composed, on each side, of the two tonsillar pillars, between which lies the palatine tonsil in the tonsillar fossa. The anterior tonsillar pillar is the palatoglossal arch. This structure curves downward and forward, from the soft palate to the tongue. The posterior tonsillar pillar, or palatopharyngeal arch, extends downward from the posterolateral border of the soft palate laterally along the pharyngeal wall. Each of the arches contains a similarly named muscle (25).

The palatine tonsil, more commonly referred to as simply the tonsil, varies tremendously in size, depending on its state of lymphoid reactivity. The surface of the tonsil is covered with epithelial-lined pits, the tonsillar crypts that pass into the underlying lymphoid tissue. Beneath the tonsil is the pharyngobasilar fascia, which sends branches of fibrous tissue into and around the tonsil, forming the so-called tonsillar capsule. Loose connective tissue between this capsule and the deeper superior constrictor muscle forms a plane of cleavage that facilitates surgical removal (25).

The parapharyngeal, or lateral pharyngeal, space is an important zone of loose connective tissue lying deep to the tonsil and lateral to the pharynx (Figure 16.26). This space is roughly pyramidal, with the base of the skull forming the base of the pyramid superiorly (18,25). Inferiorly, the apex

is formed by the attachment of the cervical fascia to the hyoid bone; medially is the superior constrictor muscle of the pharynx; and, laterally, the pterygoid lamina, inner surface of the mandibular ramus, and the deep lobe of the parotid gland (18). Contained within the parapharyngeal space are the internal carotid artery, internal jugular vein, cranial nerves IX to XII, the cervical sympathetic chain, vagal and carotid bodies, and multiple lymph nodes (18). Mass-producing lesions involving any of these structures may cause medial displacement of the tonsil and lateral pharyngeal wall. Tonsilar abscesses or other sources of infection

may also involve and rapidly spread throughout this space. Posteriorly, the parapharyngeal space is in direct continuity with loose connective tissue behind the pharynx and anterior to the prevertebral fascia of the vertebral column (25). This has been referred to as the retropharyngeal space (Figure 16.26).

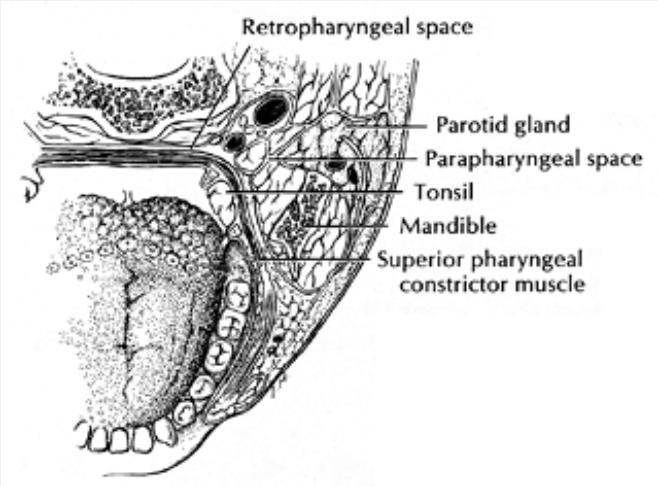

Figure 16.26 The parapharyngeal space lies deep to the tonsil and contains several vital structures. It is in continuity, posteriorly, with the retropharyngeal space.

Inferior to the fauces, the oropharynx is bounded anteriorly by the posterior aspect of the immobile portion of the tongue. The base of the tongue contains abundant submucosal lymphoid tissue that constitutes the lingual tonsil. Along with the palatine and pharyngeal tonsils, this structure forms an oblique wreath of lymphoid tissue that encompasses the oropharynx and nasopharynx and is often referred to as Waldeyer's ring.

The most important structures in the hypopharynx are the piriform sinuses (Figure 16.25). These elongated, pear-shaped gutters extend laterally along both sides of the larynx, and posteriorly from the pharyngoepiglottic fold to the opening of the esophagus

(28). Laterally, the piriform sinus lies against the thyroid cartilage. Medially, it is separated from the laryngeal ventricle by a thin layer of muscles derived from the aryepiglottic fold and the opening of the esophagus (28). Just posterior and lateral to the piriform sinus is the common carotid artery. Because of their close association, tumors arising in the hypopharynx often invade the larynx secondarily. These tumors should be distinguished from primary laryngeal neoplasms because of their poorer prognosis.

Microscopic Anatomy

The nasopharyngeal mucosa in the adult has a surface area of about 50 cm^2. Most of it is lined by stratified squamous epithelium, and about 40% is covered by respiratory-type, columnar epithelium (31). Squamous epithelium predominantly lines the lower portion of the anterior and posterior nasopharyngeal walls, as well as the anterior half of the lateral walls. Ciliated respiratory epithelium predominantly carpets the region of the posterior nares (choanae) and the roof of the posterior wall. The remainder of the nasopharynx, including the posterior lateral walls and the middle-third of the posterior wall, has alternating islands of squamous and respiratory epithelium.

The junction between squamous and respiratory epithelium may be sharp, or there may be zones of transitional or intermediate epithelium as previously described in the larynx. We prefer the term *intermediate epithelium,* as opposed to *transitional epithelium,* because these cells lack the ultrastructural features of urinary tract epithelium. Intermediate epithelium primarily forms a wavy ring at the junction of the nasopharynx and oropharynx. The intermediate cells may be basaloid with minimal cytoplasm, and they typically have a cuboidal or round configuration. As discussed under the larynx, biopsy specimens containing intermediate epithelium must not be overly interpreted as areas of dysplasia or carcinoma in situ. This is most likely to be a problem when this

zone is encountered in a frozen section.

In addition to the pharyngeal tonsil, less-prominent collections of lymphoid follicles may be present submucosally throughout the nasopharynx (Figure 16.27). These follicles are particularly abundant in the rim of the eustachian tube opening (Gerlach's, or tubal, tonsil), but they are also

present under mucosa of the lateral and posterior walls of the nasopharynx, as well as on the nasopharyngeal surface of the soft palate (28). Thus, a submucosal follicular lymphoid infiltrate is normal in nasopharyngeal biopsies and should not be overinterpreted as a pathologic inflammatory process.

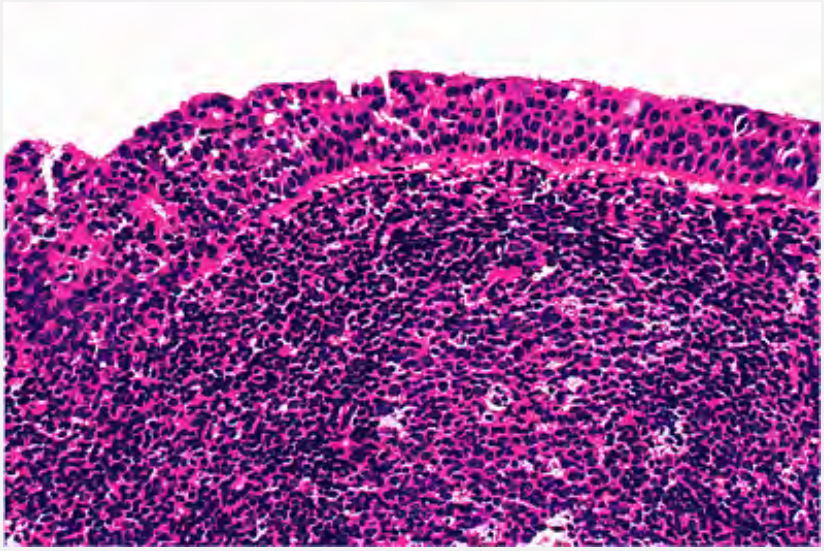

Figure 16.27 Submucosal lymphoid aggregates are present normally throughout the nasopharynx and should not be overly interpreted as severe chronic inflammation.

Throughout the nasopharynx, there are numerous submucosal seromucinous glands that produce predominantly mucin. These glands are particularly numerous in the region of the eustachian

tube opening. As with the laryngeal seromucinous glands, oncocytic metaplasia in the glandular and ductal epithelium becomes increasingly frequent with advancing age (32,33).

The anterior portion of the pituitary gland forms from an intracranial invagination of epithelium in the form of Rathke's pouch. Microscopic remnants of Rathke's pouch epithelium are present in the roof of the nasopharynx in 95 to 100% of individuals (34,35,36). In most instances, this so-called pharyngeal pituitary is located in the midline, in the region of the vomerosphenoidal articulation. The nests of epithelial cells measure 0.2 mm to approximately 6 mm in greatest dimension. They are located deep in the mucosa or in the underlying periosteum (34). Most of the epithelial cells appear undifferentiated, but occasional basophilic and eosinophilic cells may be present (Figure 16.28). Although it is not entirely clear, the pharyngeal pituitary may not have any physiologic function. Most pituitary adenomas that involve the nasopharynx reach this location by invasion from the pituitary fossa. Occasionally, however, apparently ectopic pituitary adenomas present in the nasopharynx, and it is tempting to speculate that such lesions arise from the pharyngeal pituitary (37,38).

The pharyngeal bursa is a normal embryonic structure situated posterior to Rathke's pouch. Remnants of this bursa may be found in approximately 3% of normal adults (39,40). Cysts derived from this structure may be found in all ages, occasionally as an incidental finding, and occur in the regions of the adenoid (41). The cysts are separated from the adenoid by a fibrous membrane and will not be removed with routine adenoidectomy specimens (Figure 16.29) (10). The median pharyngeal recess is a shallow depression formed normally in association with the pharyngeal tonsil. Unlike cysts derived from the pharyngeal bursa, those formed from the median pharyngeal recess are located within the adenoid and will be removed with it (10).

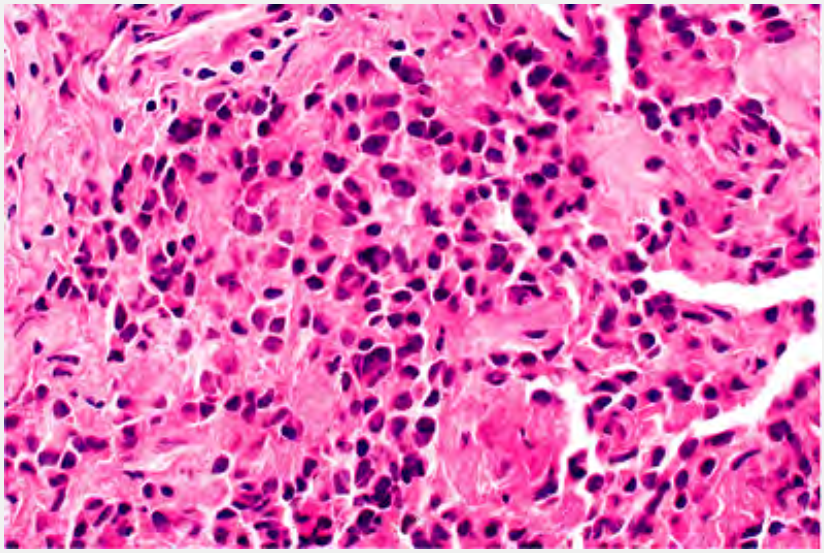

Figure 16.28 Nests of ectopic pituitary cells present in the superior portion of the nasopharynx.

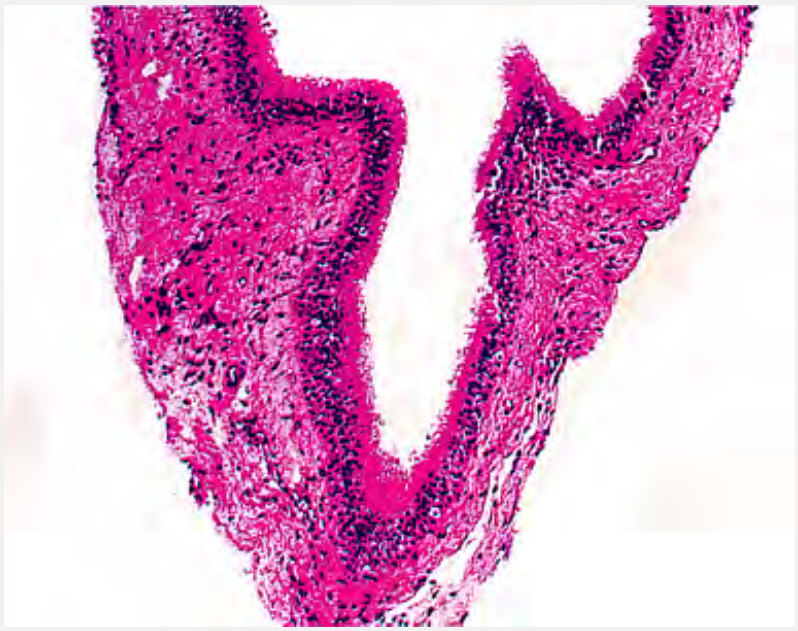

Figure 16.29 Nasopharyngeal cysts are rimmed by fibrous tissue and lined by ciliated columnar epithelium.

The cranial end of the embryonic notochord is closely associated with the roof of the developing nasopharynx (42). Although most of the notochord degenerates during embryonic and fetal development, notochordal remnants have been demonstrated in the submucosa of the nasopharynx and other closely adjacent locations (10,43). Most chordomas involving the nasopharynx are downgrowths of cranio-occipital tumors, but rare primary nasopharyngeal tumors presumably arise from these nasopharyngeal notochord remnants (42,43).

Both the oropharynx and hypopharynx are lined continuously by stratified squamous epithelium. This mucus is typically nonkeratinizing, although areas of parakeratin or orthokeratin may be seen secondary to chronic irritation. As in the nasopharynx, the submucosa of the oropharynx and hypopharynx contains scattered lymphoid aggregates, as well as prominent submucosal seromucinous glands.

The stratified squamous epithelium covering the tonsils extends into the tonsillar crypts for considerable distances. As these cords of epithelium merge with the underlying lymphoid tissue, the epithelial cells assume a more basaloid appearance and have uniform but vesicular nuclei. The junction between the lymphoid cells and the islands of squamous cells is often blurred (Figure 16.30). Apparently isolated, irregular nests of basaloid, focally keratinized squamous cells, often with vesicular nuclei, are common deep within the tonsil (Figure 16.31), and such nests must not be confused with carcinoma. Attention to the low-power

architecture will confirm that these nests are closely approximated to tonsillar crypts and are a normal finding.

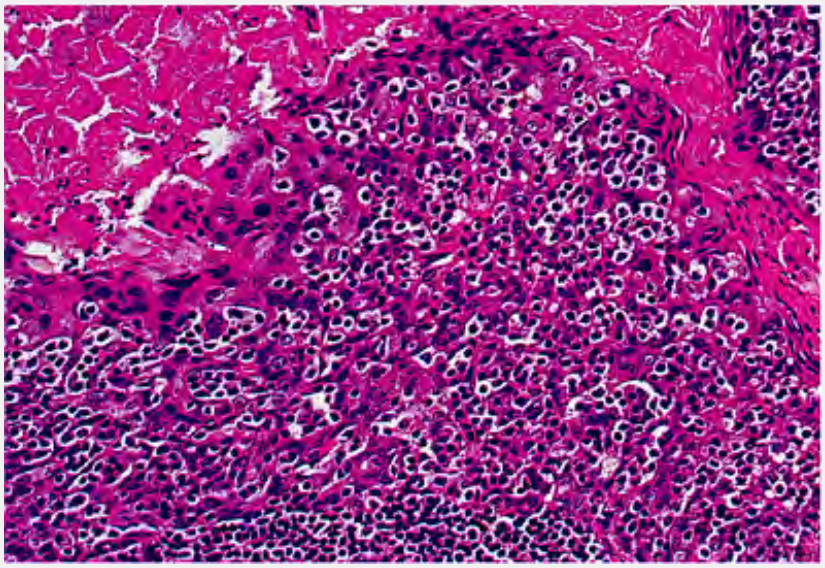

Figure 16.30 The junction between lymphoid tissue and the squamous cells lining the tonsillar crypts is often blurred.

Occasionally, islands of metaplastic cartilage and bone are encountered within or immediately adjacent to the tonsils (18,44). This presumably represents a secondary, reactive change to prior inflammation. Eggston and Wolff (44) described this change in about one-fifth of all resected tonsils. These authors noted that patients with this change had an average age of 24 years and, therefore, were older than most individuals undergoing tonsillectomy (44).

Neural, Vascular, and Lymphatic Components

The nerves supplying the constrictor muscles of the phaynrx, the stylopharyngeus muscle, and the muscles of the soft palate are derived almost entirely from the pharyngeal plexus. The latter structure is formed by the union of the pharyngeal branches of the

glossopharyngeal and vagus nerves. The inferior constrictor muscle may receive a portion of its innervation from the external laryngeal nerve, a separate branch of the vagus that primarily supplies the larynx (25).

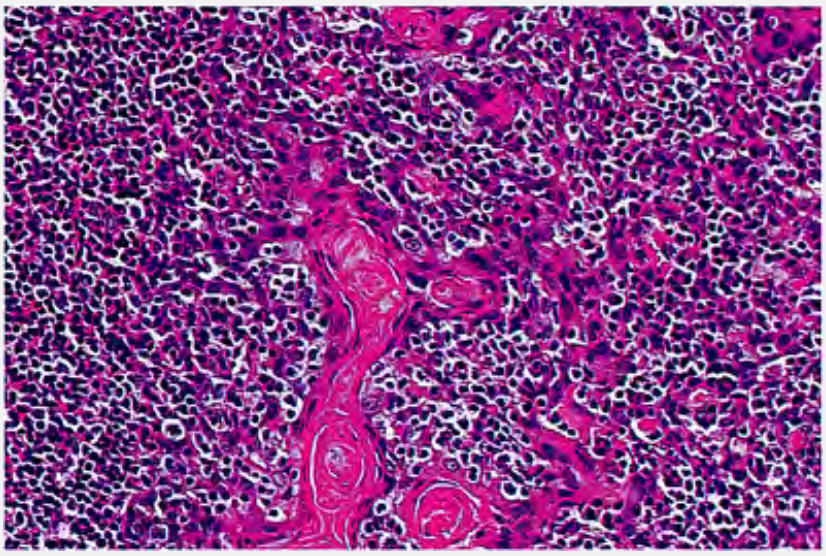

Figure 16.31 Irregular nests of epithelium are frequently present deep within the tonsil. These are closely approximated to tonsillar crypts and are a normal finding not to be misinterpreted as carcinoma.

The blood supply to the superior portion of the pharynx is from the ascending pharyngeal artery, which runs upward along the posterior lateral wall of the pharynx (25) (Figure 16.32). The inferior portion of the pharynx is supplied by branches from the superior and inferior thyroid arteries. The veins draining the pharynx merge posteriorly to form the pharyngeal plexus, which in turn drains at irregular intervals into the pterygoid plexus and the superior and inferior thyroid veins (25).

The lymphatics from the roof and posterior wall of the nasopharynx join in the midline, and pass through the pharyngeal

fascia. They then split to the right or left retropharyngeal lymph nodes. Some of the nasopharyngeal lymphatics terminate in the highest lymph nodes of the internal jugular and spinal chains (28). Most of the

lymphatics from the soft palate converge at a group of lymph nodes located below the anterior belly of the digastric muscle, immediately in front of the jugular chain (28). Lymphatics from the tonsil pass through the lateral wall of the pharynx and terminate in subdigastric nodes located anterior to the jugular chain (28). The hypopharynx is rich in lymphatics. These converge at an orifice in the thyrohyoid membrane, through which also passes the superior laryngeal artery. After exiting the thyrohyoid membrane, the lymphatics ramify into several trunks that terminate in lymph nodes of the internal jugular chain (28).

Major Salivary Glands

Fernando MartÃnez-Madrigal
Jaques Bosq
Odile Casiraghi

Introduction

The primary function of the salivary glands is to moisten the mucous membranes of the upper aerodigestive tract. In humans, this function is fulfilled by the continuous exocrine secretion of numerous minor salivary glands. These glands are located in the submucosa throughout the oral cavity, pharynx, and upper airways. In developed species, most of the saliva is elaborated by three pairs of major glands, or salivary glands, named by their location: the parotid, the submaxillary or submandibular, and the sublingual glands. They are connected symmetrically to the oral cavity, where they empty their secretion only under specific stimuli. The saliva produced by these glands (750â€“1000 mL/24 hours) plays an important role in preparing food for digestion, as well as in controlling the bacterial flora of the mouth. The quality of the saliva produced by the major glands is variable and depends on both the stimuli and the predominant participating gland.

Embryologic and Postnatal

Developmental Changes

Parotid Gland

During embryologic life, the parotid is the first of the three major glands to appear and is seen by the sixth week. It derives from the ectoderm as an epithelial bud from the primitive oral epithelium, at the angle between the maxillary

process and the mandibular arch (1). As the primordia grow, they ramify into a bushlike system surrounded by mesenchymal tissue. This mesenchyma and, particularly, the basal lamina play an important role in the lobular organization of the gland (2 ,3 ,4 ,5), and in vascular and neural development. By the seventh week, the primitive gland moves in a dorsal and lateral direction and reaches the preauricular region. Development of the facial nerve divides the gland by approximately the tenth week into superficial and deep portions (6).

By the third month, the gland has attained its general pattern of organization. The epithelial structures are arranged in lobules, limited by a capsule of loose connective tissue (Figure 17.1A). The mesenchyma is then colonized by numerous lymphocytes that are later disposed in intraglandular and extraglandular lymph nodes. By the sixth month, the epithelial cordons are canalized and exhibit a double-cell ciliated cover. Cell differentiation begins in the excretory ducts with the progressive transformation of ciliated cells by columnar, squamous, and goblet cells (Figure 17.1B) (7). Intralobular duct and acinar differentiation, including myoepithelial cell formation, begins about the eighth month (8) and myoepithelial cell differentation by the nineteenth- to twenty-fourthâ€“week period. These cells, arranged in the basal portions of the acini and intercalated ducts, appear as clear cells with electron microscopy. Between 25 and 32 weeks, the myoepithelial cells become flattened and show cytoplasmal prolongations (9 ,10 ,11). Saliva production starts as a mucinous liquid at this time; but several studies in rodents suggest that full

maturation is completed only after birth (12 ,13 ,14 ,15).

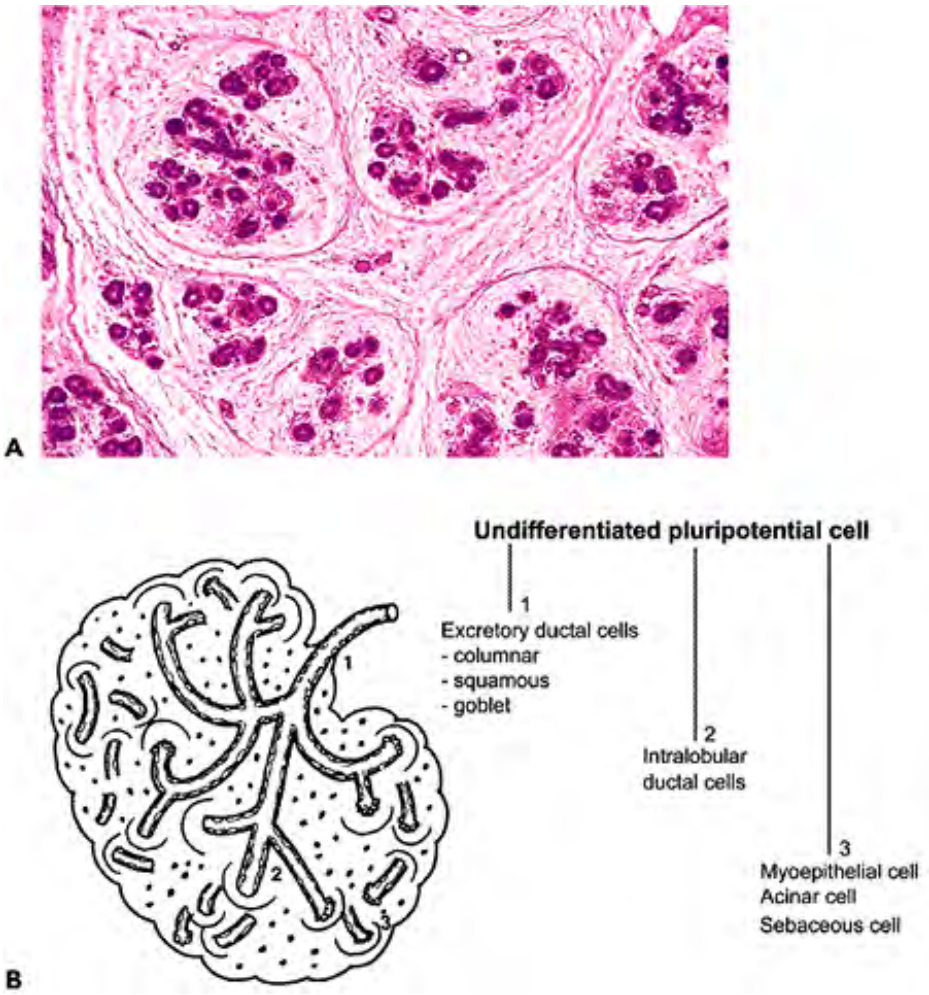

Figure 17.1 Development and histogenesis of the epithelial constituents of the salivary gland. A. Fetal parotid gland at 4 months; a lobular architecture is present. B. Drawing of (A), showing the cellular lines of differentiation for the excretory ducts, (1); excretory ducts, (2); intralobular ducts, (3); and acini.

The definitive location of the parotid is behind the inferior facial nerve maxillary branch, below and in front of the external ear. It is enclosed within a fibroadipose capsule in a depression whose anterior limit is the masseter muscle. Its superior limit is the zygomatic arch; the posterior limit is the tragus, and the inferior limit is the anterior border of the sternocleidomastoid muscle (16). The adult parotid is

the largest of the three major salivary glands and weighs between 14 and 28 g. The gland is surrounded by a fine capsule and is divided into two portions by the facial nerve. The main portion, or superficial lobe, is flattened and quadrilateral; it is here that the majority of salivary tumors develop. This observation has permitted the development of conservative surgical treatment of many parotid tumors. The rest of the gland, called the deep lobe, is irregularly wedge-shaped in anatomic relationship with the parapharyngeal space (17).

The surgical anatomic area where the parotid gland is located, is called the parotid region. In this region it is important to keep in mind the anatomical relations between the facial nerve, the gland, and the subcutaneous planes. The facial nerve has four parts, designated as retro-, inter-, intra-, and preglandular. The parotid gland is covered by a superficial musculoaponeurosis and the skin (18). Accessory parotid tissue is found in approximately 20% of cases. Nevertheless, in a recent study, the incidence was found to be 56% with no differences between right and left sides or between sexes (19). This accessory tissue may be found on the anterior surface of the gland, as well as along the parotid duct (20).

Like all the exocrine glands, the parotid is composed of numerous tubuloacinar units connected through the excretory ducts to a main duct (Stensen's duct) located in the anterior portion of the gland. The parotid duct follows a twisted course of 7 cm, crossing the masseter muscle, the corpus adiposum of the cheek, and the buccinator muscle before opening into the oral vestibule. The secretion of the accessory parotid is emptied by an independent duct reaching the parotid duct in the masseter portion.

Blood supply is by arterial branches from the external carotid. The veins are tributaries of the external jugular, and the lymphatics join the superficial and deep cervical lymph nodes. Innervation is derived from the sympathetic and auriculotemporal nerves.

Submaxillary Gland

In the submaxillary gland, the primordia appear at the end of the sixth week and, unlike the parotid, are probably of endodermal derivation (21 ,22). However, a recent study suggests that the sublingual process of the submandibular gland originates from a lateral ectodermal bud of the anlage of the submandibular gland (23). The epithelial bud appears in the groove between the lower jaw and tongue, at one side of the midplane. Extension of the glandular tissue in the mesenchyma goes backward beneath the lower jaw. Subsequent maturation and cell differentiation are similar to those of the parotid gland except for the lymphoid tissue, which is less obvious than in the parotid. In addition, there is no lymph node formation inside the gland. Recent studies have demonstrated that the extracellular matrix protein fibronectin is essential for cleft formation during the initiation of epithelial branching in submaxillary gland. It has also been demonstrated that inhibition of fibronectin blocks cleft formation and branching (24 ,25). This mechanism could be applied for other salivary glands and other exocrine glands (such as the mammary glands).

The submaxillary gland is finely encapsulated; it lies inside the submandibular triangle, an osteofibrous cavity from which it takes the form of a triangular prism. This gland weighs approximately 7 to 8 g and, like the other major salivary glands, is organized in lobules connected to a main excretory ductâ€”the submaxillary duct (Wharton's duct)â€”which measures 5 cm in length and 2 to 3 mm in diameter. The duct originates near the surface; runs between the mylohyoideus, the hyoglossus, and genioglossus muscles; and finally opens through a narrow orifice in a small papilla called the caruncula sublingualis on each side of the frenulum linguae. A submandibular gland having three ducts that open separately into the oral cavity has also been reported (26). The blood supply is from branches of the facial and sublingual arteries. The secretomotor nerves are fibers from the cranial parasympathetic branch of the facial nerve; the vasomotor

nerves are derived from the superior cervical ganglion. The lymph nodes are arranged in a row in the spaces between the mandible and the gland and are disposed in anterior, medial, and posterior groups (16 ,17).

Sublingual Gland

The sublingual glands are the last of the three major salivary glands to appear. Their primordia are located immediately lateral to the submaxillary glands for the greater sublingual glands and in the linguogingival sulcus for the lesser sublingual glands. The epithelial buds grow downward from the groove between the lower jaw and the tongue. Parenchymal organization and differentiation are similar to those of the submaxillary gland and are also probably of endodermal derivation.

The principal sublingual gland weighs 3 g. It lies in the sublingual fossa of the mandible and is surrounded by loose connective tissue. Its secretion is drained through a main duct called the Bartholin's duct, which opens into the submandibular duct, and various small ducts (Rivinus' ducts) that open separately into the mouth in the plica sublingualis or join the submandibular duct (16 ,17).

Vascular supplies come from the sublingual and submental arteries; the veins are tributaries of the external jugular. Innervation is similar to that of the submaxillary gland.

Apoptosis

In the literature, studies concerning apoptosis in salivary glands are not very frequent. Contrary to other glandular tissue, programmed cell death in the salivary glands has been sporadically studied in less-developed and developed species, using experimental animals such as rats or monkeys and, less frequently, humans (27 ,28 ,29).

In normal salivary glands, apoptosis was uncommon when observed in acinar cells and epithelial duct cells and never observed in

myoepithelial cells. In specific pathologic contexts, such as duct obstruction or irradiation of the salivary glands, programmed cell death was observed with

many significant changes in the structure of the glands (30 ,31). In some salivary gland diseases, such as SjÃ¶gren's syndrome, accelerated apoptosis may explain acinar and ductal cell loss with the typical functional loss of the secretory activity seen in patients with this disease.

In experimental models, apoptosis is regulated by two kinds of protein families, bcl-2-related proteins and the inhibitor of apoptosis proteins (IAP). Activation of caspase-3 is inhibited by bcl-2 or Bcl-XL and accelerated by Bax. In addition, an X chromosomeâ€“linked inhibitor of apoptosis called XIAP inhibits caspase-3 activation. Several gene products induce apoptosis in salivary gland diseases (32 ,33 ,34). A particular focus has been put on the expression of Fas (CD95) and its ligand FasL (CD95L), which are members of the TNF (tumor necrosis factor) receptors superfamily. In SjÃ¶gren syndrome, contradictory results have been found so the importance of apoptosis in epithelial cell loss in these patients remains speculative (35 ,36 ,37).

Duct obstruction due to calculi or strictures induces salivary gland atrophy. Histologically, the disappearance of acinar cells within the presence of groups of ductlike structures in a fibrous and inflammatory stroma was observed. The acinar cells had disappeared by apoptosis; this acinar cell death was observed a few hours after duct obstruction. In the first cell death, a few days after duct obstruction, the number of intraepithelial macrophages located in the acinar and duct epithelium of a normal salivary gland multiplied. These macrophages removed the dying cells and apoptotic cellular fragments by phagocytosis, and then they migrated to the interstitium. Simultaneous proliferation of duct epithelial cells by an increase in mitosis contributed to the groups of ductlike structures with some features of squamous metaplasia. Myoepithelial cells became more prominent at the periphery of residual ducts. According to many experimental studies, myoepithelial cells

become more prominent as the epithelial cell loss increases, and no myoepithelial cell apoptosis has been observed (38 ,39 ,40 ,41 ,42 ,43 ,44 ,45).

Irradiation of the major salivary glands is unavoidable during radiotherapy for many head and neck cancers. In fact, radiotherapy induced dryness of the oral cavity, contributing to deterioration of oral mucosa and loss of teeth.

The death of salivary gland acinar cells by apoptosis was observed within 24 hours after irradiation. This mode of cell death occurs with relatively low doses of radiation. An acute inflammatory response located among the destroyed acini was observed.

In normal adult salivary glands, cell division is infrequent in the acini. Development and replenishment of acini destroyed by low doses of radiation comes from stem cells that are located in the terminal intralobular ducts. It is possible that radiation-induced apoptosis of acinar cells could be a stimulus for replication of duct stem cells. However, the death of the ductal stem cells by high-dose radiation did not induce complete regeneration of the destroyed acini and resulted in atrophy of the salivary glands (46).

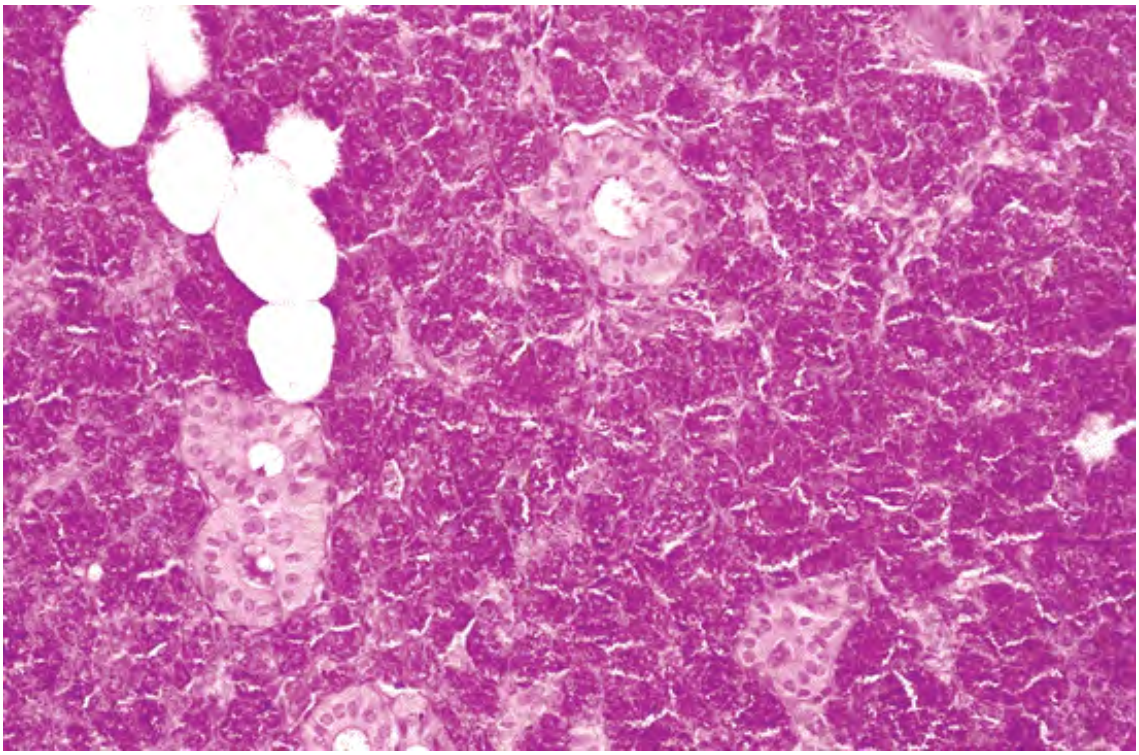

Figure 17.2 Serous-type acini of a parotid gland, with dense secretory granules.

Light Microscopy

The salivary glands are compound exocrine tubuloacinar glands characterized by the aggregation of numerous secretory units. These units consist of acini, where secretion is produced, and a duct system that carries the secretion to the oral cavity and regulates the concentration of water and electrolytes. There are three types of salivary secretory units: the serous ones that contain amylase; the mucous ones that secrete sialomucins; and mixed units made up of mucous and serous cells. According to the predominance of these types of secretory units, the salivary glands may be classified into three categories: serous, mucous, and mixed glands.

With the exception of some mucous units, the parotid gland is of the serous type (Figure 17.2). The submaxillary and the sublingual glands are mixed, with a predominance of serous units in the submaxillary

glands (Figure 17.3) and

a mucous predominance in the sublingual glands (Figure 17.4). Mixed secretory units can be found in accessory parotid glands (19).

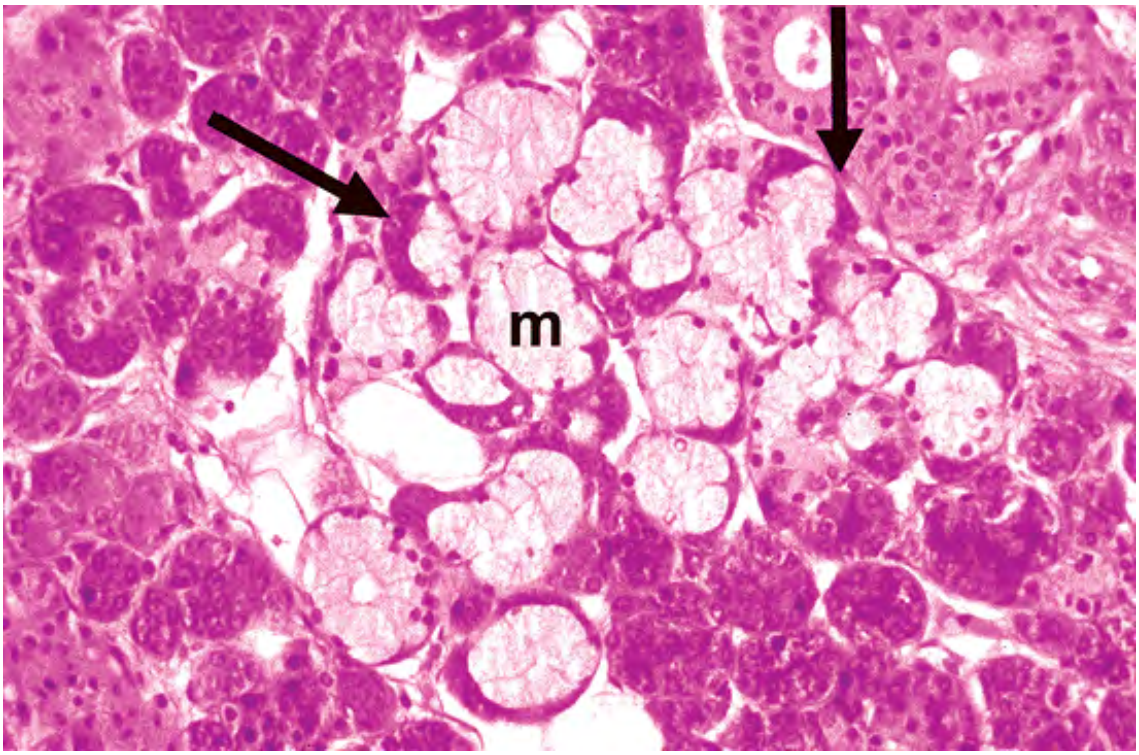

Figure 17.3 Histologic section of a submaxillary gland. In mixed units (*arrows*), serous cells are grouped in a crescent-shaped formation on the periphery of the acini, whereas the mucous cells (*m*) are in direct contact with the duct system.

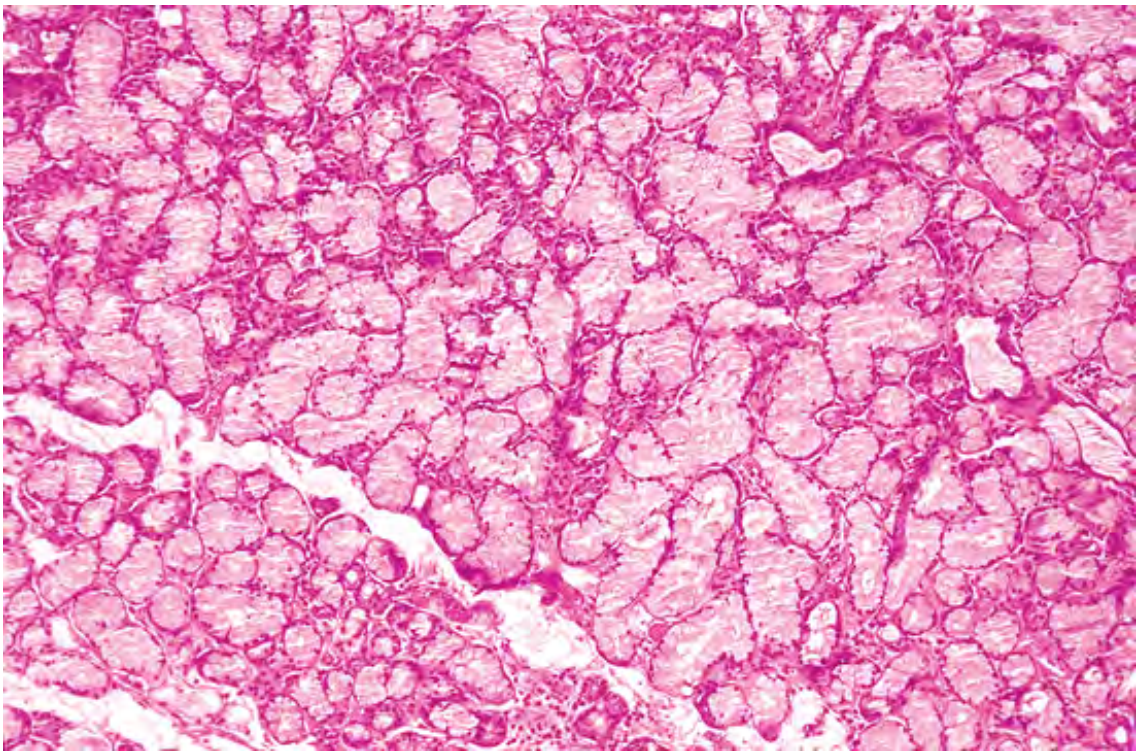

Figure 17.4 Mucous-type acini of the sublingual gland; they are larger and more irregular than the serous and mixed types. Note an inconspicuous duct system.

The lobular architecture of the glands is well defined by the anastomosed connective tissue trabeculae carrying the vascular and neural branches, as well as by the excretory ducts.

Secretory Units

Acini

Serous acini consist of pear-shaped groups of epithelial cells surrounded by a distinct basement membrane. The epithelial cells have a basal nucleus and dense cytoplasm packed with basophilic [periodic acid-Schiff (PAS)-positive] zymogen granules. They vary in number, depending on the different phases of the secretory cycle (Figure 17.2) (46). The primary enzyme present in the zymogen granules is

amylase, or Î±â€“amylase, which splits starch into smaller water-soluble carbohydrates. However, there are other proteins in these granules, including agglutinin, proline-rich proteins, and histatins (47). Other enzymes, such as nonspecific antibacterial lysozyme, lactoferrin, trypsin- and chymotrypsin-like proteases, lysine endopeptidase, and histidine peptidase, also have been shown in the cytoplasm of acinar cells (47 ,48 ,49 ,50 ,51). Each acinus has a central lumen, rarely visible by light microscopy, through which the secretion drains into the intercalated ducts. The excretion seems to be promoted by the contraction of myoepithelial cells that lie between the outer surface of the acinus and the basement membrane. (Given the importance of myoepithelial cells in the pathology of salivary glands, a separate section, below, is devoted to their description.)

Mucous acini are larger than the serous type and have an irregular pattern (Figure 17.4). The secretory cells have abundant cytoplasm filled with clear mucous substance. They contain acid sialomucins (Alcian blue and mucicarmine-positive) and neutral sialmucins (PAS-positive) in different concentrations (52). The characteristics of these sialomucins also differ between submandibular and sublingual glands (53).

Mixed acini (Figure 17.3) are typically found in the submaxillary gland. These structures are characterized by the concentration of mucous cells near the intercalated duct and bordered by a crescent-shaped formation of serous cells. In mixed acini, the serous cells are more or less conspicuous, according to the amount of secretion accumulated in the mucous cells.

Ducts

A peculiar duct system transports the saliva from the gland to the oral cavity and modifies its water and electrolyte concentration. The first two segments, the intercalated and the striated ducts, are intralobular (Figure 17.5). They are also known as secretory ducts because of their metabolic activity (54). The other segments are interlobular and

are called excretory ducts (54).

The intercalated duct lies directly in contact with the acinus. It is lined with a single layer of cuboidal epithelium and an irregular layer of myoepithelial cells. The epithelial cells show a progressive transformation between the secretory and ductal cells and a strong cytoplasmic activity of lactoferrin and lysozyme (55). The lengths of the intercalated ducts are variable in the three major glands (Figure 17.6). In the parotid gland, because they are relatively long, they are easy to recognize in the histologic sections (Figure 17.5A). In contrast, they are short in the submaxillary gland and hardly visible in the sublingual gland (Figure 17.4). Some authors have found undifferentiated cells on the basal side of the intercalated and striated ducts (56). These cells are positive for cytokeratins 13 and 16 on immunohistochemical staining (57 ,58).

The striated ducts are obvious in routine sections, particularly in the submaxillary gland, where they are relatively longer (Figures 17.3 , 17.6). The epithelial lining is simple columnar. On the basal side, it has characteristic parallel striations caused by the deep cell membrane invaginations and mitochondria (Figure 17.5B). This structure represents a specialized surface on the epithelia involved in the transport of water and electrolytes. The numerous mitochondria are correlated with the strong eosinophilia of the duct. Various enzymes such as adenosine triphosphatase (ATPase), succinyl dehydrogenase, and carbonic anhydrase (59) are present in the cytoplasm of the striated ducts and provide them with a metabolic and energy system capable of concentrating some of the elements present in the saliva.

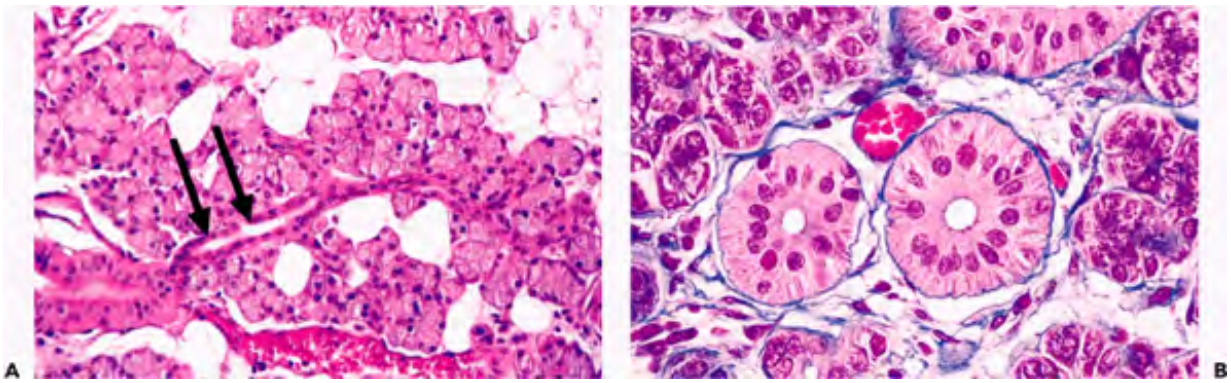

Figure 17.5 Parotid intralobular ducts. A. The intercalated ducts (*arrows*) (sectioned longitudinally) lie in contact with the acinus. B. The striated ducts (sectioned transversely) are lined with a columnar epithelium of basal-striated appearance.

The striated ducts are connected with the interlobular ducts located in the septal connective tissue. These ducts are lined with a columnar pseudostratified epithelium with sparse goblet cells (Figure 17.7). They become progressively larger before joining the principal duct. The principal function of interlobular ducts is to transport saliva, but their role in regeneration is proposed by means of the hypothetical undifferentiated pluripotential cells. In theory, these cells may follow the same cellular lines as in embryonic development (Figure 17.1B) and are perhaps implicated in the metaplastic and neoplastic alterations of salivary glands (60), which are more frequent in these ducts.

The principal duct consists of a thick external fibrous coat of collagen (similar to dermal collagen) and elastic fiber bundles. The epithelium is pseudostratified columnar and becomes squamous and stratified near the opening in the mucous membrane (Figure 17.8).

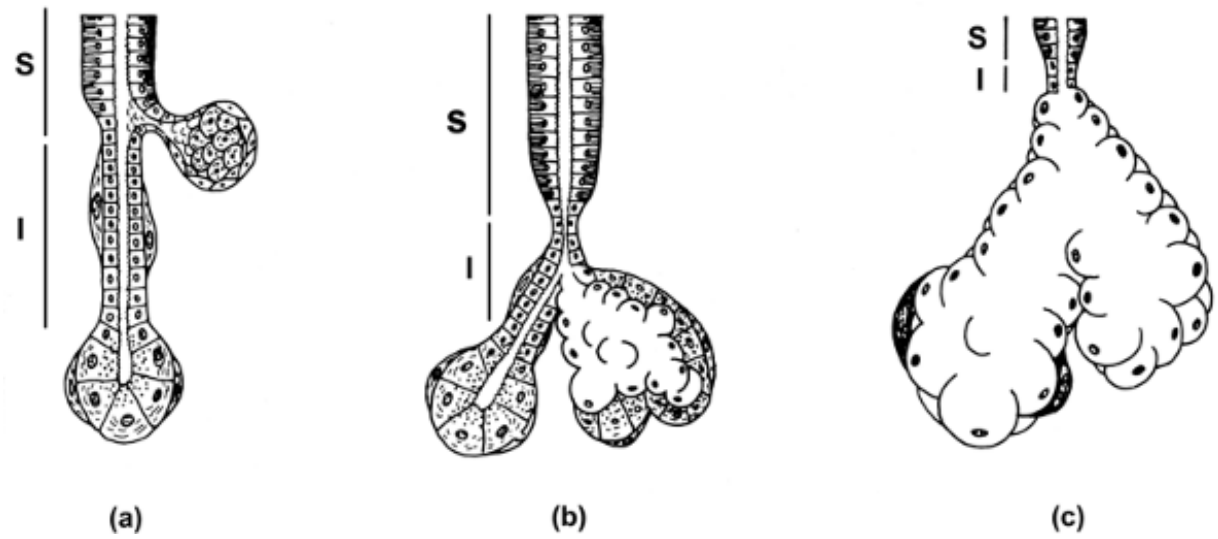

Figure 17.6 The morphology of the major salivary glands is characterized by three types of secretory unit. In the parotid (A) the intercalated duct (*I*) is longer than in the submaxillary (B) and sublingual glands (C). In contrast, the striated duct (*S*) is longer in the submaxillary gland. Sebaceous glands are more frequent in the parotid gland; in the sublingual gland. the intralobular ducts are inconspicuous.

Ultrastructure

At the electron microscopy level, the serous cells show all the characteristics of a specialized cell for secretion and export of proteins. The cytoplasm possesses abundant endoplasmic reticulum, Golgi vesicles, mitochondria, lipid droplets, and secretory granules (Figure 17.9). The last are more common on the apical side of the cell. They consist of a membrane, which encloses the secretion, and a matrix of low-electron density and homogeneous aspect in immature granules and high-electron density in mature granules (61 ,62). The electron density of the granules differs according to the package of the different proteins within the same granule (46). All the cytoplasmic organelles increase during protein synthesis and decrease during discharge (59). The basal surface of the cell shows numerous folds of

plasma and basal membranes. They cover the entire cell base and

extend beyond the lateral margins in the manner of foot processes. Therefore, the basal surface of the cell is greatly expanded, facilitating diffusion of materials into the cell (59). Most of the cytoplasm in mucous cells is occupied by mucous vacuoles and Golgi apparatus. Only a small basal and lateral portion of the cytoplasm contains endoplasmic reticulum and mitochondria (63).

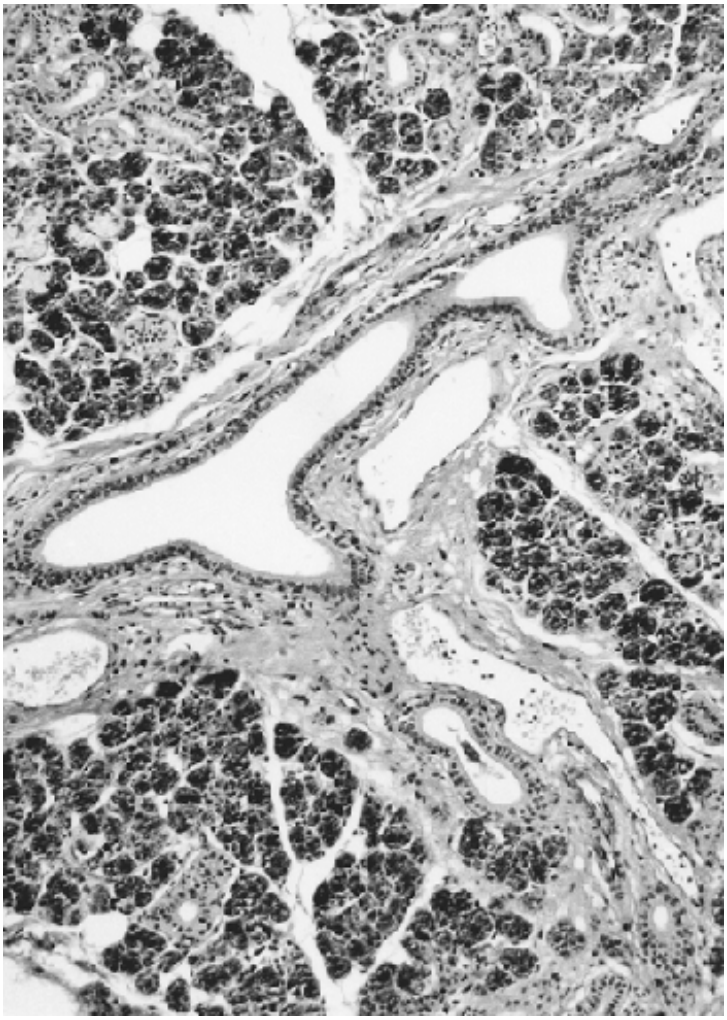

Figure 17.7 Interlobular duct adjacent to vessels in the septal connective tissue.

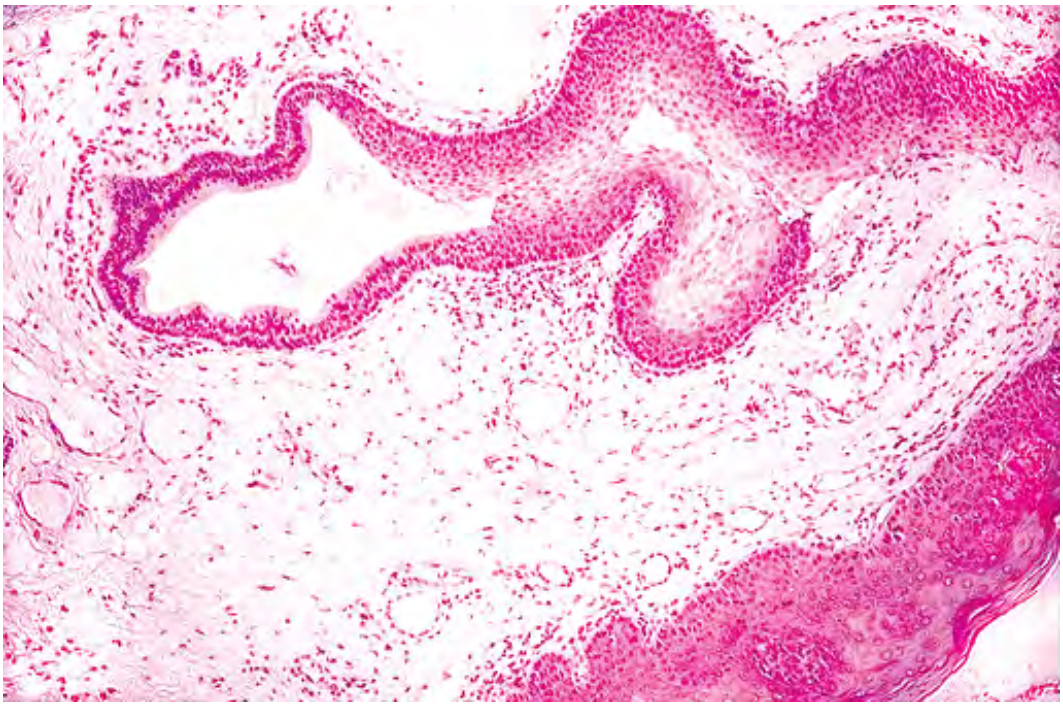

Figure 17.8 Main excretory duct in the caruncula sublingualis. Near the oral surface, the duct is lined with a squamous stratified epithelium.

At the apical pole, the secretory cells are joined by an adhesive zone, whereas the basal side is adhered by desmosomes (62). Between the junctions, virtual spaces form the secretory capillaries, which are in continuation with the acinar lumen. Numerous microvilli protrude into the capillary lumen (Figure 17.9).

The cytoplasm of myoepithelial cells may be separated into two portions (61): one, in contact with the basal lamina, is occupied by myofilaments and pinocytotic vesicles; the other portion is in contact with the secretory cell and contains mitochondria, endoplasmic reticulum, lysosome-like complexes, and Golgi vesicles. The visualization of myofilaments may vary in different myoepithelial cells; some of them have only focal aggregates of myofilaments, while others show a typical basal distribution resembling

smooth muscle cells (62). The junction between myoepithelial and

secretory cells is ensured by desmosomes.

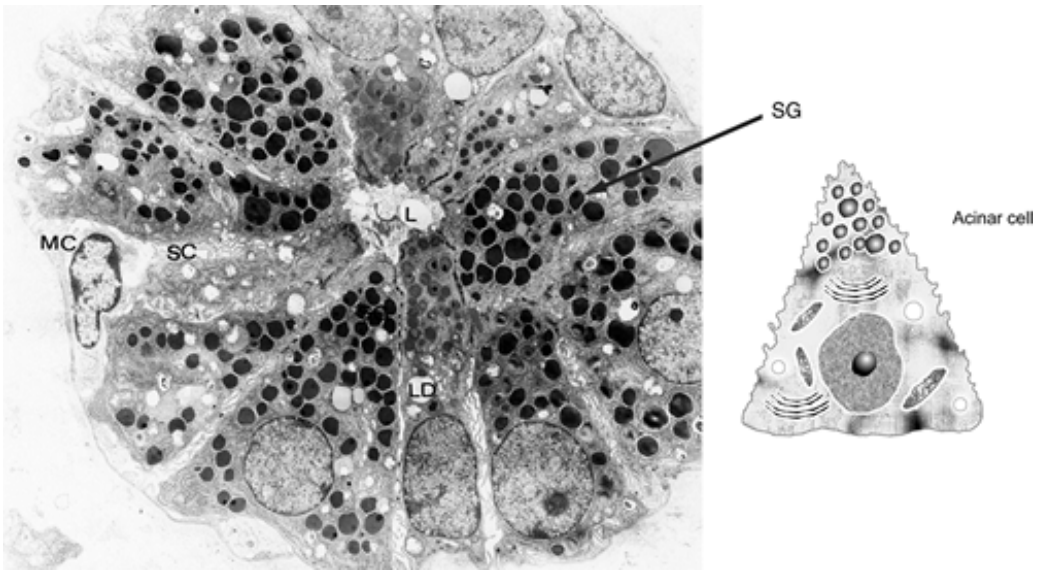

Figure 17.9 A. Ultrastructure of a parotid acinus: lumen (*L*), secretory granules (*SG*), lipid droplets (*LD*), secretory capillaries (*SC*), and myoepithelial cell (*MC*) (Ã—6000). B. Drawing of an acinar cell.

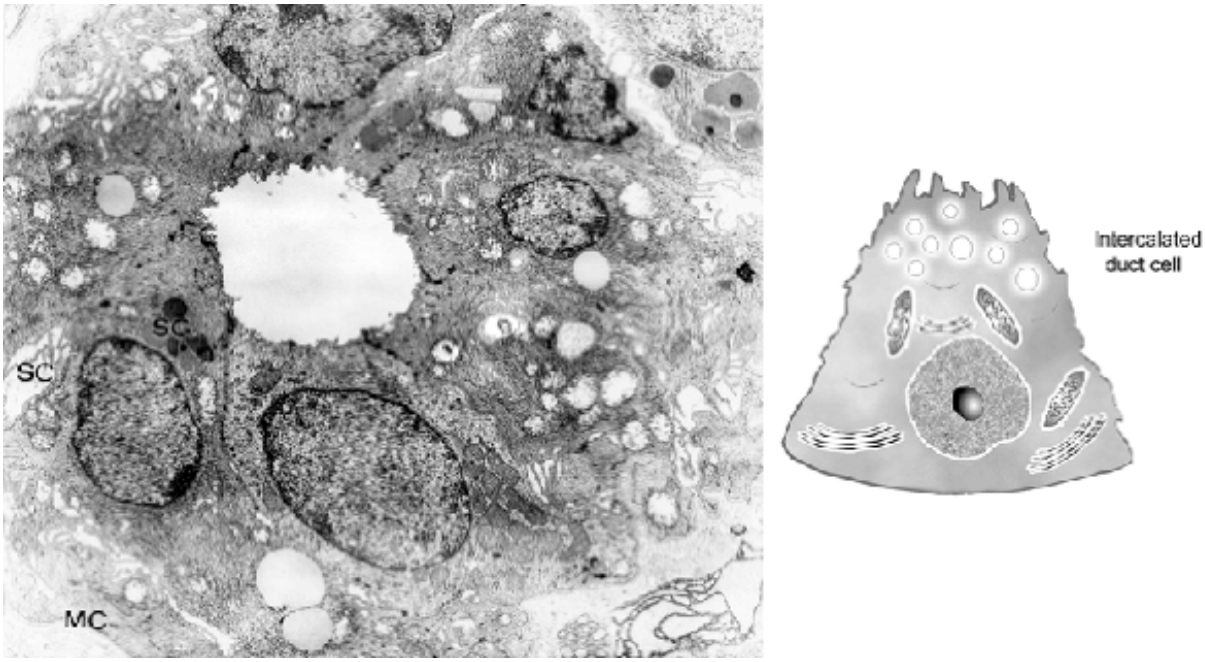

Figure 17.10 A. Intercalated duct of parotid gland. Some secretory granules (*SG*) and secretory capillaries (*SC*) are present on the apical

side. On the external surface, myoepithelial cell prolongations (*MC*) are found (Ã—10,300). B. Drawing of an intercalated ductal cell.

Transition from acinus to intercalated duct is gradual. In the latter, epithelial cells have relatively large nuclei and few cytoplasmic organelles, consisting principally of mitochondria, some cisternae of endoplasmic reticulum, lipid droplets, and a few apical secretory granules (54 ,58) (Figure 17.10). Scattered secretory capillaries may be found, as well. On the external surface, myoepithelial cell prolongations are usually present.

The striated ducts (Figure 17.11) are composed of tall cylindrical cells with central nuclei. On the basal side, the cell membrane is extensively folded into fingerlike structures. The space between these folds is occupied by vertically oriented mitochondria. This cytoplasmic organization is specialized in the active transport of water and electrolytes from the vascular system to the lumen of the duct; the rest of the cytoplasm contains mitochondria and scattered endoplasmic reticulum (63 ,64 ,65).

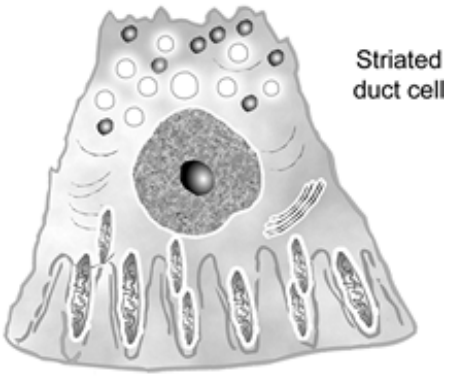

Figure 17.11 A. Striated duct cells possess vertically oriented

mitochondria and extensively folded plasma membrane; the basal side is in close relationship to the blood capillary (Ã—7920). B. Drawing of a striated duct cell.

Sebaceous Glands

In 1931, Hamperl (66) described the presence of sebaceous glands histologically similar to those of the cutaneous adnexa. Other authors have indeed recognized such structures, which appear as isolated cells in the wall of either an intercalated or a striated duct (Figure 17.12A) (67 ,68 ,69 ,70). Larger cell accumulations form a sebaceous gland limited by a well-defined basal membrane (Figure 17.12Bâ€“C). They vary in size, have a diverticular aspect, and are permanently linked to an interlobular duct. At the periphery of the gland, the cells are flattened with round or oval nuclei. The central cells have an abundant vacuolated cytoplasm rich in lipids, which may be stained, in frozen sections, with fat colorations (Sudan III and IV, oil red O, osmic acid). The nuclei become irregular or pyknotic and finally disappear. When the gland reaches a certain size, the holocrine-type secretion is emptied into the ductal system and is mixed with the saliva (Figure 17.12D).

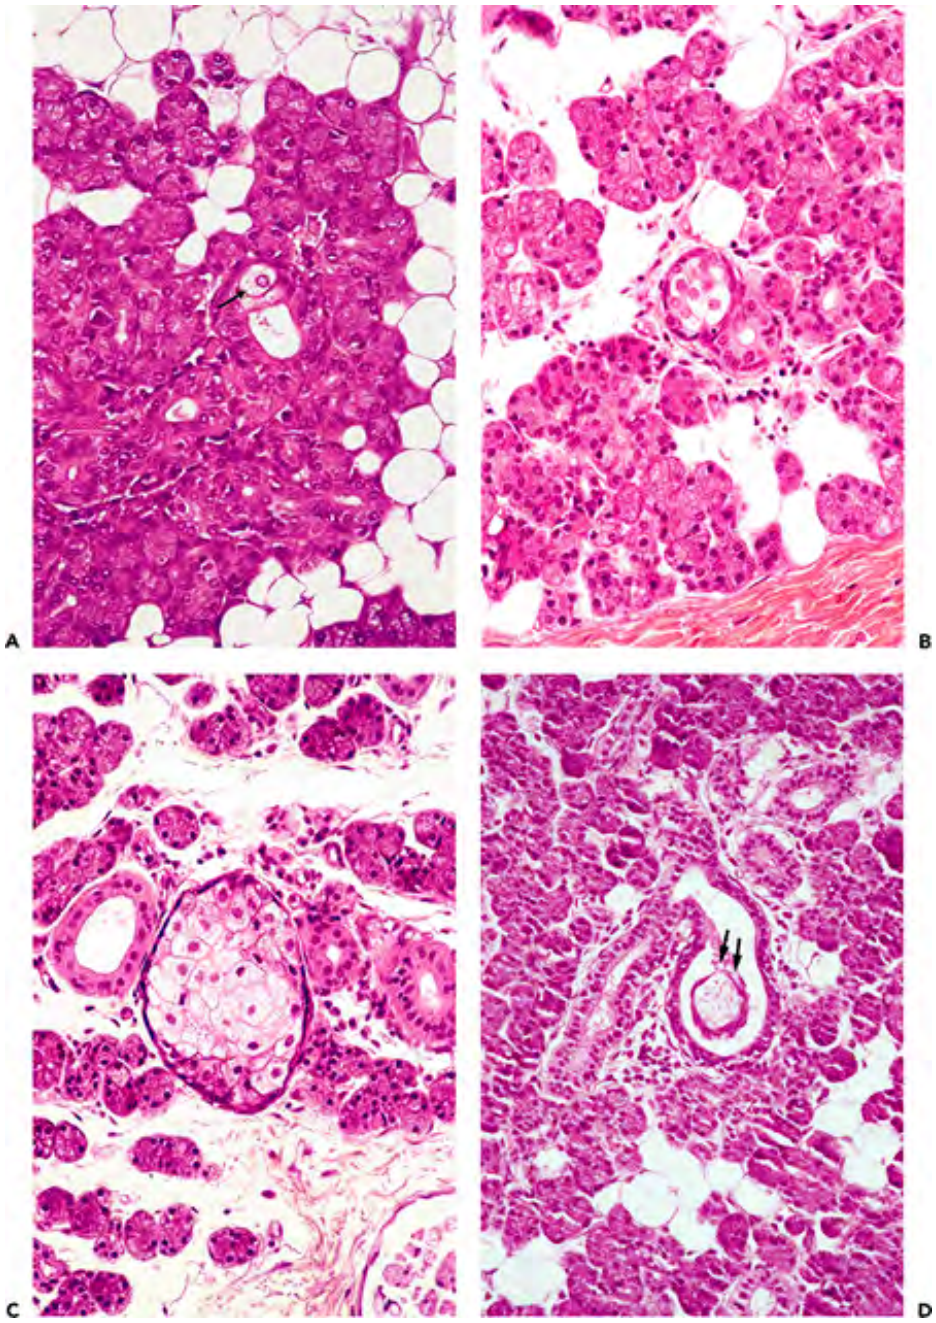

Figure 17.12 Sebaceous elements in a parotid gland. A. Isolated sebaceous cells can be seen in the duct wall (*arrow*). They proliferate to form a well-defined gland (B, C); secretion is present in the lumen of the duct (D) (*arrows*). E. Drawing illustrates the previous features.

The number of sebaceous glands in major salivary glands varies; they are common in the parotid gland, rare in the submaxillary gland, and probably absent in the sublingual gland. They are diffusely scattered throughout the parenchyma, where their numbers also vary greatly. Their presence or absence in the different lobules is not related to either age or sex (70).

In a review of 100 parotid glands selected at random from our material, we found sebaceous glands in 42% of cases. They were also found in 5% of 100 submaxillary glands. These findings are in agreement with other authors. Thus, we conclude that their incidence in the parotid gland is more frequent than imagined. The more sections that are examined, the more sebaceous glands are found; it is, therefore, merely a question of looking for them. If the entire parotid gland were examined meticulously, it would be difficult not to find a sebaceous gland (69).

The presence of sebaceous glands in the salivary tissue has not been satisfactorily explained. A heterotopic phenomenon (67 ,68) similar to the occurrence of sebaceous glands in the oral mucosa (Fordyce's disease) seems unlikely. In the mouth, this condition may result from aberrant buds along the fetal line of closure (70 ,71 ,72); but in the parotid and submaxillary glands, there are no lines of closure. Metaplasia (66 ,70) beginning in the ducts does not explain the high frequency of sebaceous glands in parotid parenchyma. Therefore, it seems reasonable to consider the sebaceous glands as a normal holocrine differentiation. Their occurrence in the parotid gland appears to be related to a specific function that is not yet understood. Sebaceous glands analogous to those of the salivary glands have been found in the oral mucosa. In the oral mucosa, androgen receptors participate in the histogenesis of sebaceous glands (73 ,74). A similar mechanism may be proposed for the histogenesis of sebaceous glands in salivary glands.

The belief that a potential for sebaceous differentiation exists in the salivary parenchyma is further supported by the fact that salivary

tumors or tumorlike conditions with a sebaceous character or sebaceous gland participation have been described. These rare lesions include sebaceous adenoma, sebaceous lymphadenoma, sebaceous carcinoma, and parotid cyst. They have also been noted in pleomorphic adenoma and mucoepidermoid carcinoma (69 ,74 ,75 ,76 ,77 ,78 ,79 ,80 ,81 ,82 ,83 ,84 ,85 ,86 ,87).

Myoepithelial Cells

Myoepithelial cells (basket cells) are derived from early modification and differentiation of primitive pluripotential salivary duct cells by the tenth week of gestation. It has also been suggested that the precursor of myoepithelial cells are the clear cells located in the terminal and striated ducts (63). In regeneration, these cells migrate from the acinar periphery to the duct-acinar region (32).

These cells lie between the epithelial cells and the basal lamina of acini, in the intercalated ducts, and probably also in the union of the striated and intercalated ducts (56 ,87 ,88). The cells are flat and have long cytoplasmic processes extending over the epithelial surface (Figure 17.13) in a network that makes it difficult to discern them in routine histologic sections. However, myoepithelial cells may assume morphologic modification at different anatomic locations within the ductal acinar structure (56 ,64). These cells are best studied by electron microscopy.

The most outstanding characteristic is the presence of cytoplasmic filaments on the basal side. Most of these consist of the myofilaments actin, tropomyosin, and myosin (63 ,88 ,89 ,90), which are arranged in a pattern similar to that of the smooth muscle. Tonofibril-like bundles of intermediate filaments are attached to the cellular junctions, particularly in desmosomes where the filaments are cytokeratin. Some forms of myoepithelial cells may also show scattered, rather than basal, cytoplasmic distribution of these filaments, which may reflect structural and functional

differences (64). The presence of vimentin is not constant, and the filament desmin is absent in normal myoepithelium (91). The cytoplasm shows a strong activity of ATPase and alkaline phosphatase (92 ,93).

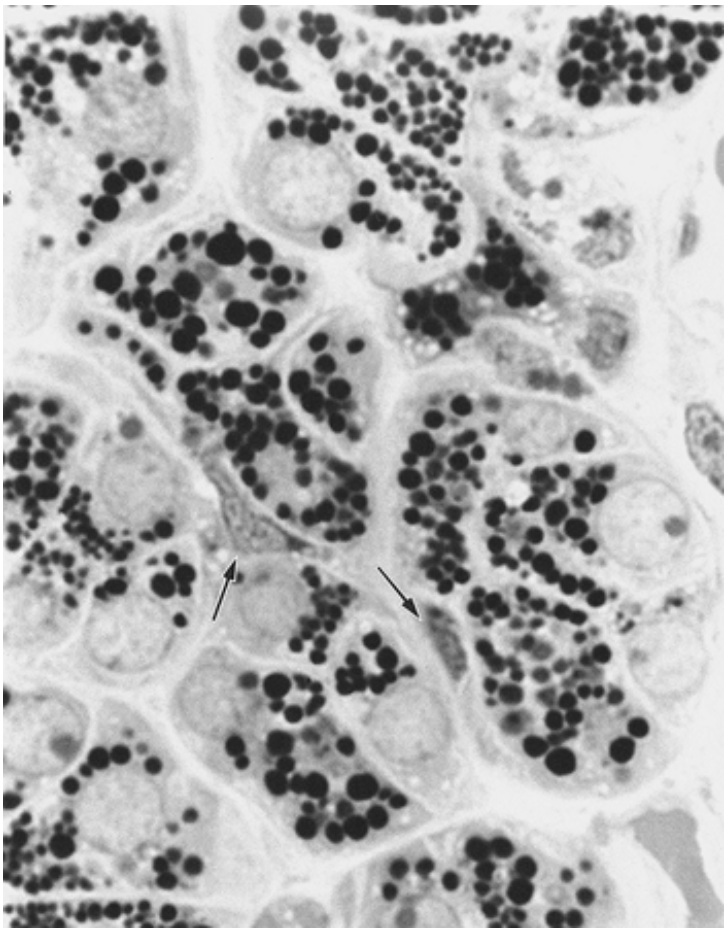

Figure 17.13 Myoepithelial cells (*arrows*) on the acinic surface (semithin section, toluidine blue).

It is generally accepted that myoepithelial cells are contractile. This function speeds up the outflow of the saliva by increasing the pressure on the excretory unit (94). It has been extensively studied in the mammary gland of the rat, where these cells are more frequently found. Oxytocin-induced contraction in the myoepithelial cells is similar to that of true muscle cells (95). The presence of myofilaments in the cytoplasm of these cells correlates strongly with

this function. In addition, myoepithelial cells support the underlying parenchyma and participate in the elaboration of the basal lamina. This last function is important in some hyperplastic and neoplastic alterations, where the myoepithelial cells produce fibronectin, laminin, and type III collagen (96 ,97 ,98 ,99 ,100 ,101 ,102 ,103). All these proteins are constituents of the basal lamina (104). In addition, myoepithelial cells are also involved in the production of tenascin, an extracellular matrix glycoprotein (105 ,106).

Regardless of endodermal or ectodermal origin, the myoepithelial cells share an epithelial and mesenchymal structure and function. Altered myoepithelial cells may manifest (in neoplastic proliferation) one or both characteristics. These cells are now considered the key factor in the morphology of many salivary neoplasms and in the morphologic variability of some tumors (106).

The Role of Myoepithelial Cells in Salivary Gland Tumors

The presence of myoepithelial cells in different histologic types of salivary gland tumors (Table 17.1) is well documented, as is the role of these cells in the pathogenesis and in its biologic behavior.

The role of myoepithelial cells in the histogenesis of the pleomorphic adenoma has been extensively studied. This tumor, sometimes called a mixed tumor because of the epithelial and mesenchymal mixture of tissues, is the most frequent neoplasm of the major salivary glands (107 ,108). It is now accepted that myoepithelial cells play a crucial role in the neoplastic process by expressing both epithelial and mesenchymal structures in the majority of pleomorphic adenomas (109 ,110 ,111 ,112 ,113 ,114 ,115 ,116 ,117). The participation of the contractile elements is also accepted in epithelial-myoepithelial carcinoma [clear cell carcinoma, a malignant tumor that mimics the normal structure of the intercalated duct (118 ,119 ,120 ,121 ,122 ,123)] and myoepithelioma [in which the myoepithelial cells are the

only tumoral element showing different cellular forms (124 ,125 ,126 ,127 ,128 ,129)]. They also have been demonstrated in terminal duct adenocarcinoma (polymorphous low-grade adenocarcinoma) (130 ,131); monomorphic adenoma, which includes basaloid monomorphic adenoma (132 ,133 ,134); adenoid cystic carcinoma (96 ,100 ,113 ,135 ,136 ,137 ,138); and basaloid adenocarcinoma (139). Myoepithelial cell participation is also present in congenital tumors of salivary gland origin, such as sialoblastoma (140) and the salivary gland anlage tumor (141). Although there are rare reports of myoepithelial cells in mucoepidermoid carcinoma (135 ,142), it is difficult to fully accept these statements because mucoepidermoid carcinoma arises from a ductal segment that lacks myoepithelial cells.

Table 17.1 Salivary Gland Tumors with Myoepithelial Cell Participation

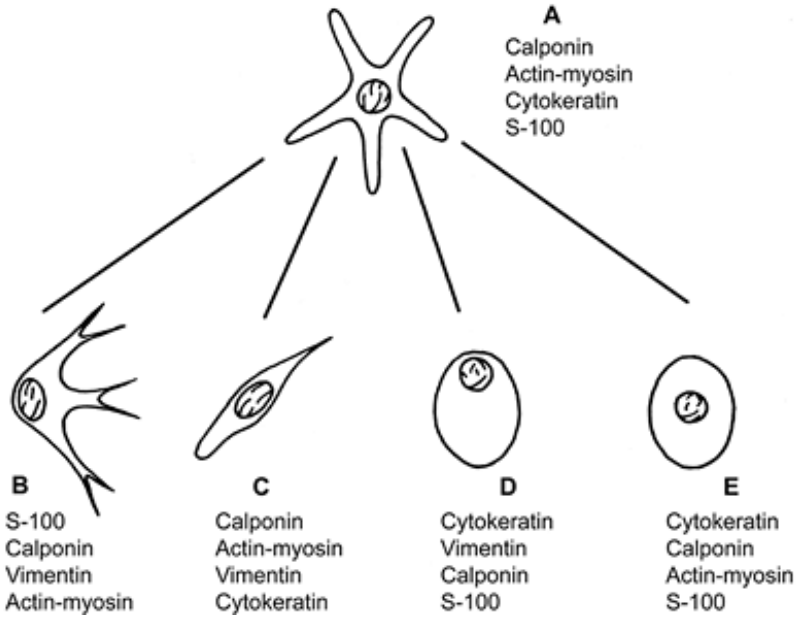

Figure 17.14 Morphology and histologic markers of the normal (A) and modified myoepithelial cells (Bâ€“E). The most constant markers are present in order of frequency: chondromyxoid type (B), spindle-shaped type (C), hyalin or plasmocytoid type (D), and epithelial (clear) type (E).

The principal morphologic types of altered myoepithelial cells are (Figure 17.14):

- Stellate or myxoid cells, which are typically present in chondromyxoid areas of pleomorphic adenoma.
- Spindle-shaped or myoid cells, which can be identified in pleomorphic adenoma and some types of myoepithelioma.
- Hyalin or plasmocytoid cells (143), which can be seen in pleomorphic adenomas and can be present in myoepitheliomas. These cells show abundant cytoplasmic filaments that give a hyalin eosinophilic aspect.
- Clear or epithelial cells, which are found in many salivary tumors on the external surface of ducts or ductlike structures. This is also characteristic in epithelial-myoepithelial carcinoma.

Bidirectional differentiation of the modified myoepithelium has been well documented. Myoepithelial cells with mesenchymal characteristics secrete mesenchymal mucins such as the acid glycosaminoglycans (hyaluronic acid, heparin sulfate, chondroitin-4-sulfate, and chondroitin-6-sulfate) (144 ,145), basement membrane constituents, elastin (111 ,112), and tenascin (105). In addition to contractile filaments (actin and myosin) and related proteins such as calponin, vimentin becomes strongly positive, particularly in spindle-shaped form (138 ,139 ,140 ,146 ,147 ,148). The S-100 protein, which is a common marker used for the myoepithelium, enhances its positivity in chondroid, myxoid, and stellate cells, particularly if they are associated with a myxoid stroma (104 ,149 ,150). Plasmocytoid myoepithelial cells are frequently negative for the muscular markers (151). However, these cells express several ultrastructural and immunomarkers characteristic of myoepithelial cells (127). On the other hand, epithelial differentiation may take the form of clear or squamous cells, which can contain both vimentin and keratin filaments in the same cell (110). Figure 17.14 illustrates the histologic and immunohistochemical patterns of modified myoepithelium.

Myoepithelial cells are a central element in the histologic formation and organization of different salivary gland tumors. The cytomorphologic features and the variability of the extracellular products account for the morphologic heterogeneity of these lesions. The presence of these cells varies widely, from minimal as in monomorphic adenomas (136), to marked, as in myoepitheliomas. Evidence of the protective effect of myoepithelial cells in malignant tumors is growing. Protease inhibitors like maspin, Î±1-antitrypsin, TIMP-1, and nexin II are anti-invasive factors produced by the myoepithelial cells in myoepithelial cells rich tumors (152 ,153). Now it is well accepted that malignant tumors with important myoepithelial cell components behave less aggressively. Myoepithelial carcinoma tends to be lobulated tumors rather than infiltrating, and patients with myoepithelial carcinoma show a better survival when they are

compared to carcinomas that do not express myoepithelial cell differentiation. In addition, there is also evidence that myoepithelial cells may inhibit angiogenesis (154).

Lymphoid Tissue

The immune system of salivary glands comprises two elements of the mucosa-associated immune system. One is the secretory component, a glycoprotein receptor for dimeric IgA and pentameric IgM that is produced by epithelial cells in the acini, intercalated ducts, and striated ducts (155 ,156). The other element is lymphoid tissue, which is either distributed diffusely or organized in lymph nodes. Isolated

lymphoid cells are present in the connective tissue near the acini and ducts. They are variable in number in the different glands (157) and yield principally IgA (nearly 80% of the immunoglobulins in saliva), along with a lesser quantity of IgG and IgM (159). Small lymph nodes are usually present near the surface of the parotid gland but not in the other salivary glands. Nevertheless, lymphoid cell aggregates are present in fetal submandibular and sublingual glands (158). These nodes usually contain salivary ducts and acini in the medullary region (Figure 17.15A), a phenomenon probably due to the close relationship between developing gland and lymphoid tissue during embryonic life.

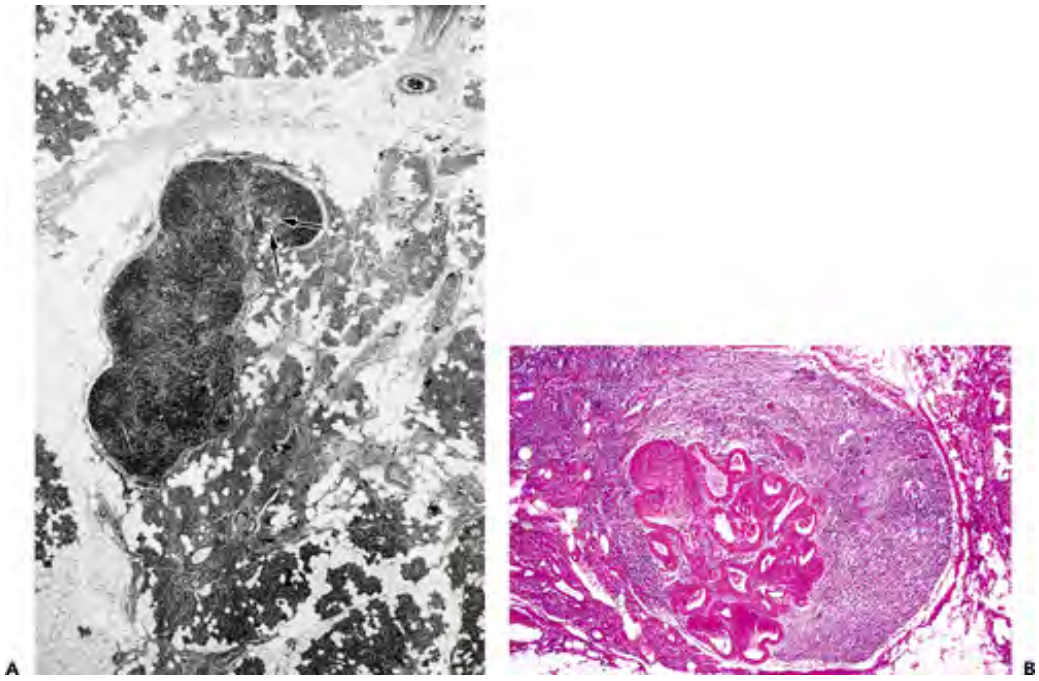

Figure 17.15 Lymph node of the parotid gland. A. Presence of glandular ducts in the medullary region (*arrows*). B. Duct dilatation and oncocytic transformation in another lymph node of the same patient.

Lymph nodes are thought to participate in the histogenesis of Warthin's tumor. Although they have been pinpointed as the origin of the lymphoid tissue that characterizes this neoplasm, the hypothesis is still under debate. Different mechanisms have been proposed, but the most widely accepted one states that the lesion originates from the ducts inside lymph nodes within or adjacent to the parotid gland (85,160,161,162). According to this concept, the epithelial component of the tumor corresponds to altered ducts inside a lymph node, and the lymphatic component is, in fact, a lymph node. The following arguments support this hypothesis: salivary tissue is frequently present in intraparotid or periparotid lymph nodes (Figure 17.15A); with the exception of a few cases, this tumor is exclusive to the parotid region; it is common to find early stages of oncocytic and papillary transformation in lymph nodes of the parotid region (Figure 17.15B); and, finally, tumors identical to the epithelial structure of

Warthin's tumor occur outside the lymph nodes but without lymphocytic components (160).

The diffuse lymphoid tissue may increase in chronic sialadenitis, particularly in immunologic reactions such as the benign lymphoepithelial lesion associated with SjÃ¶gren's syndrome. In these instances, lymphoid tissue may obscure the glandular parenchyma in a diffuse or nodular manner, and epimyoepithelial islands may be formed (91 ,160). The polyclonal character of the lymphoid cells and the presence of epimyoepithelial islands are useful criteria in the differential diagnosis of malignant lymphoma, which can occur in a preexisting benign lymphoepithelial lesion (162).

The Heterotopic Salivary Tissue and its Significance

The presence of salivary tissue outside the major salivary glands and the oral cavity, pharynx, and upper airways is considered heterotopia. This heterotopia may be classified as intranodal and extranodal in a number of locations in the head and neck.

Heterotopia is common in the lymph nodes near the parotid gland but is much less frequent in the submaxillary region and in other upper cervical nodes (163 ,164). The glandular elements are either normal or atrophic; they consist mainly of ducts, but acini are also found. They are localized in the medullary region and comprise a variable proportion of lymphoid and salivary tissues. Although all types of secretory units are found, serous ones are predominant. The histologic architecture is similar to a normal gland. The lymph nodes exhibit a normal structure or some degree of lymphoreticular hyperplasia.

The incidence of heterotopic salivary tissue in the lymph nodes has been well documented (165). It is typically found in the parotid region of fetuses during various stages of development, usually in more than one lymph node. In adults, although the incidence is not

constant, it is nonetheless frequent (166). In most of the reports, the histogenetic mechanisms of this phenomenon have been related to embryonic development. From this point of view, the salivary tissue is trapped during embryologic development. In the fetus, the parotid gland is closely related to lymphoid tissue from the beginning of the second month. Moreover, Bairati (166) found that, at least in the first years of life, this salivary tissue is connected to the parotid gland. Although lymphatic dissemination has been proposed as a mechanism of salivary heterotopia in lymph nodes, in particular when they are located in the lower neck, this hypothesis is only speculative (167).

Extralymphatic heterotopias are rare and often latent but may be responsible for symptomatology. Heterotopic salivary tissue has been described in several sites, including head and neck, thorax, and abdomen (Table 17.2). In the upper neck, heterotopia is limited to the mandible, ear, palatine tonsil, mylohyoid muscle, pituitary gland, and cerebellopontine angle (164 ,168 ,169). All these sites, with the exception of the last, may be related to the embryonic migration of the salivary glands. In the lower neck, heterotopias are localized in the base of the neck, particularly around the sternoclavicular joint and in the thyroid gland and parathyroid glands (Figure 17.16) (167 ,171).

Most examples of high salivary heterotopia are explained in relation to lines of migration of the parotid and submaxillary glands. In the mandible, the presence of salivary heterotopia may be related to a bone cavity and usually contains submandibular gland tissue. These inclusions are most common in the posterior lower jaw, near the angle. Originally described in 1942 by Stafne, they are often

considered as heterotopias (172). This defect may be found in the anterior position (173). A recent study showed the heterotopic salivary tissue is present in 0.3% of maxillofacial marrow samples. The origin of this tissue is a matter of debate, but the most accepted hypothesis is the metaplasia of the odontogenic epithelial lesions (174). In the lower neck, an association with cysts and sinuses is frequent. This condition, along with the topographic presentation, has been related to the branchial apparatus (164 ,170) and, in particular, to a defective closure of the precervical His's sinus. The different abnormalities related to this defect (175) correspond embryologically to topographic distribution

through the neck from the ear to the clavicle. When this defect occurs, the salivary tissue is the result of abnormal tissue differentiation (heteroplasia). Willis (176) has argued that this is the mechanism of heterotopia. This mechanism may also account for the salivary tissue in remnants of Rathke's pouch (169) and the thyroglossal duct.

Neoplastic transformation in heterotopic salivary tissue may pose a problem in differential diagnosis of metastasis in a cervical lymph node (163). Pleomorphic adenoma, mucoepidermoid carcinoma, and adenoid cystic carcinoma are the most frequent tumors arising in heterotopic salivary tissue. In fact, heterotopia is an explanation for many aberrant salivary tumors (167 ,177) and some cervical lymph node metastases that are thought to be metastases of an unknown primary tumor (178). Primary salivary tumors of the mandible may originate in this aberrant tissue (179).

Aging Changes

Oncocytes

The oncocyte is an altered swollen epithelial cell characterized by an abundant eosinophilic granular cytoplasm that is rich in altered mitochondria and enzymes (Figure 17.17A) (180). This cell is

frequently present in interlobular ducts and is less frequent in acinar cells. Oncocytes are more common in the parotid gland. They are rare before 50 years of age, increase in frequency with advancing years, and become constant after 70 years (66 ,181). Oncocytes may be detected by histochemical methods using phosphotungstic-acid hematoxylin or by more specific immunohistochemical methods with antibodies to human mitichondria (182).

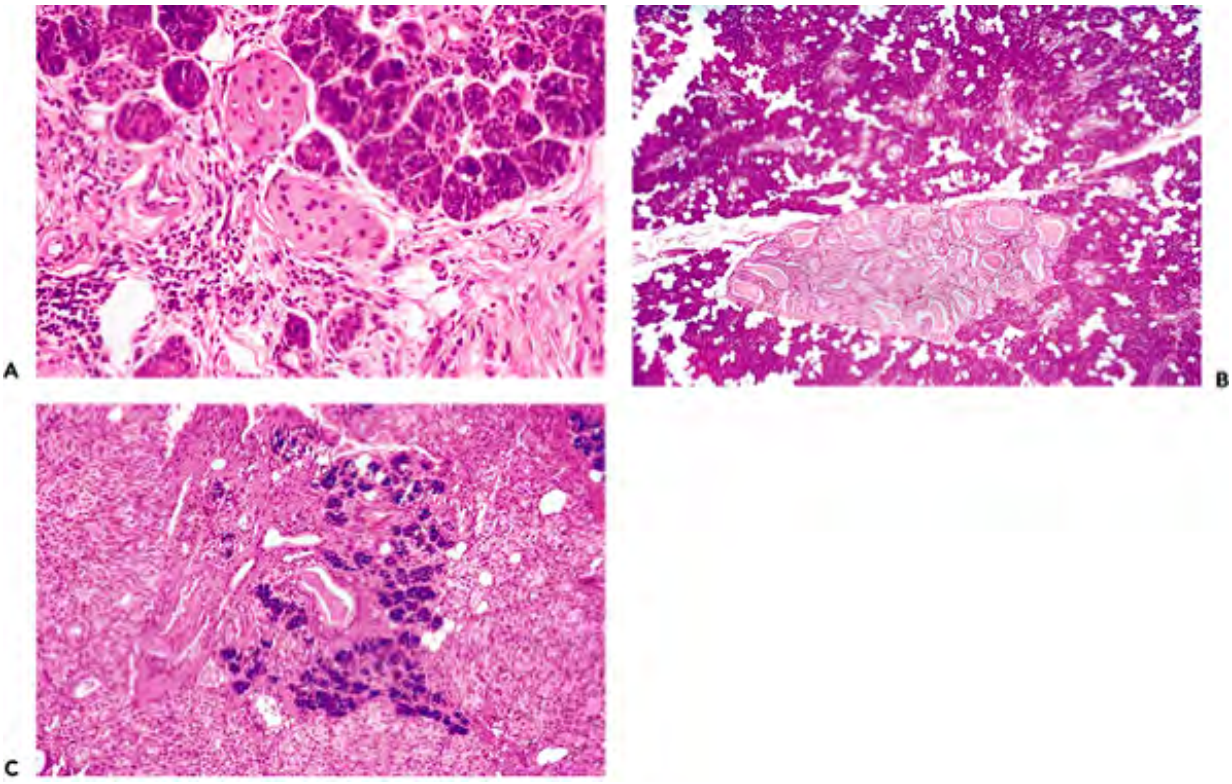

Figure 17.17 A. Oncocytes in intralobular ducts of a normal submaxillary gland. Note the abundant and granulated cytoplasm. B. Nodular oncocytic hyperplasia. C. Diffuse oncocytosis.

The nature and function of oncocytes are unknown. Their proliferative character is a common finding in organs with endocrine function or endocrine dependence (183). Numerous researchers are presently interested in the production of various peptides with endocrine function in the intralobular ducts of rodent salivary glands (184 ,185 ,186). On the other hand, a number of workers are investigating the

presence of neuroendocrine peptides such as the substance Pâ€“like, Î²-endorphinâ€“like (187 ,188), and a calcitonin-related peptide (189). In addition, neuroendocrine regulation of inflammation by the submandibular gland has been explained by an immunoneuroendocrine communication controlled by cervical sympathetic nerves (190).

The proliferation of oncocytes is called oncocytosis or oncocytic metaplasia when it is diffuse and generally without pathologic significance. In other cases, this proliferation presents a nodular pattern known as nodular hyperplasia (191). Histologically, it is easy to distinguish in the

salivary parenchyma as one or several small foci of oncocytes that are well circumscribed but not encapsulated. The cells may be arranged in solid cords or ductal structures and, in rare cases, may replace most of the gland (Figure 17.17Bâ€“C). Oncocytes participate in various salivary gland tumors in approximately 10% of cases (192); the most common is Warthin's tumor, and they are also observed in basal cell adenoma, pleomorphic adenoma, myoepithelioma, polymorphous low-grade adenocarcinoma, mucoepidermoid carcinoma, and acinic cell carcinoma (193 ,194 ,195 ,196). The neoplastic proliferation called oncocytoma is rarely found in salivary glands (197).

Fatty Infiltration

Normally, some adipose cells are present in the areolar connective tissue of the salivary glands. This fatty tissue increases in adults; in the elderly, it forms an important proportion of salivary gland tissue. Fatty infiltration may reach huge proportions, especially in alcoholics and the malnourished (198).

Reactive Changes

Metaplasia

Squamous metaplasia may be present in larger salivary ducts in chronic inflammatory processes, particularly when associated with calculi (Figure 17.18A) (199). (Remember that when the major salivary ducts open into the oral cavity, they are lined with a stratified squamous epithelium). Metaplastic squamous transformation is also present in intralobular ducts and acini in ischemia and radiation injury (200 ,201).

Mucous metaplasia is found on interlobular ducts and, less frequently, on intralobular ducts in cases of obstructive and postradiotherapy forms of sialadenitis (202). An important proliferation of mucous goblet cells is accompanied by prominent ciliated cells mimicking the respiratory epithelium (Figure 17.18B). Necrotizing sialometaplasia is a type of metaplasia peculiar to salivary tissue, but it is exceptional in major salivary glands (Figure 17.19) (203). It consists of ischemic lobular infarction or necrosis of some acini, accompanied by extensive squamous metaplasia of salivary gland ducts and acini. Severe inflammation and granulation tissue are present. Necrosis of mucous acini is represented by small pools of mucin that, along with the squamous elements, may be mistaken for mucoepidermoid carcinoma (204). The preservation of general lobular morphology and prominent granulation tissue are criteria in favor of benignity. Subacute forms are also described (205).

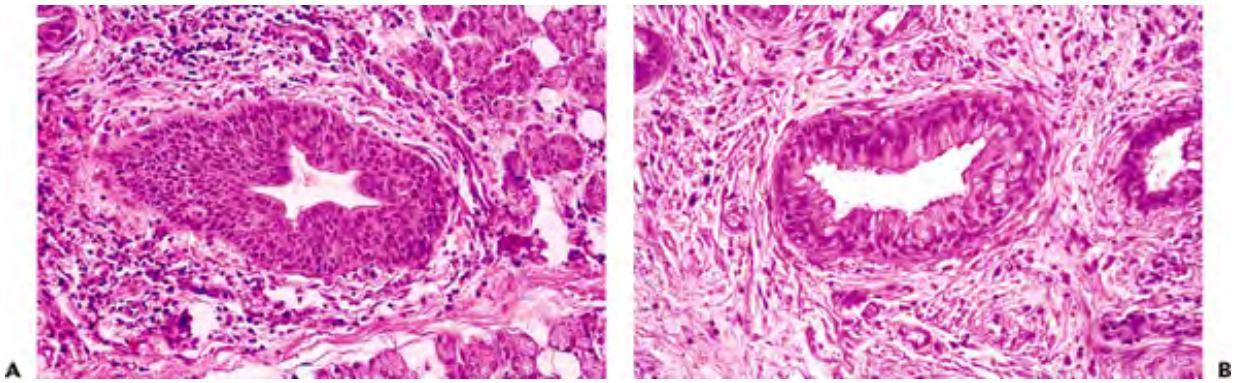

Figure 17.18 Metaplasia of excretory ducts. Squamous (A) and mucous metaplasia (B) showing cilliated cells simulating respiratory epithelium.

Hyperplasia

Hyperplasia of mucous acini is an alteration exclusive to the minor salivary glands. In contrast, serous hyperplasia occurs in parotid and, rarely, in submaxillary and sublingual glands; it is called sialadenosis (206). This hyperplasia is associated with a number of metabolic, nutritional, and endocrine conditions or follows the ingestion of chemicals and drugs (207). In most cases, a bilateral swelling of the glands is caused by enlarged acini and an accumulation of secretory granules in the cytoplasm. In other cases, granulation is lost and the cytoplasm looks vacuolated (22). The myoepithelial cells may present nuclear pyknosis or cytoplasmic vacuolation. Adenomatoid salivary gland hyperplasia should be distinguished from true tumors. Recently, adenomatous ductal proliferation in salivary glands has been described; these cases may be misdiagnosed as true adenomas. Adenomatoid hyperplasia contains clusters or lobules of mucous or serous glands with normal or enlarged appearance, whereas adenomatous ductal proliferations show prominent ductal proliferation with some

acinar cells complexes, but the normal lobular pattern is preserved (208 ,209).

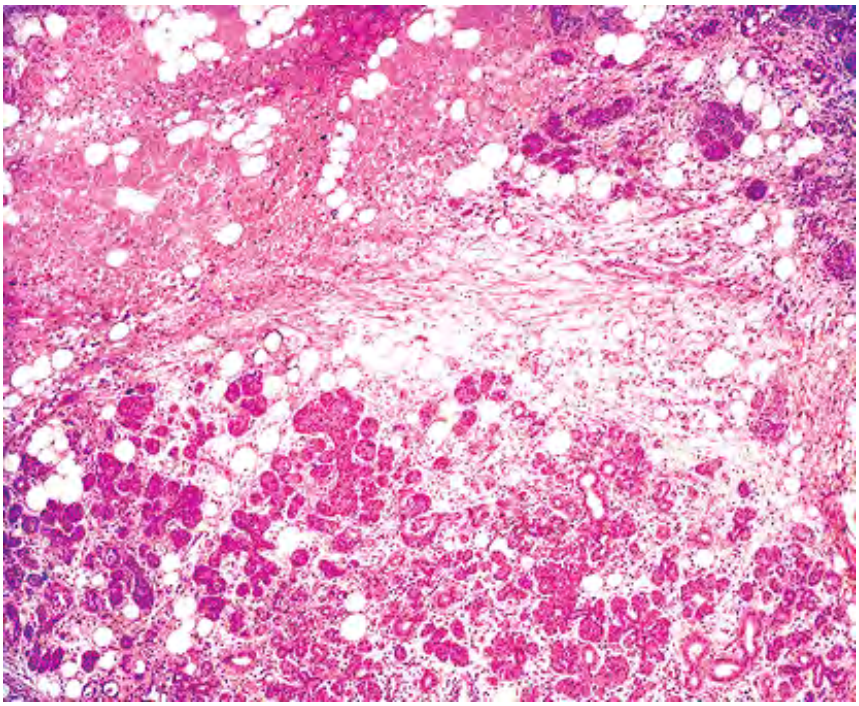

Figure 17.19 Necrotizing sialometaplasia of submaxillary gland.

Atrophy

Atrophy of the salivary tissue is a common finding in surgical specimens of tumoral salivary glands that have one or more atrophied lobules. This atrophy is caused by partial or total obstruction of an excretory duct. Accordingly, secretory units distal to the obstructed duct are dilated, and the acinar lumina become visible. The secretory cells lose their granules and have a similar aspect to that of the intercalated duct. The atrophic lobule has an inflammatory component; the cells gradually disappear, and the parenchyma is replaced by adipose tissue and collagen fibers (Figure 17.20A). The extent of atrophy depends on the size of the affected duct. It is generally greater in lithiasic obstruction. The atrophy present in terminal stage chronic sialadenitis shows a diffuse pattern with prominent periductal sclerosis and dense inflammatory infiltration (Figure 17.20B) (202). In the submaxillary gland, diffuse atrophy is frequent after radiotherapy, and the gland has a firm consistency (Kuttner's tumor)

that may be clinically mistaken for a submaxillary neoplasm. Atypical cells are often found in postradiotherapy atrophy. Dilated ducts lose cell polarity and exhibit hyperchromatic nuclei and prominent myoepithelium. In addition, interlobular ducts lose their continuity, and the interstitium is densely infiltrated with plasma cells (201). In experimental models, atrophy takes place after ligation of main salivary duct. Duct cells persist, in contrast to the disappearance of most acinar cells, which are deleted by apoptosis (210).

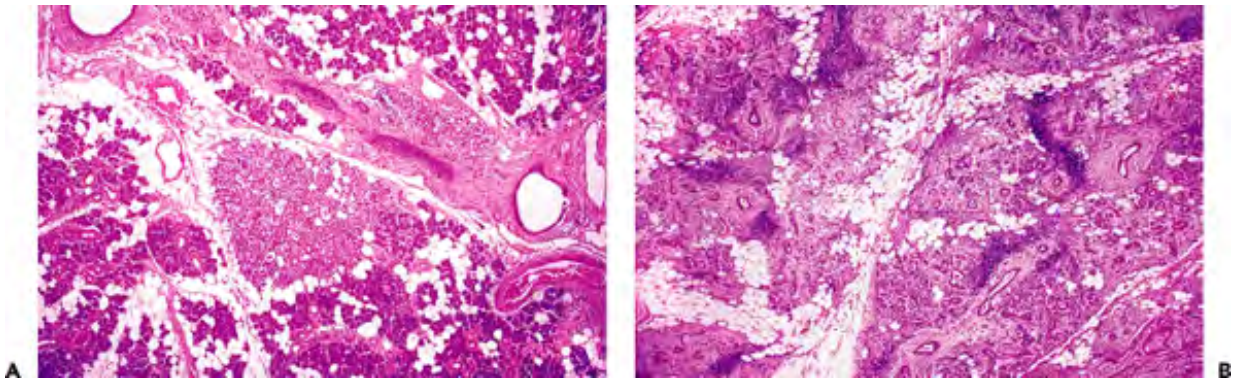

Figure 17.20 Atrophy of the salivary parenchyma. A . Focal atrophy in the vicinity of a parotid tumor; note the duct dilatation. B. Diffuse atrophy in chronic sialadenitis showing prominent periductal sclerosis.

Regeneration

The parenchyma of salivary glands have a capacity for regeneration. It is particularly notable in the salivary gland a few weeks after partial resection. In general, regenerating tissue follows an embryonic pattern, showing solid buds and branching columns of undifferentiated cells that eventually form excretory units (22) (Figure 17.21A). In some cases, such regenerating tissue exhibits an atypical appearance. Proliferating solid buds of undifferentiated cells may simulate basal cell adenoma (211) or other undifferentiated cell neoplasms (Figure 17.21B). However, unlike neoplasms, the regenerating tissue preserves the lobular architecture characteristic of the normal salivary gland (Figure 17.21Bâ€“C) (22 ,39). Regeneration after atrophy due

to duct obstruction is completed from residual parotid ducts that differentiate into acinar cells (212); this is probably achieved by a stem cell that resides in one of the ducts. The pattern is similar to the high proliferative activity of the terminal tubule, proacinar, and acinar cells during normal embryonic development of the rat submandibular gland (213).

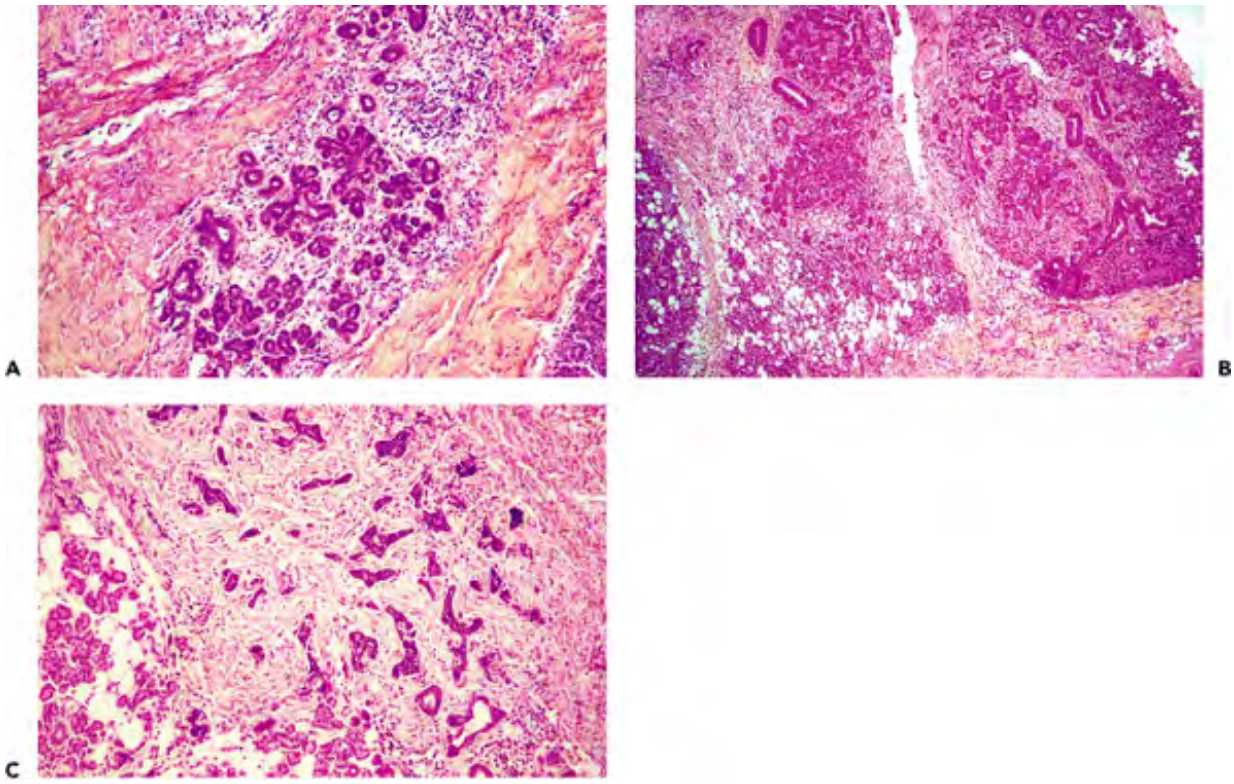

Figure 17.21 Regenerating salivary tissue of parotid gland. A. Formation of secretory units with an embryonic pattern. B. Atypical regenerating tissue; the lobular pattern is preserved. C. Infiltrating residual adenoid cystic carcinoma in a parotid gland. Solid buds consist of undifferentiated cells without lobular arrangement.

Correlative Normal and Neoplastic Histology

A characteristic of salivary glands is the ability to give rise to a large number of histologically distinct tumors (214). The histogenetic origin of these neoplasms is an interesting topic, but the numerous mechanisms that have been proposed remain hypothetical. The most attractive hypotheses attempt to relate this phenomenon to embryonic development and, particularly, to the presence of ductal reserve cells (56 ,60 ,193 ,214 ,215 ,216 ,217). A conjectural role of these reserve cells is the regeneration of salivary parenchyma, as well as the development of metaplastic tissue in reactive conditions. Batsakis (216) hypothesized two stem cells progenitors located at proximal and distal regions of the duct system that are related to tumors mimicking the terminal ductoacinar complex and the excretory ducts system, respectively. Some researchers have demonstrated, by immunohistochemical methods, the presence of basal cells with an undifferentiated aspect in salivary ducts (57 ,58). However, this does not prove that they act as reserve cells. Conversely, experimental evidence exists of the proliferative capacity of differentiated acinar and myepithelial cells (218 ,219 ,220).

A correlation between the normal structure of the salivary gland and the histologic appearance of salivary tumors can help us to understand morphologic classifications. Nevertheless, we must realize that this histologic similarity does not necessarily imply that a particular tumor arises from the structure that it mimics (217). However, the morphogenetic approach proposed by Dardick relates morphology to cell differentiation derived from different genes' expression of a stem cell (221 ,222).

The intercalated duct represents the most important segment of the salivary gland in the morphologic organization of many salivary tumors (217). Many distinctive tumors have been related to it, including pleomorphic adenoma, adenoid cystic carcinoma, basal cell adenoma, epithelial-myoepithelial carcinoma, terminal duct carcinoma, basal cell carcinoma, and embryonic tumors (Figure 17.22). These tumors show both epithelial and myoepithelial cell differentiation (93 ,109 ,112 ,113 ,118 ,131 ,132 ,134 ,136 ,139 ,148 ,149 ,217 ,222 ,223), as does the

normal intercalated duct. According to Batsakis (216), these tumors develop from â€œintercalated duct reserve cellsâ€• that follow the same direction as the embryonic terminal tubular cell. Statistically, approximately 80% of salivary tumors develop in the parotid gland, where the intercalated ducts are relatively long (Figure 17.6). In contrast, in the sublingual gland, which gives rise to less than 1% of salivary tumors (22), intercalated ducts are hardly visible.

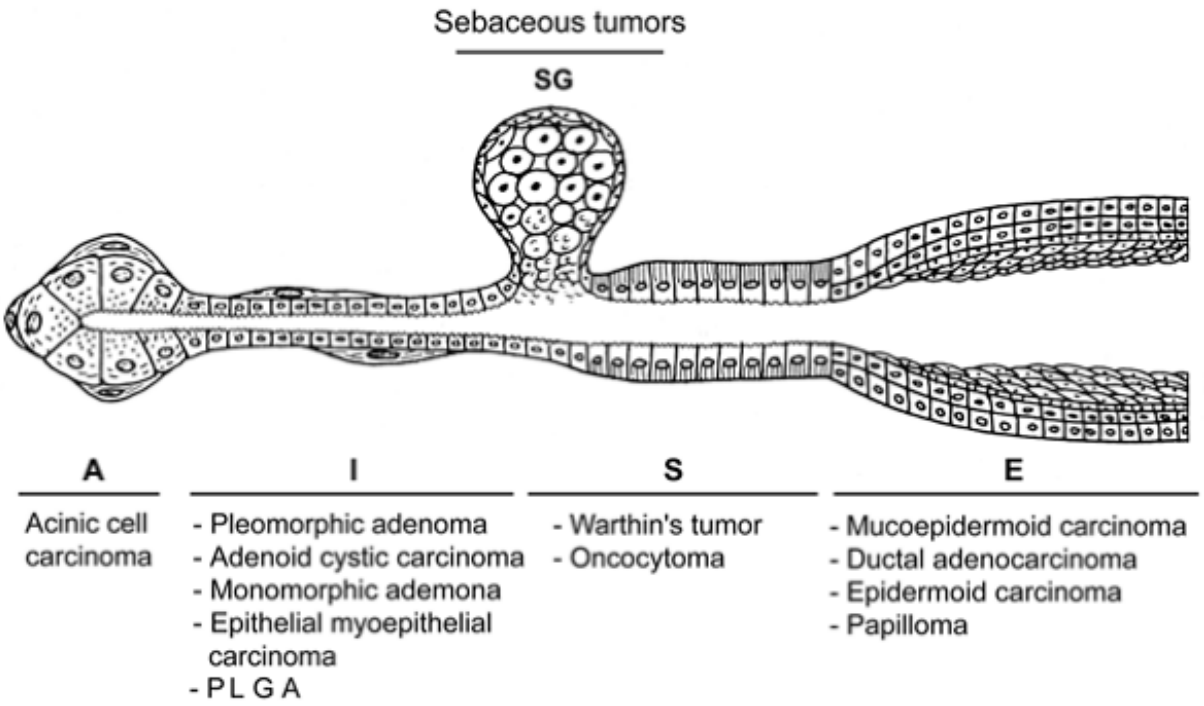

Figure 17.22 Morphologic similarity of some salivary tumors and the different epithelial structures of the salivary gland: acinus (*A*), intercalated duct (*I*), striated duct (*S*), sebaceous gland (*SG*), and excretory ducts (*E*). Not necessarily related to histogenesis.

A similar morphologic link exists between the acini, the most differentiated structure of the gland, and the acinic cell tumor, a well-differentiated neoplasm (Figure 17.23Aâ€“B) (224); between the mitochondria-rich cells of the striated duct, Warthin's tumor, and oncocytomas (180 ,181); and between the sebaceous glands and

sebaceous tumors (69 ,76 ,86). A morphologic analogy also may be found between the larger excretory ducts and mucoepidermoid carcinoma, salivary duct adenocarcinoma, epidermoid carcinoma, adenosquamous carcinoma, and papillary tumors (Figure 17.22) (225 ,226 ,227 ,228 ,229 ,230 ,231 ,232 ,233).

Immunohistochemistry

An important aspect of cytodifferentiation in normal and neoplastic salivary tissue is the expression of different intermediate filaments, enzymes, immunologic components, and other proteins. These proteins may be stained by immunohistochemical methods.

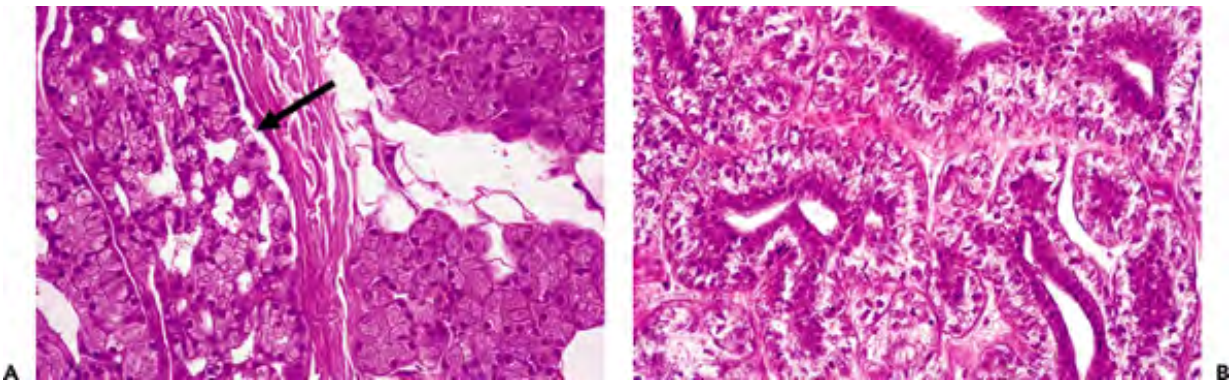

Figure 17.23 A. Acinic cell carcinoma of tha parotid gland (*arrow*), mimicking the normal gland. B. Epithelial-myoepithelial carcinoma of parotid gland, showing both epithelial and myoepithelial cells of the intercalated duct.

In normal salivary glands, the immunohistochemistry may be summarized as follows (Table 17.3): the expression of cytokeratin varies according to individual cell types of the secretory unit. Acinar cells are stained by several types of lower weight cytokeratins such as CK7, CK8, and CK19. In addition, these cells may be marked by the enzymes usually present in the normal acinus, such as amylase and lysozyme (234). Cytokeratins 6 and 12 are weakly positive in acinar cells but strongly positive in ductal cells, especially in excretory ducts

(Figure 17.24) (57). Basal cells are stained with anticytokeratin 19 and 18. Myoepithetial cells may coexpress cytokeratins 14, 17, 19, and vimentin (57 ,146 ,148). The most specific markers for myoepithelial cells are S-100 protein, Î±-smooth muscle actin, calponin, caldesmon, and myosin heavy chain (149 ,235). In addition, normal myoepithelial cells are

sometimes stained with glial fibrillary protein (236). The secretory component, except for the mucous units, is present in acinar cells and intercalated and striated ducts (55 ,237). Carcinoembryonic antigen (CEA) is present in acinar and intercalated duct cells; it is strongly positive in inflamed glands (238). Basal cells are stained with CK14, CK17, and p63 (234). Ductal epithelial cells of intercalated, striated, and interlobular ducts are strongly positive for epithelial membrane antigen (EMA) (239). Recently, the presence of Î±-fetoprotein in the human submandibular gland has been documented (240). Used as functional markers, the following enzymes may be stained: amylase and lactoferrin in serous acinar cells (241), lysozyme in intercalated ducts (49 ,50), and alkaline phosphatase and ATPase in myoepithelial cells (92). When used as histologic markers, all these proteins have proven useful in surgical pathology.

Specimen Handling

The parotid gland is the most common location of major salivary gland tumors. Because most of them are benign and located on the superficial lobe, partial parotidectomy of the superficial lobe (lateral lobectomy) is the most common treatment. Superficial parotidectomy also suffices for small, well-differentiated, low-grade malignant neoplasms that have not compromised the facial nerve (242). The specimen should be sectioned horizontally, and the relationship between the tumor and the gland should be stated (Figure 17.25). The surgical limits should be described even in benign tumors (Figure 17.26). Total parotidectomy with preservation of the facial nerve is usually indicated in recurrent or multiple benign tumors and large

benign tumors of the isthmus and deep lobe.

Figure 17.25 Histologic section of a parotid gland showing a pleomorphic adenoma. The tumor is apparently well delimited; tumoral buds may be found separate from the principal tumor.

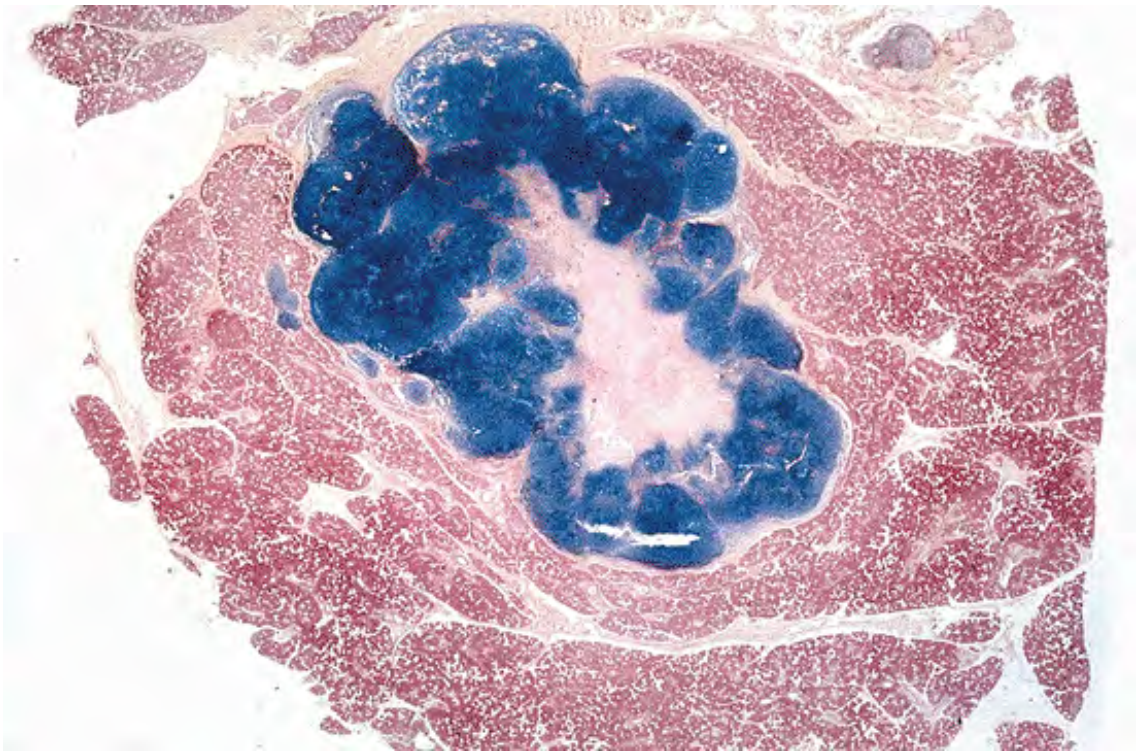

Figure 17.26 Superficial parotidectomy for a pleomorphic adenoma. Note the tumor is well delimited within the normal gland.

Total parotidectomy, including facial nerve resection (radical parotidectomy), is indicated in aggressive malignant tumors, malignant tumors situated in the deep lobe, or those that have compromised the facial nerve. All these specimens should be sectioned on their major axis to evaluate periparotid tissue infiltration (Figure 17.27). Intraparotid and periparotid lymph nodes should be identified; and, when radical parotidectomy includes neck dissection, the lymph nodes should be separated according to the different anatomical regions.

Benign and malignant submandibular gland tumors are rare. Single gland resection is indicated for benign tumors, whereas malignant tumors are treated by a monobloc resection of the gland lesion along with associated muscles, nerves, and mucous membrane.

Sublingual tumors are rare, and most (80%) are malignant. They are also treated by local monobloc resection, including the sublingual

compartment and surrounding tissues (243).

Figure 17.27 Radical parotidectomy for a high-grade mucoepidermoid carcinoma. Note the infiltration of the periparotid tissues.

Lungs

Thomas V. Colby
Kevin O. Leslie
Samuel A. Yousem

Normal Structure and Histology

The following review is based on several standard references on the topic (1 ,2 ,3 ,4 ,5 ,6 ,7 ,8 ,9 ,10 ,11 ,12 ,13 ,14 ,15 ,16).

General

The lungs are paired intrathoracic organs that are divided into lobes (three on the rightâ€”right upper lobe, right middle lobe, right lower lobe; two on the leftâ€”left upper lobe, left lower lobe). The lingula is a rudimentary appendage arising from the left upper lobe and is analogous to the middle lobe on the right. The lobes are further divided into bronchopulmonary segments (Table 18.1).

The segmental anatomy of the lung is important for radiologists, bronchoscopists, and pathologists in defining the location of lesions. The lobes are divided by fissures and have their own pleural investments. The segments are not separated by fissures and do not normally have separate pleural investments, although

they are recognizable on the basis of their supplying bronchi (segmental bronchi).

The primordial lungs arise as ventral buds of the foregut extending into the primitive thoracic mesenchyme. Bronchial cartilages, smooth muscle, and other connective tissues are derived from the mesenchyme that surrounds these dichotomatously branching buds. The phases of airway and lung parenchymal development are summarized in Table 18.2 .

As the lung progresses through these phases of development, there is a complex series of epithelial-mesenchymal reactions modified by physiologic mechanical forces and humoral factors. These events are overseen by master genes (such as homeobox genes), nuclear transcription factors, hormones, and other soluble mediators such as growth

factors (17 ,18). Some of these mediators and their relationship to lung development are shown in Table 18.3 .

Table 18.3 Lung Development and Regulatory Factors *

Airways

The airways serve as conduits for air traveling to and from alveoli; for evacuation of material along the mucociliary escalator; and for immunologic, protective, air-moisturizing, and warming functions.

The airways arise by unequal dichotomous branching of the bronchial buds. In a normal individual, there are approximately 20 generations (range: approximately 10â€“30 divisions, depending on the location in and distance from the trachea) extending from the trachea to the respiratory bronchioles. In histologic sections from normal lungs, the diameter of an airway is approximately the same as its accompanying artery (and vice versa) (19). Disparities in size (of either airway or artery) suggest a pathologic condition. Airways are defined as follows:

- *Bronchi* are cartilaginous airways and are usually more than 1 mm in diameter (Figure 18.1). They are conducting airways, and the cartilage plates in their walls prevent their collapse. The posterior wall is smooth muscle. The cartilage may calcify.

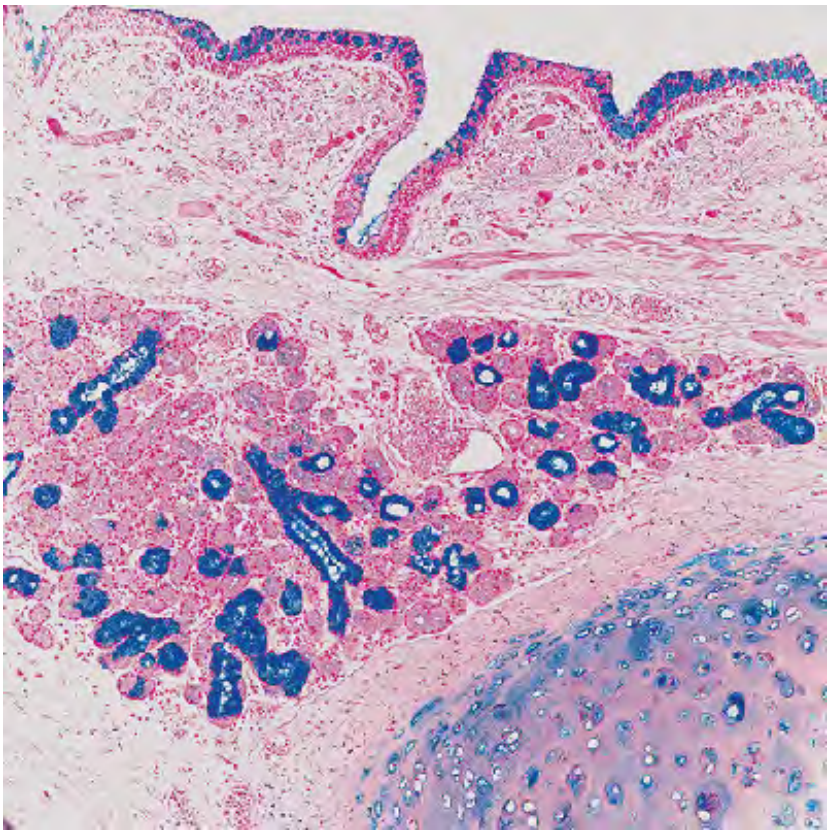

Figure 18.1 Bronchus. Alcian blue staining of the bronchus highlights the presence of goblet cells in the mucosa (slightly increased in this case), as well as the bronchial submucosalglands. Beneath the epithelial basement membrane, there is a vascularized layer of connective tissue with wisps of smooth muscle above the submucosal glands.

- *Bronchioles* are airways that are usually less than 1 mm in diameter; they lack cartilage (Figure 18.2).
- *Nonrespiratory bronchioles* represent all bronchioles proximal to respiratory bronchioles.
- *Terminal bronchioles* are nonrespiratory bronchioles just proximal to respiratory bronchioles.
- *Respiratory bronchioles* are airways that have alveoli budding from their walls.

In the large bronchi, the surface epithelium rests on a basement membrane, below which there is an elastin-rich layer of connective tissue; together these elements comprise the *bronchial mucosa* . Beneath the bronchial mucosa lies the *submucosa,* in which submucosal glands, cartilage, nerves, ganglia, and branches of the bronchial artery may be found. There is no clear histologic boundary between mucosa and submucosa. Outside the submucosa, there is a peribronchial sheath of loose connective tissue, which is continuous with that of the accompanying artery. The bronchial epithelium is a pseudostratified columnar epithelium composed primarily of ciliated columnar cells with interspersed mucous (goblet) cells. Lesser numbers of neuroendocrine cells, basal cells, brush cells, and migratory inflammatory cells are also normally present (see below).

The height of the pseudostratified columnar epithelium decreases progressively toward the periphery of the lung.

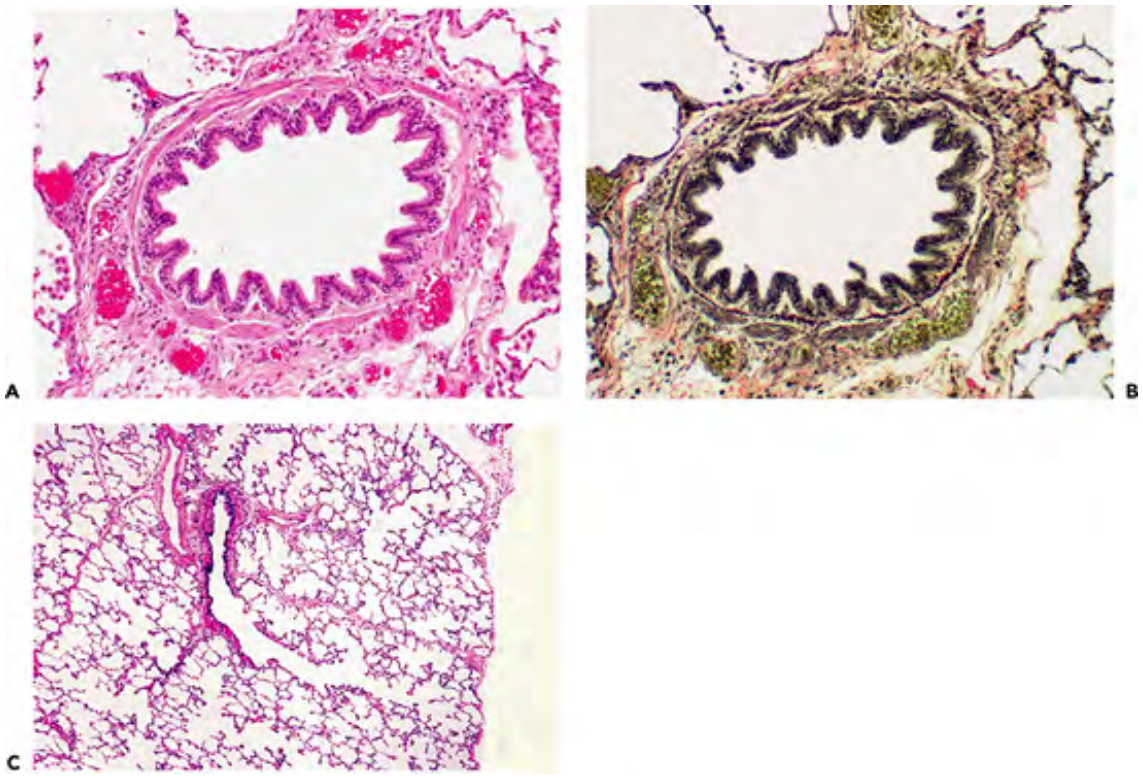

Figure 18.2 Bronchioles. Hematoxylin and eosin (A) and elastic tissue stains (B) illustrate normal bronchioles with a thin layer of connective tissue just beneath the epithelium overlying the elastica (B) and the smooth muscle investiture. The mucosa is low columnar, and there is no thickening of the subepithelial region. The smooth muscle is circumferential and is surrounded by an adventitial layer. C. A terminal bronchiole is continuous with the respiratory bronchiole, which extends into the alveolar ducts and ultimately the alveoli.

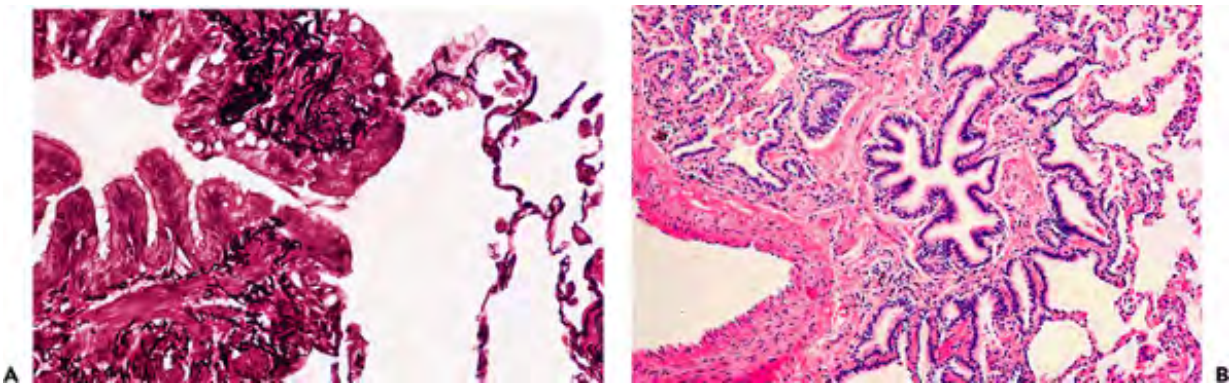

Figure 18.3 Lambert's canals. A. These canals represent communications between nonrespiratory bronchioles and adjacent alveoli and are only rarely observed in histologic sections. B. It is these canals that are thought to be the origin of peribronchiolar metaplasia, which is seen as a repair phenomenon involving peribronchiolar alveoli after bronchiolar injury.

The walls of bronchioles are normally much thinner than those of the bronchi. The surface epithelium rests on a basement membrane, which overlies a thin layer of loose elastin-rich connective tissue. This is surrounded by a muscle layer (muscularis), which is in turn invested by a peribronchiolar connective tissue sheath continuous with that of the adjacent artery. The distinction of mucosa from submucosa in bronchioles is arbitrary, and sometimes the tissue beneath the basement membrane is referred to as submucosal or submembranous connective tissue.

The airway basement membrane region consists of three layers: lamina lucida, lamina densa, and lamina reticularis. The last of these consists of very fine fibrillary collagen and is only found in adults. It is not technically part of the basement membrane, and it is this zone that is thickened in asthma and other inflammatory airway conditions. The basement membrane stains with digested PAS stains and immunostains for type IV collagen and laminin.

Direct communications between nonrespiratory bronchioles and

alveoli have been identified and termed Lambert's canals (20). These are thought to be involved in collateral ventilation. Lambert's canals are rarely visible in histologic sections (20). Lambert's canals may be conspicuous in scarred airways surrounded by metaplastic bronchiolar epithelium, which is seen to be continuous with the bronchiolar surface epithelium through Lambert's canals. This has been termed â€œLambertosis,â€• bronchiolarization, and peribronchiolar metaplasia (Figure 18.3). Sometimes the marked peribronchiolar metaplasia is the most prominent pathologic finding in a surgical biopsy. Peribronchiolar metaplasia is a not uncommon incidental finding in a variety of diffuse lung diseases. It may also be the sole or predominant change and the cause of the diffuse lung disease as described in some recent studies (21 ,22 ,23).

Cell types lining the airways include basal cells, Kulchitsky cells, ciliated cells, Clara cells, goblet cells, intermediate cells, and brush cells. Ultrastructural abnormalities in the ciliated cells of the respiratory tract are known to be associated with pathologic conditions (e.g., primary ciliary dyskinesia). Goblet cells and ciliated cells decrease in number as the terminal bronchioles are approached; there is a concomitant increase in Clara cells, and the mucosa becomes less columnar and more cuboidal in appearance. Clara cells have secretory functions (e.g., surfactant-like material) and also act as progenitor cells after bronchiolar injury. Clara cell differentiation in tumors of the lung may be appreciated by the presence of apical periodic acid-Schiff (PAS)-positive, diastase-resistant granules, as well as by their electron microscopic apical-dense granules. Kulchitsky cells contain dense core granules and are part of the diffuse neuroendocrine system. Aggregates of neuroepithelial cells are called neuroepithelial bodies; they tend to occur at airway bifurcations. The finding of goblet cells in bronchioles usually signifies chronic airway injury. The cell types in the airways and parenchyma are summarized in Table 18.4 and illustrated in Figures 18.4 , 18.5 , and 18.6 .

Smooth muscle of the airways plays an important functional role in regulating airflow and is arranged in a complex spiral pattern that becomes progressively less prominent in the distal conducting airways. This muscle receives nutrition from the bronchial arteries. At the level of the alveolar ducts, bundles of airway smooth muscle can be seen, interrupted by alveolar openings; in cross section, these may appear as isolated round or oblong aggregates.

Submucosal salivary-type glands containing both serous and mucous cells are found in the larger bronchi. In older individuals, oncocytic metaplasia can be seen in these glands (Figure 18.7). Within the walls of the large airways, ganglia, nerves, and bronchial arteries are found.

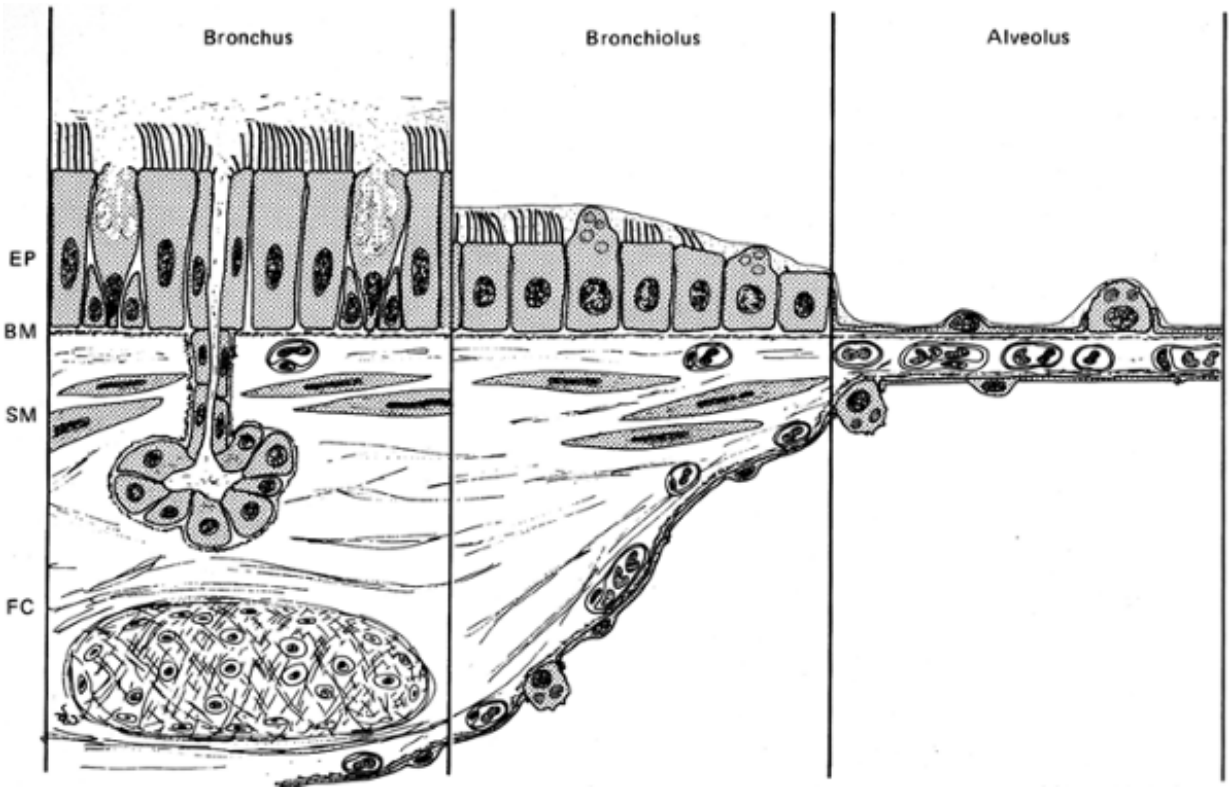

Figure 18.4 Respiratory tract epithelia. There is a progression of pseudostratified columnar epithelium in the large airways, to a more cuboidal epithelium in the small airways, to squamous type epithelial cells (type I pneumocytes) in the alveoli. The epithelium

in the large airways is designed for maintaining and moving the mucous stream, whereas the squamous pneumocytes in the airspaces facilitate gas transfer. )

Figure 18.5 Bronchial epithelium. A. Normal bronchial epithelium is pseudostratified and columnar, with numerous ciliated cells and scattered basophilic and flocculent-appearing goblet cells. B. This

ultrastructural schematic of bronchial epithelium shows the various cell types present. (Figure 18.5B reprinted with permission from: Sorokin SP. The respiratory system. In: Weiss L, ed. *Cell and Tissue Biology: A Textbook of Histology* . 6th ed. Baltimore: Williams & Wilkins; 1988:769.
)

Ciliated
Columnar, cuboidal, ciliated bronchial lining cells; each cell has approximately 250 cilia at the apical surface, and each cilium is approximately 6 Âµm long
Proximal transport of mucous stream (mucociliary escalator)
Bronchi and bronchioles
Epithelial markers[2]
Goblet
Columnar mucus-secreting cells; contain mucous glycoprotein, which discharges apically
Contribute to airway mucus
Bronchi (more numerous proximally); small numbers in bronchioles
Epithelial markers[2] , histochemical mucin stains, MUC5
Basal
Short cells with relatively little cytoplasm; oriented along the basement membrane; do not reach the luminal surface of the epithelium
Precursor cell of ciliated and goblet cells
Bronchi; rare in bronchioles
Epithelial markers[2]
Neuroendocrine (Kulchitsky or K cells)
Basal-oriented cells with numerous dense-core (neurosecretory) granules; single or in groups (neuroepithelial bodies), the latter near sites of airway bifurcation
Specific functions not known; considered part of the diffuse

neuroendocrine system
Bronchi; rare in bronchioles
Chromogranin-A, synaptophysin, NCAM
Brush
Found infrequently at all levels of the airways; some have termed these type III pneumo-cytes; they are named for a brush border of microvilli approximately 2 Âµm in length
Thought to be involved in fluid absorption or chemoreceptor function
All airways
Ultrastructurally identified
Serous
Identical to serous cells in the minor salivary gland tissues
Produce secretion of lower viscosity than that from mucous cells
Primarily bronchioles
Lysozyme
Neuroendocrine bodies
Clusters of 4â€“10 neuroendocrine cells adjacent to the subepithelial basement membrane
Unknown; hypotheses include chemoreceptor, tactile receptor, vasoconstrictive functions
Bronchi, bronchioles, and alveoli
Chromogranin-A, synaptophysin
Oncocytic
Eosinophilic mitochondrial-rich cells in submucosal gland ducts
Ion secretory functions
Submucosal glands
Epithelial markers[2]
Squamous
Stratified squamous epithelium is an abnormal metaplastic replacement of normal pseudostratified respiratory epithelium
Protective, reparative
Bronchi, bronchioles, and occasionally alveoli
Epithelial markers[2] , cytokeratin 5/6

Clara

Columnar nonciliated bronchiolar cells; protuberant apical cytoplasm with large, ovoid electron-dense granules; comprise the majority of nonciliated bronchiolar cells

Secretory functions contributing to the mucous pool and maintaining extracellular lining fluid; progenitor for other bronchiolar cells; role in surfactant

Predominantly in bronchioles

CC10, diastase-resistant PAS-positive apical granules

Type I alveolar pneumocyte

Large, flat, squamous alveolar lining cells; cover some 93% of alveolar surface area; incapable of division

Provide a thin air-blood interface for gas transfer

Alveoli

Epithelial markers[2], caveolin, and aquaporin

Type II alveolar pneumocyte

Columnar alveolar lining cells; microvillous surface; synthesize and secrete surfactant (lamellar ultrastructural inclusions); capable of division

Maintain alveolar stability; progenitor for type I pneumocytes

Alveoli

Epithelial markers[2], surfactant protein C

Minor salivary tissue: Serous, Mucous, Ductal Cells

Submucosal minor salivary glands identical to other sites with serous and mucinous acinar cells that secrete into the ducts, which empty at the mucosal surface

Secretion and contribution to airway mucous stream

Bronchial submucosa

Epithelial markers[2], histochemical stains for mucin, Alcian blue/PAS

Smooth muscle

Bundled smooth muscle surrounds the conducting airways to the level of the alveolar ducts

Contraction of the airway

Peripheral in the airway and external to the cartilage in bronchi
Muscle specific actin, smooth muscle actin, desmin, vimentin
Other cells[1]

[1] Endothelial cells and pericytes; interstitial fibrocytes, fibroblasts, and myofibroblasts; macrophages; lymphoid cells, including Langerhans cells; mast cells; mesothelial pleural lining; cartilage and bone; smooth muscle; peripheral nerves; and myoepithelial cells.

[2] For example, AE1/AE3 and EMA.

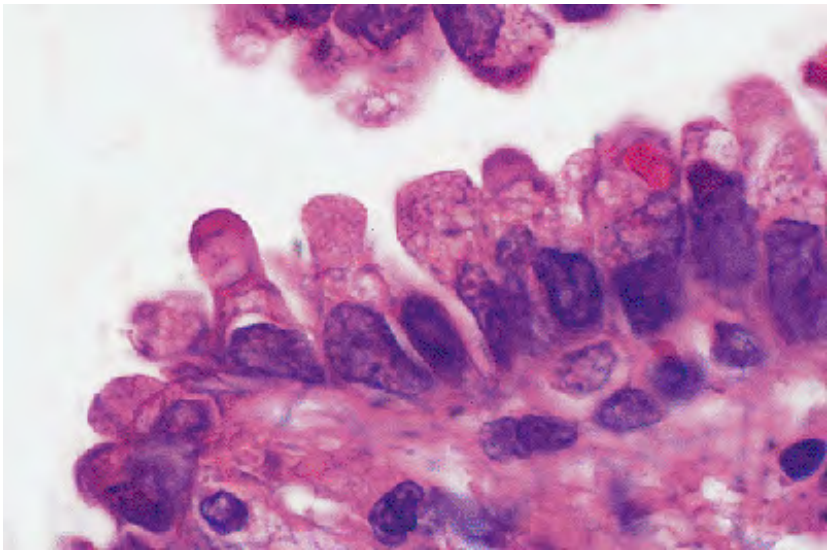

Figure 18.6 Clara cells. Although Clara cells sometimes can be identified in bronchioles, these are seen to best advantage in neoplasms such as this nonmucinous bronchioloalveolar carcinoma. The apical snouting and increased cytoplasmic density are apparent.

Lobule and Acinus

The lung lobule is grossly visible and represents the smallest anatomic subunit of the lung that is bounded by connective tissue

(interlobular) septa, which may appear to invaginate from the visceral pleura (Figure 18.8). Lobules are 1 to 2 cm in diameter and are visible to the naked eye on both the pleural surface of the lung and on cut surfaces of the parenchyma by their septal demarcations. Lobules are accentuated in fibrotic conditions in which the septa contract (e.g., honeycombing, healed infectious pneumonia, chronic pleural inflammation). Pulmonary lobules are identifiable with high-resolution computed tomography (CT) scanning of the lung. The term *lobule* as used here has also been referred to as the secondary lobule of Miller (12). The use of the term *secondary lobule* is discouraged because it implies that there is a primary lobule, and the latter term is not in current use.

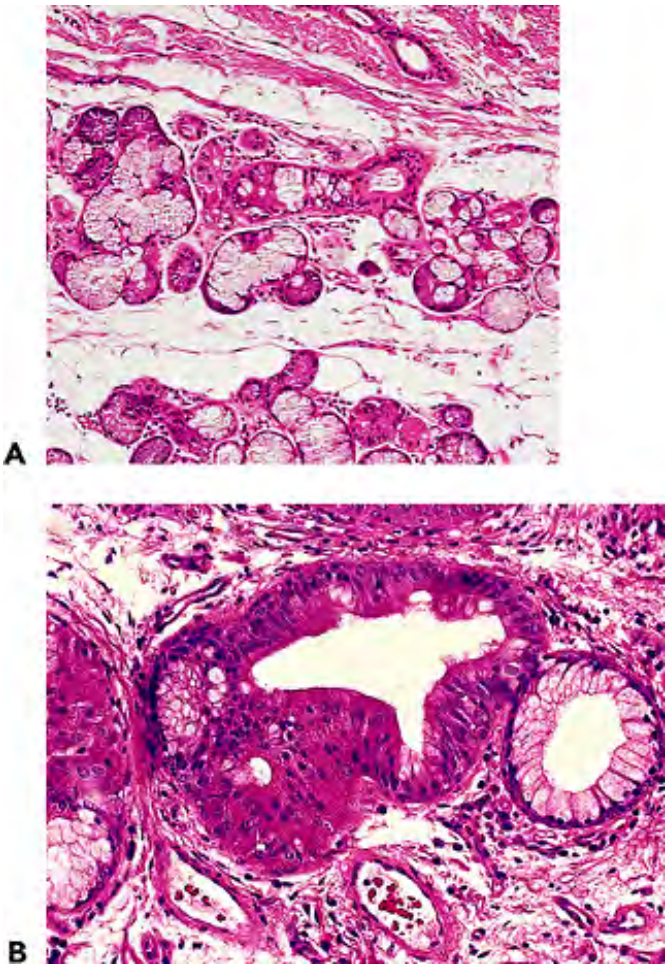

Figure 18.7 Bronchial submucosal glands. A. The bronchial submucosal glands are normally located in the submucosa above

the bronchial cartilage and contain mixed seromucous glands with a duct leading to the bronchial mucosa (also Figure 18.1). B. Oncocytic metaplasia involving bronchial submucosal glands is relatively common.

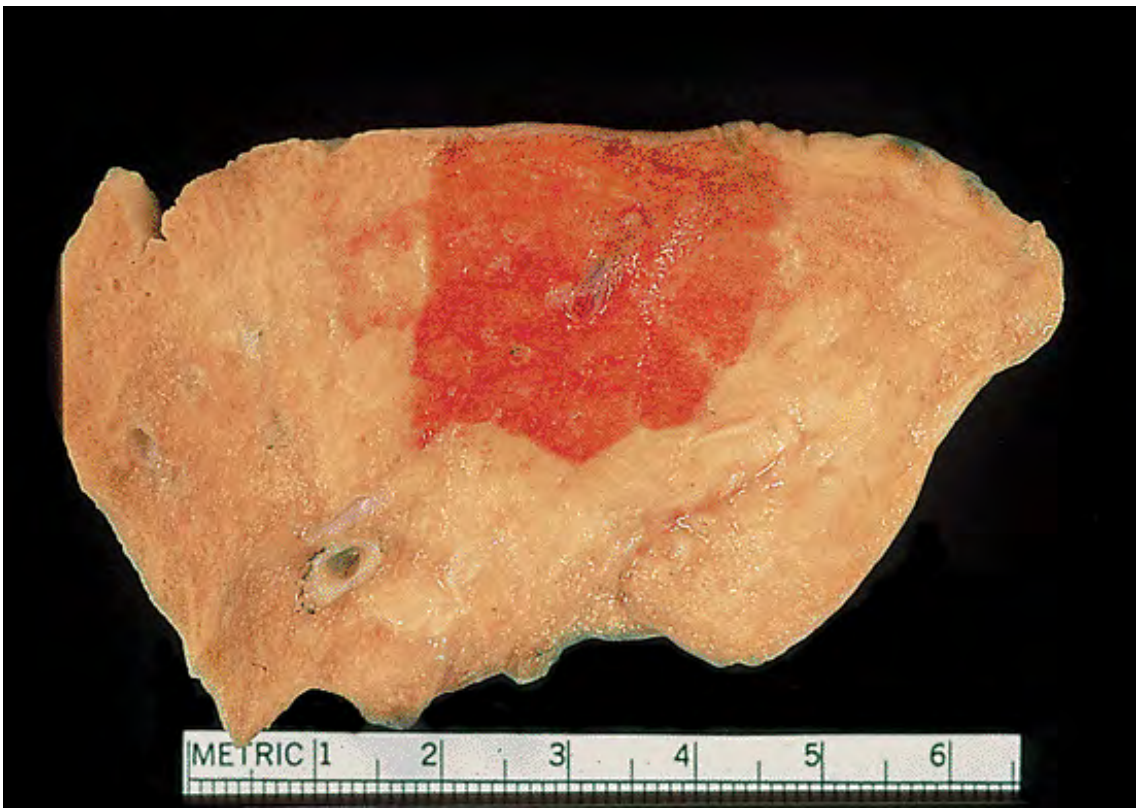

Figure 18.8 Pulmonary lobule. This cut section of normal lung tissue (from an explant that could not be used for technical reasons) shows focal hemorrhage highlighting a pulmonary lobule. The hemorrhage stops abruptly at the interlobular septa and, centrally, a bronchovascular bundle can be appreciated. The lobule is approximately 2.0 cm in diameter.

The functional unit of the lung is the acinus, where gas transfer takes place (Figure 18.9). The precise definition of the acinus has varied. Some define it as the lung tissue supplied by a single terminal bronchiole (12 ,15). According to this definition, each

pulmonary lobule comprises some 3 to 10 acini. The acinus has also been defined as a respiratory bronchiole and its supplied alveolar ducts and sacs (10 ,13); using this definition, each lobule comprises some 20 to 30 acini and the acini are 1 to 2 mm in diameter.

Squamous (type I pneumocytes) and cuboidal (type II, or granular, pneumocytes) epithelial cells line the alveoli (Table 18.4). Gas exchange takes place across the cytoplasm of type I cells. Type II cells are the progenitors for type I cells, produce surfactant, and proliferate after injury to restore alveolar epithelial integrity. Type II cell hyperplasia represents a nonspecific marker of alveolar injury and repair (Fig 18.10). Macrophages are a normal finding in the lung, scattered over the surfaces of the alveoli and percolating into the interstitium; a number of subpopulations of pulmonary macrophages are definable, based on their anatomic locations and their role in host defense clearance functions (31). Pulmonary macrophages are greatly increased in cigarette smokers; increased Langerhans cells are also found in the

bronchiolar epithelium of smokers, but their recognition requires special stains (e.g., CD1a) and quantitative studies.

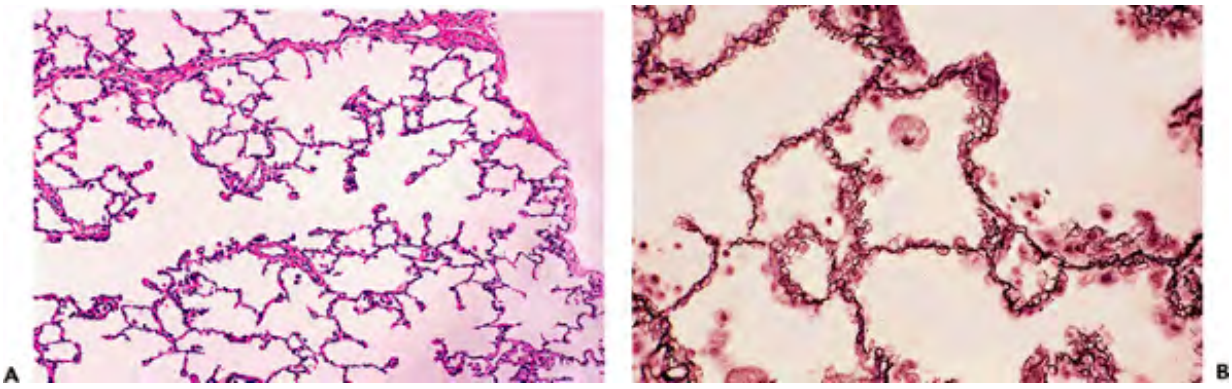

Figure 18.9 Distal lung parenchyma. The acinus is the functional unit of the lung where a gas transfer takes place. A. An alveolar duct extends from the left to right and communicates directly with

alveolar spaces; a small interlobular septum (*top*) and the pleura (*right*) are present. (From the case illustrated in Figure 18.2C .) B. Reticulin stain highlights the vasculature of the alveolar septum, showing pulmonary capillaries winding around the access of the alveolar wall to maximize gas transfer surface area. A foamy macrophage is present (*upper center*), a normal finding in lung parenchyma.

The epithelial and capillary basement membranes in the alveolar septum are irregularly fused. Gas transfer takes place across the alveolar-capillary membrane, which includes the attenuated cytoplasm of the type I cell, the endothelial cell cytoplasm, and their fused basement membranes. Pores of Kohn represent direct communications between adjacent alveoli via a â€œporeâ€• in the alveolar wall. They are thought to be involved in collateral ventilation. Pores of Kohn are rarely visible with the light microscope.

The lung is invested with a rich framework of connective tissue coursing throughout the interstitium. It is well developed and easily visible along bronchovascular sheaths and in the septa that delimit lobules. This framework is continuous from the hilum to the pleura and encompasses the interstitial compartment of the lung down to the level of the alveolar wall and perivascular areas. Within the alveolar walls, collagen, elastic fibers, mesenchymal cells, and a few inflammatory cells can be identified ultrastructurally. This alveolar interstitial space is normally inconspicuous by light microscopy in adults. In children (up to approximately age 4), some interstitial widening and increased cellularity are a normal histologic finding.

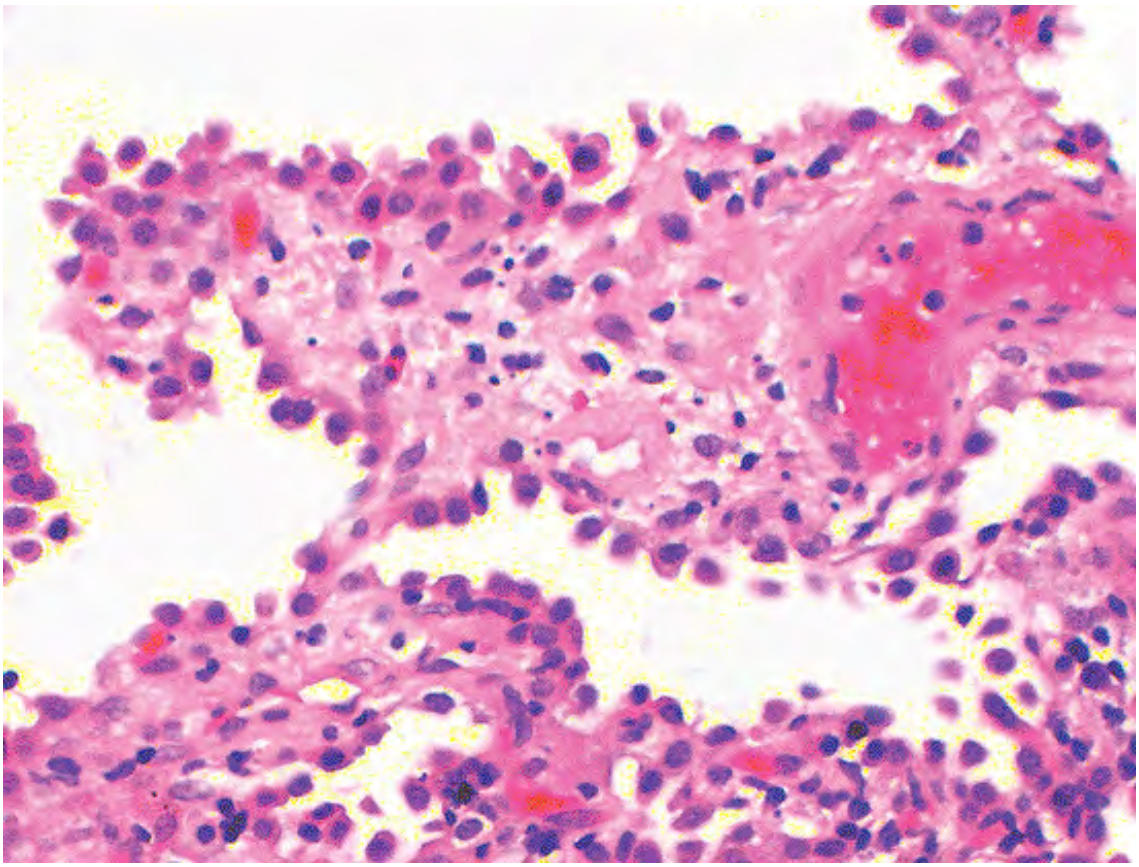

Figure 18.10 Alveolar cell hyperplasia. A reactive proliferation of type II cells (alveolar cell hyperplasia) is common after injury. This case illustrates how this appears as a single row of cells protruding from the alveolar surface. Cytologic atypia is lacking. The interstitium shows edema, inflammatory cells, and some fibrinous exudate consistent with recent lung injury.

Given the concentration of nuclei of the various cell types comprising the alveolar wall, it may be difficult to decide when some degree of cellularity is pathologic. Although one may attempt to count nuclei in a single alveolar wall, it is more practical to assess inflammatory cell infiltrates in the perivenular regions and to compare various foci in the biopsy since interstitial infiltrates are rarely perfectly uniform in distribution.

Vasculature

The lungs have vascular systems: bronchial (systemic) arteries and veins and pulmonary arteries and veins. The alveolar microvasculature is designed for oxygenation of venous blood derived from the pulmonary arteries. Large (elastic) pulmonary arteries in infants are similar to the aorta in structure; the elastic fiber lamellae become more irregular, fragmented, and less compact in adulthood. Elastic tissue remains relatively prominent in the pulmonary arterial tree to approximately the point where bronchi become bronchioles. At this juncture, the pulmonary arteries become primarily muscular arteries. The muscular pulmonary arteries and arterioles have an internal and external elastic

membrane (Fig. 18.11A); pulmonary veins have only a lamellated single (outer) elastica (Fig. 18.11B). Small intra-acinar pulmonary veins merge into larger veins in the interlobular septa. The bronchial arteries in the walls of bronchi are part of the systemic circulation and have pressures similar to systemic arterial pressures. The pulmonary circulation is a low pressure system with a normal mean pressure of approximately 10 mmHg (it is somewhat higher at higher elevations).

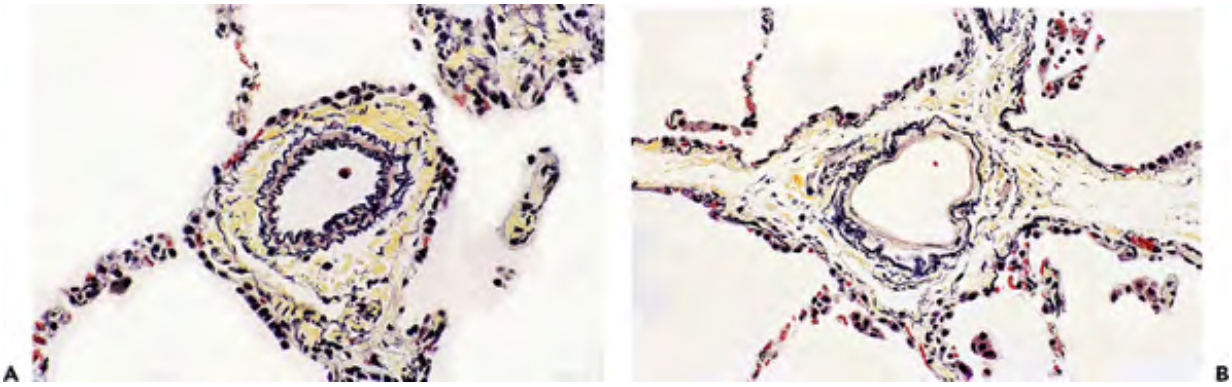

Figure 18.11 Pulmonary vasculature (elastic stains). Normal pulmonary arteries contain two elastic lamina (A), whereas veins have a single elastic lamina (B). The location of a vein within a septum (B) is also very helpful in identifying it as a vein.

It may be difficult to separate small pulmonary arterioles from venules, especially since a single elastic lamina forms as arterioles get smaller. In pathologic states, the veins may develop muscular hypertrophy and increased mural thickness (arterialization), making the distinction of arteries from veins difficult. The location of the vessel, particularly if it is in a septum or accompanied by an airway, is extremely helpful (and sometimes the only way) when separating pulmonary veins from pulmonary arteries. In mild pulmonary hypertension, the pulmonary arteries may appear histologically normal; in general, pressure measurements taken at catheterization are more reliable than histologic subtleties in determining the pressure and degree of pulmonary hypertension. Only plexiform lesions and dilatation lesions connote unequivocal pulmonary hypertension. Conversely, the presence of some degree of diffuse interstitial fibrosis or localized pulmonary scars is commonly associated with mural thickening of pulmonary vessels in the absence of pulmonary hypertension.

Lymphatics and Lymphoid Tissue

The lung is invested with a rich supply of lymphatics and lymphoid tissue. Lymphatic drainage is toward the hilum of the lung. Lymph fluid from the lower lobes tends to drain to infratracheal lymph nodes, with lymph fluid from the remaining portions of the lung draining to tracheobronchial lymph nodes. On the left side, the lymph fluid drains into the thoracic duct; and, on the right side, it drains into the right bronchomediastinal trunk. Both of these ultimately drain into the left and right subclavian veins, respectively. Lymphatic channels are found along bronchovascular structures and pulmonary veins and in the septa and pleura. Valves may be apparent in some sections. Lymphatics do not extend into alveolar walls. The lymphatics vessels are inconspicuous except in pathologic states, such as pulmonary edema or lymphangitic carcinoma. Lymphoreticular infiltrates and

some pneumoconioses tend to be distributed along the lymphatic routes, but the lymphatic vessels themselves may not be prominent.

Lymphoid tissue may be seen as small collections of lymphocytes along the lymphatic routes, especially branch points of the bronchovascular bundles; lymphoid tissue is generally absent or inconspicuous except in pathologic states. Lymphoid tissue along the airways is part of the diffuse mucosa-associated lymphoid tissue (MALT) and in the lung is referred to as bronchus-associated lymphoid tissue (BALT). Submucosal lymphoid tissue in the intermediate and small airways is associated with flattening and attenuation of the overlying respiratory mucosa (lymphoepithelium), which has increased HLA class II antigens. At these sites, B lymphocyte emperipolesis is common and is thought to reflect active antigen processing by the BALT. Bronchus-associated lymphoid tissue displays the same reactions observed in lymphoid tissue at other sites; for example, reactive hyperplasia and immunoblastic proliferation, which can be confused with lymphoreticular malignancies.

Immunophenotypically the lymphoid tissue of BALT has an immunoarchitecture with four identifiable compartments, including B-cellâ€“rich follicles, B-cell follicular mantle and marginal zones, and T-cellâ€“rich interfollicular regions. A follicular dendritic cell network is present. Polyclonal plasma cells are identified in the perifollicular tissue. The finer details of the immunoarchitecture and the

immunophenotypic characterization of these cells are beyond the scope of this review. The follicles tend to be polarized into a darker side and a paler side, with the latter oriented toward the epithelial surface; BALT also shares features of MALT as seen at other sites. In normal adult lungs, BALT is rarely present, and its presence correlates with some form of chronic antigenic stimulation (32 ,33 ,34). According to Tschernig et al. (34), BALT

is not present at birth but is found normally with increasing age, probably as a result of exposure to environmental antigens. After the individual has been exposed to most of the common antigens, the BALT regresses and dendritic cells in the airways assume the role of antigen uptake and presentation. Its reappearance in adults follows chronic antigen stimuli, such as chronic infection.

As currently defined, BALT refers only to lymphoid tissue along the airways (35) and not to the lymphoid tissue that may be seen in the pleura and septa as part of diffuse lymphoid hyperplasia in the lung. Hyperplasia of BALT is frequently accompanied by lymphoid hyperplasia at these other sites.

Intrapulmonary peribronchial lymph nodes are a normal finding, but peripheral intraparenchymal lymph nodes are less common; however, in smokers and others with high dust exposure, they are increasingly recognized (and biopsied) with current imaging techniques (36). Intrapulmonary lymph nodes are usually septal or subpleural in location (see below). Anthracosis and small amounts of silica and silicates in these nodes is common and nonspecific.

Pleura

The visceral pleura is composed of connective tissue, elastic tissue, and an outer mesothelial layer (Figure 18.12). The elastic tissue is often not a single layer, and several layers may be apparent. In pathologic conditions the elastic tissue may greatly increase. Elastic tissue stains are useful in assessing whether a given pathologic process, such as carcinoma, has transgressed the visceral pleura (37), but interpretation is difficult when the pleura is fibrotic and the elastic tissue is increased. Pleural assessment is important in separating T1 carcinomas from T2 carcinomas; the latter invade the visceral pleura (21). Lymphatic vessels that are continuous with those in the interlobular septa are also identifiable in the pleura. When the pleura is fibrotic and in foci of pleural

adhesions, vessels may be thick and sclerotic or even pseudoangiomatous in appearance. Fatty metaplasia is often striking in foci of pleural and subpleural scarring. The visceral pleura often remains viable over pulmonary infarcts because it has a separate vascular supply. Submesothelial fibroblasts may undergo mesothelial metaplasia (and become cytokeratin-positive) in inflammatory conditions of the pleura.

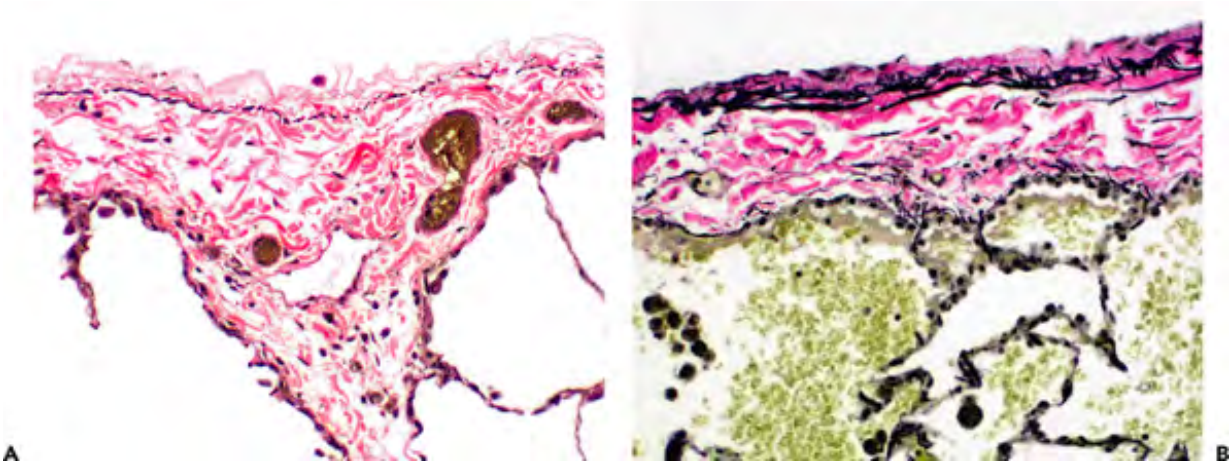

Figure 18.12 Pleural elastic tissue (elastic stains). The pleura contains an elastic tissue membrane, which may appear as a single thin layer of elastic tissue (A) or as a richer network with occasional elastic fibers distributed through the thickness of the visceral pleura (B.). The field illustrated in (A) shows a normal lymphatic at the juncture between an interlobular septum and the visceral pleura.

Special Stains and the Evaluation of Lung Histology

While most diagnostic work in lung histology and pathology can be performed with routine *hematoxylin-eosin (H&E) staining* , there are a number of special stains that aid interpretation and or highlight findings. *Elastic tissue staining* is helpful in evaluating the pulmonary vasculature, airways, and pleura. Sometimes

arteries and veins can be distinguished from each other with elastic tissue staining. Elastic tissue staining highlights damage to the intima and media that might not be apparent on H&E staining. Elastic

tissue stains are also useful in highlighting abnormalities of bronchioles and may confirm the bronchiolar or alveolar duct origin of small scars in cases of complete obliteration of the small airways. Elastic tissue staining is helpful in highlighting the pleural elastica and its relationship to tumors.

Trichrome staining (or other stains highlighting connective tissues) may also be useful in highlighting normal and pathologic findings in the lung, but they do not provide quite as much information as elastic tissue stains. Trichrome staining may be useful in assessing the distribution and extent of fibrosis in fibrosing diseases. *Reticulin stains* and stains for *collagen type IV* may be used to highlight the reticulin network of the lung. This staining may be useful in research studies and in highlighting normal histology but is not generally useful in diagnostic surgical pathology of the lung.

Immunostains for epithelial markers (such as EMA and cytokeratin stains) may be beneficial in atelectatic or fibrotic lung when it is difficult to appreciate the architectural features on H&E staining. Comparing these stains with stains for endothelial cells (such as CD31 or CD34) may provide an additional aid in assessing lung architecture and structural relationships. Use of CD31 may be somewhat confusing since alveolar macrophages frequently show prominent staining. Lymphoid tissue in the lung is assessed with the panoply of lymphoid markers used at other sites. Both CD3 and CD20 are often useful to check the proportion and distribution of T and B cells, respectively. In general, most inflammatory conditions have a preponderance of T cells as the diffuse component of the infiltrates, with scattered B-cell follicles. In lymphoproliferative conditions, cytokeratin staining highlights lymphoepithelial lesions. Both S-100 and CD1a are useful in

identifying Langerhans cells; the latter stain is much more specific.

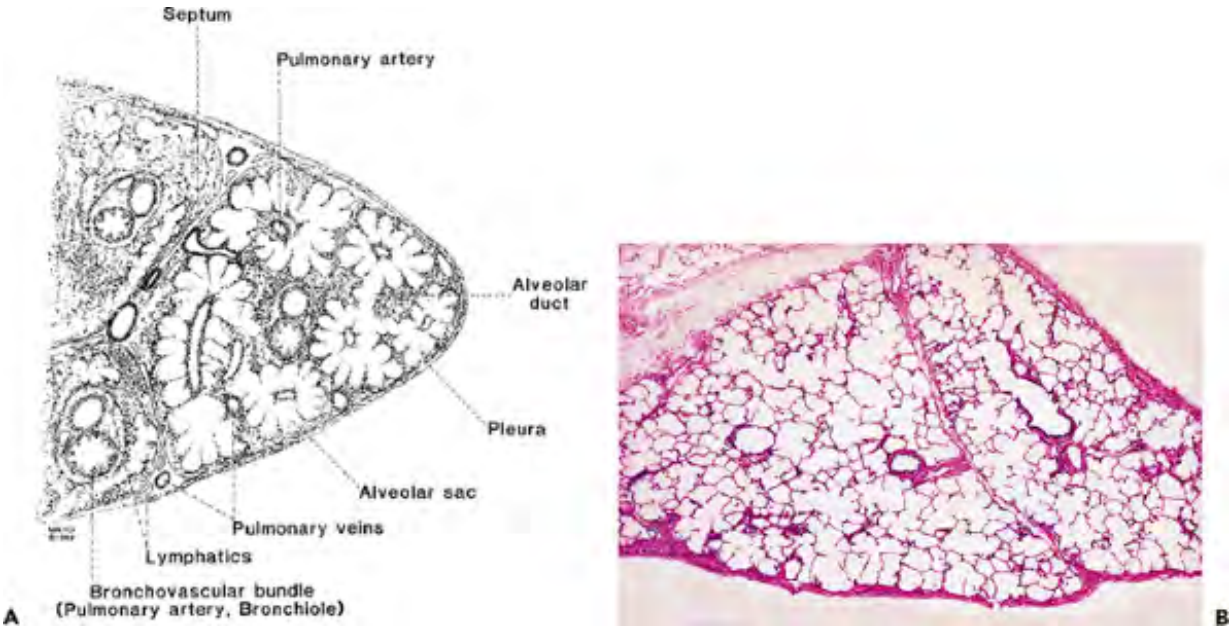

Figure 18.13 Wedge lung biopsy. A. This stylized diagram is used to depict anatomic landmarks. Structures depicted in (A) can be appreciated in an actual wedge biopsy specimen (B).

Mesothelial cells lining the pleura typically stain with calretinin, cytokeratin 5/6, and WT-1 (nuclear positivity).

Pattern Recognition Based on Normal Anatomic Landmarks

It is useful to define pathologic conditions in the lung in relation to normal anatomic landmarks (Figure 18.13). This can usually be done with diffuse diseases and often with localized processes. Such an exercise in diffuse lung disease is extremely useful in correlation with gross findings, as well as with high-resolution computed tomography (HRCT) scanning (38). Histologic patterns and their corresponding HRCT patterns can be recognized and are shown in Table 18.5 .

It is apparent that there is close correlation (but not a 1:1 relationship) between histology and HRCT. With some communication between the pathologist and the radiologist, there is a significant mutual appreciation for the similarity of the abnormalities seen. In this regard, the pathologist may be significantly aided by HRCT findings, which may suggest distributions that might not be apparent in biopsy material because of such things as the size of the biopsy (e.g., transbronchial biopsy) or sampling issues (nonrepresentative biopsies).

Table 18.5* Corresponding Histologic and Radiologic Patterns

Site-Related Changes Commonly Seen in Surgical Pathology Material

Site specific changes that may be primary lesions or incidental findings in surgical material are shown in Table 18.6 .

Biopsies from lobar tips, particularly from the lingula or right middle lobe, may show incidental inflammatory and fibrotic changes (39), including interstitial fibrosis, epithelial metaplasia, and even focal honeycombingâ€”all of which may not be representative of a diffuse process. Myointimal proliferation is common in the arteries and veins of these biopsies. The airspaces may contain aggregates of macrophages and neutrophils. Because of their accessibility, these sites are often biopsied. Incidental changes in lobar tips are usually obvious as such, since the more proximal lung tissue is either not affected or significantly less affected. Thus, in evaluation of lobar tip wedge biopsies, the findings of greatest significance are often in the more proximal portions of the specimen. Nonspecific inflammatory changes in lobar tips become a problem in small wedge biopsies, particularly those that are 2 cm or less in greatest dimension. Since lobar tips are so readily accessible to the surgeon, it is difficult to discourage

surgeons from biopsying them. If possible, such biopsies should be at least 3.0 cm in greatest dimension. The possibility of middle lobe syndrome (which may affect the lingula, the right middle lobe, or both) (40 ,41) should be considered for persistent infiltrates in these sites.

- Inflammatory changes at lobar tips, especially lingula and right middle lobe
- Apical caps: pleural and subpleural fibrosis in the apex and the upper lobes and superior segments of the lower lobes
- Upper lobe centriacinar emphysema
- Visceral pleural/subpleural fibrosis (â€œsubpleural blebsâ€•)

Table 18.6 Site-Specific Changes in Lung Tissue

Apical caps (Figure 18.14) were once thought to be the result of healed tuberculosis, but they are common in patients who have never had tuberculosis; they are now thought to be an ischemic alteration related to their apical position (42 ,43). Apical caps are best known in the apex of the upper lobe, but they are also encountered in the upper regions of the lower lobe (44). Apical caps are regions of fibrosis in the pleura and subpleural lung parenchyma that

are rich in thickened elastic fibers; the background structure of collapsed alveolar walls and interposed eosinophilic collagen can often be discerned in the tissue; elastic tissue stains enhance these features. Ossification and nests of metaplastic pneumocytes may be present. The changes are sufficiently distinctive that apical caps can often be suspected histologically, even when one does not know the site of origin; even so, any ancient lung scar may sometimes show a similar elastotic appearance. Apical caps in older individuals are sometimes biopsied or resected to exclude a

carcinoma or a visceral pleural tumor (44).

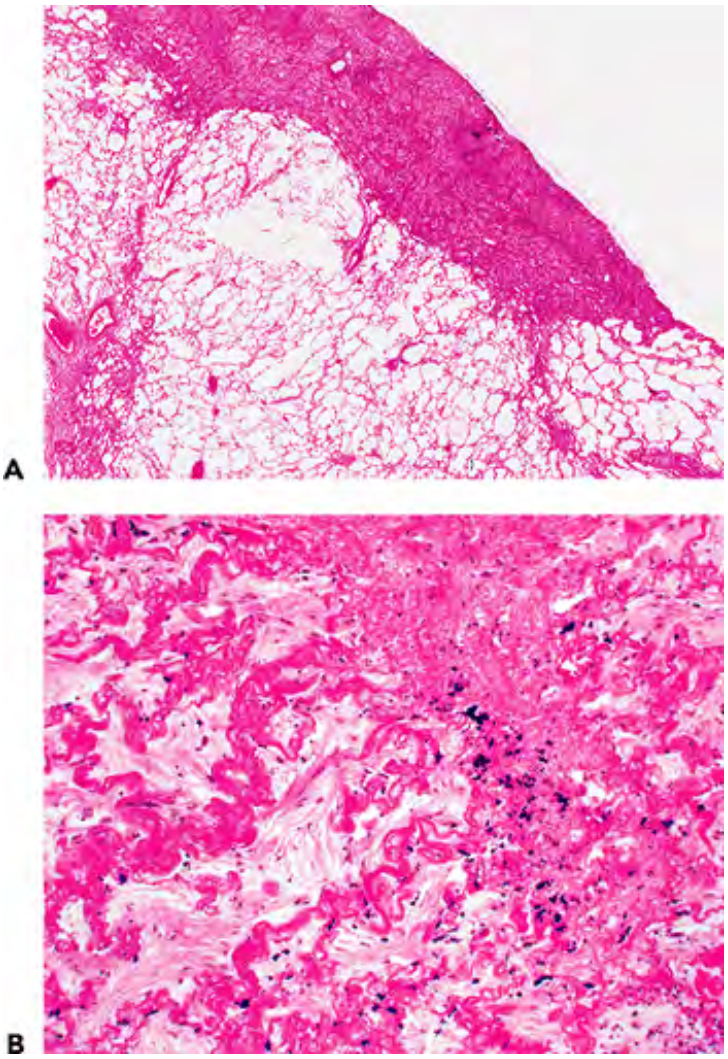

Figure 18.14 Apical cap. A. Apical caps are found at the apex of the upper lobe, as well as the apex of the lower lobe. They represent regions of pleural and subpleural thickening by elastotic fibrous tissue that may be grayish or eosinophilic in appearance. B. Higher power sometimes shows a rich elastic tissue network that appears to highlight alveolar wall structure; some anthracotic pigmented is also noted.

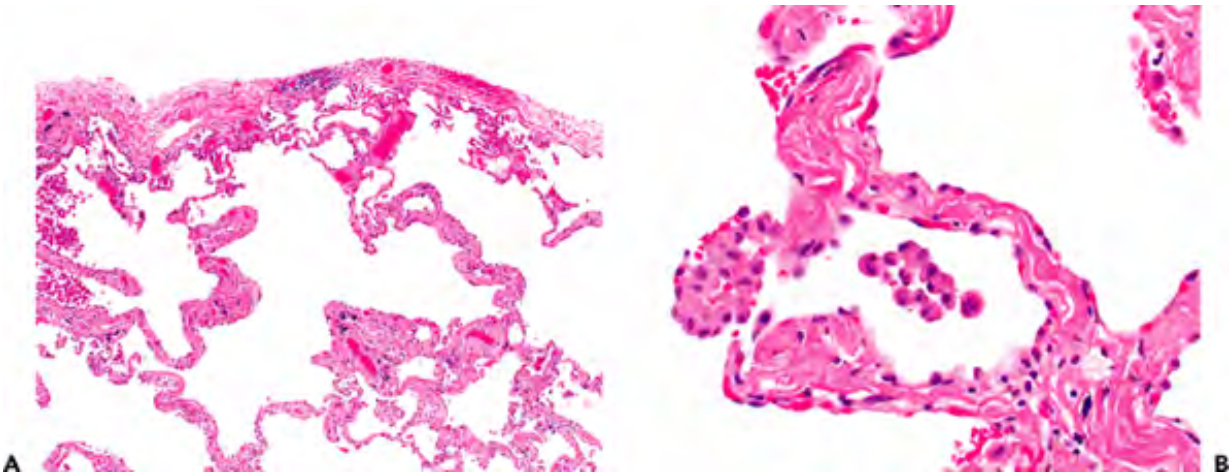

Figure 18.15 Subpleural emphysematous change in smoking. A. There is simplification of airspaces. B. Some of the alveolar walls show mild fibrosis with hyaline appearing collagen. Occasional clusters of pigmented alveolar macrophages are also noted.

Centriacinar (centrilobular) emphysema is a pathologic abnormality that is more common and more severe in the upper lobes (45); it is found predominantly in cigarette smokers and is a common finding in lobes resected for bronchogenic carcinoma. Emphysematous changes are frequently accompanied by some degree of fibrosis, particularly when bullous change is present. The fibrosis tends to appear as strands of dense, hypocellular, brightly eosinophilic collagenous septa traversing the emphysematous spaces. Anthracosis is also a common finding in smokers and urban dwellers. Focal pleural and subpleural fibrosis (Figure 18.15) is extremely common, especially as an incidental microscopic finding in lobar resections from smokers (46); abnormal airspaces formed by irregular fibrous septa are accompanied by smooth muscle hyperplasia, mucostasis, and bronchiolar metaplasia.

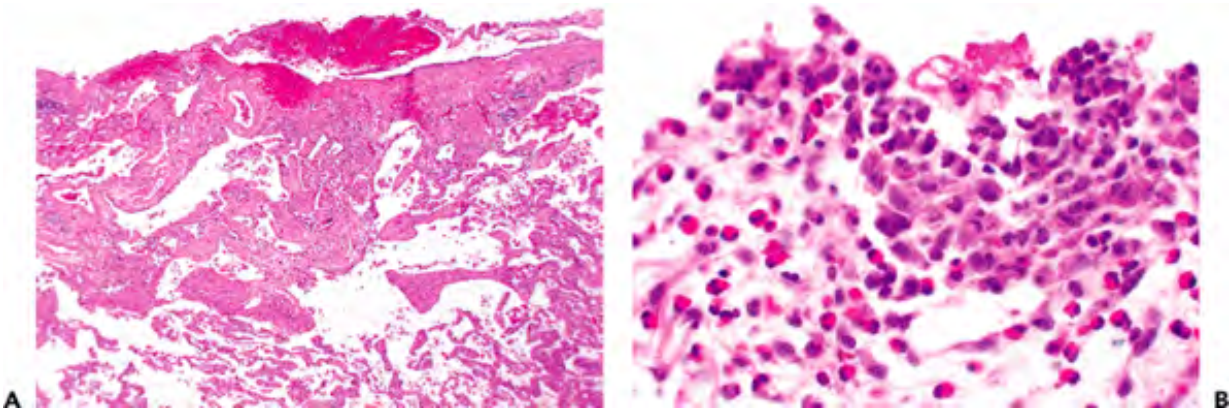

Figure 18.16 Pneumothorax. A. So-called â€œsubpleural blebsâ€• are thought to predispose to pneumothorax. These are regions of pleural and subpleural scarring with abnormal airspaces somewhat reminiscent to smoking-related changes (also Figure 18.15). B. Pneumothorax is often associated with a pleural reaction (*top*), which has been labeled eosinophilic pleuritis because of the association of eosinophil infiltrate and mesothelial and macrophage reaction on the pleural surface.

Subpleural blebs (Figure 18.16) are often the only pathologic change found in patients with recurrent pneumothoraces and who don't have diffuse lung disease (47). These are typically evident in the upper lobes. By convention, *blebs* are defined as being less than 1.0 cm in diameter and some are derived from air dissection into the visceral pleura; *bullae* are 1.0 cm or greater in diameter (48).

Their rupture introduces air into the pleural space, inciting a mesothelial proliferation with numerous macrophages, giant cells, and eosinophils (referred to as eosinophilic pleuritis), and this reaction may accompany any condition that is associated with pneumothorax (49). Collections of interstitial air in the lung tissue, with or without giant cell and/or eosinophilic reaction, may be an accompanying finding. Focal subpleural scarring can usually be distinguished from chronic fibrosing interstitial pneumonias by

its restriction to the subpleural region, lack of active fibroblastic proliferation, and the relative abrupt transition to normal alveolar walls. Clinical history and radiographic findings may also be supportive. When an interstitial lung disease such as pulmonary Langerhans cell histiocytosis (eosinophilic granuloma) or lymphangioleiomyomatosis has resulted in pneumothorax, both the primary process and the secondary eosinophilic pleuritis may be recognizable on the biopsy.

Adhesions between the pleura and chest wall are composed of fibrovascular tissue with pockets of bland mesothelial cells and are identical to their peritoneal counterparts. The adhesions identified in surgical specimens and even autopsy tissue often have no obvious cause and represent an incidental finding. Dense, hyalinized fibrotic pleural (visceral or parietal) plaques (50 ,51 ,52) are the consequence of a variety of prior inflammatory events. Their presence bilaterally often is an incidental finding; and, if there is no obvious inflammatory cause, prior asbestos exposure is likely (53).

Artifacts Seen in Lung Biopsy and Resection Material

Artifacts related to lung biopsy of prior procedures are described in Table 18.7 .

Knowledge of the clinical course of events prior to lung biopsy usually allows the pathologist to avoid misinterpreting changes of prior instrumentation. Previous bronchial biopsies may cause hemorrhage, airway inflammation, ulceration, and a granulation tissue reaction. Strips of epithelium may be dislodged by mechanical trauma and embedded in inspissated mucus; residual basal cells may be all that is left adhering to the basement membrane. Bronchoalveolar lavage can produce vacuolation of alveolar pneumocytes and macrophages. Previous needle biopsies

may induce necrosis and hemorrhage in the parenchyma, followed by organization and reactive epithelial atypia (Figure 18.17). Patients who have been on positive-pressure ventilation (Figure 18.18) may have disproportional bronchiolar and alveolar duct distension, especially when high inspiratory pressures are used in the adult respiratory distress syndrome (ARDS). Some associated acute inflammatory exudate in the lumen is common, often with relative absence of associated inflammation in the airway wall or surrounding alveolar spaces.

- Changes related to prior instrumentation including bronchoscopy, bronchoalveolar lavage, needle aspiration, and ventilatory assistance
- Compression/atelectasis; pseudolipoid change (â€œbubble artifactâ€•)
- Hemorrhage/inflammatory changes
- Septal edema; lymphatic dilatation
- Material from surgical gloves (e.g., talc and starch)
- Inflation-induced alveolar distension resembling emphysema and patchy atelectasis in underinflated zones
- Sponge artifact

Table 18.7 Artifacts Seen in Lung Biopsies and Resections

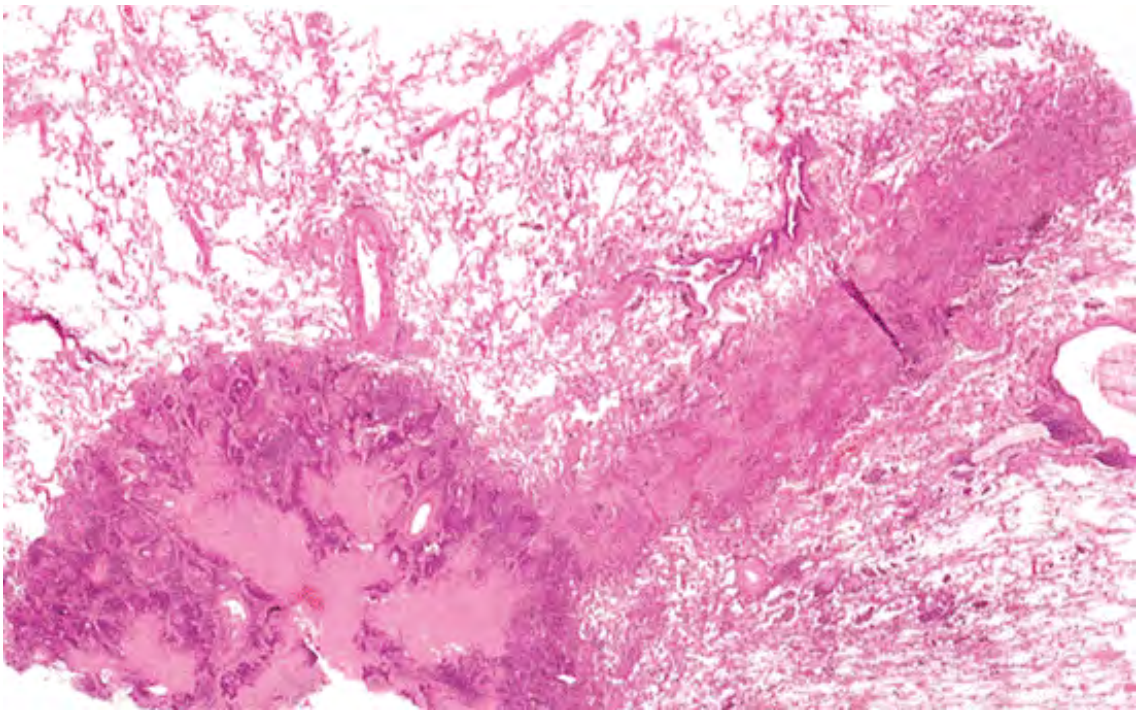

Figure 18.17 Needle tract to a small peripheral adenocarcinoma. The biopsy had been performed a week earlier, and the needle tract shows evidence of hemorrhage, necrosis, organization, and epithelial regeneration.

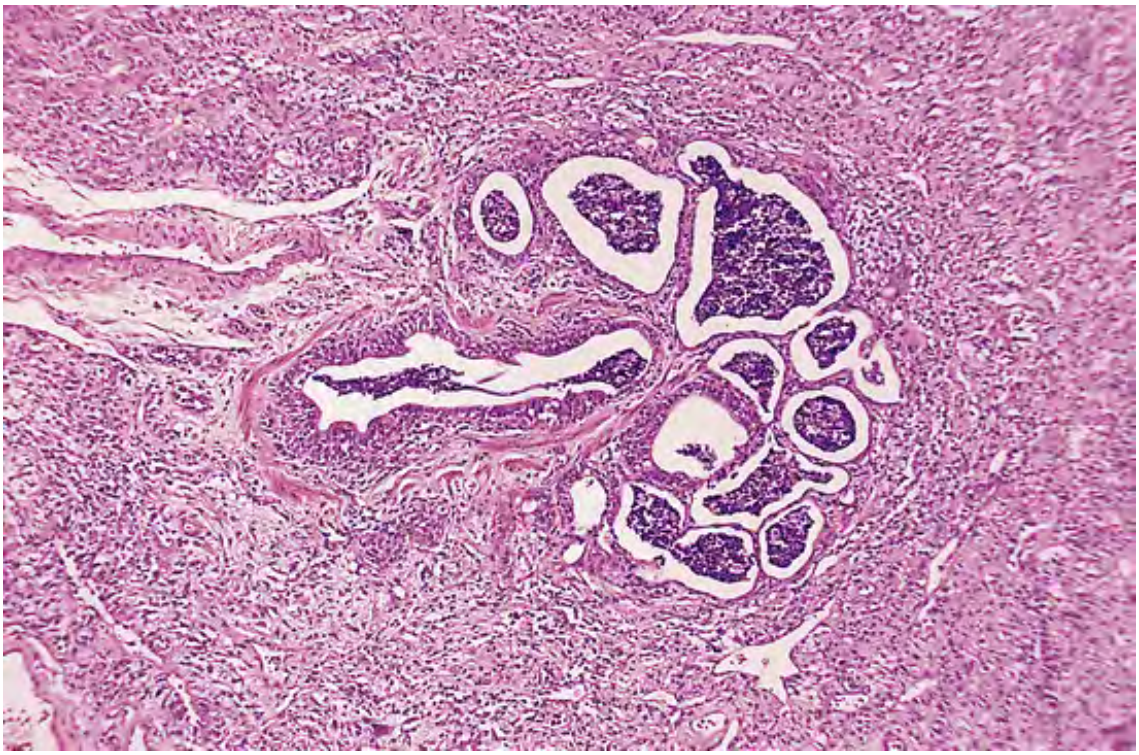

Figure 18.18 Ventilator-associated changes. Common changes in the setting of positive-pressure ventilator therapy include distension of bronchioles, flattening of their epithelium, and an acute inflammatory exudate in the lumen with minimal change in the surrounding alveolar wall.

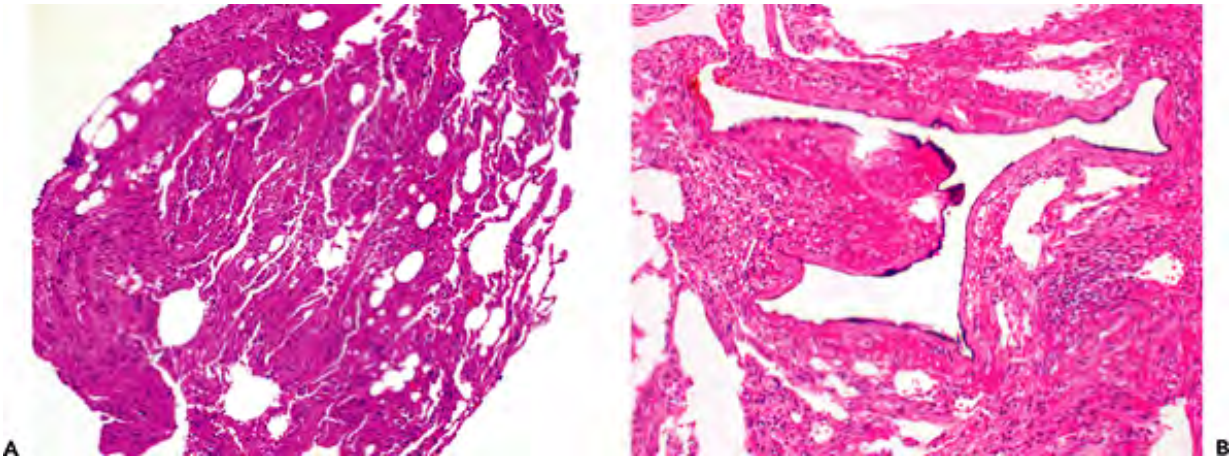

Figure 18.19 Bubble artifact. A. This fragment from a transbronchial biopsy shows compression and atelectasis (*left*)

with some recognizable alveolar walls (*right*). The rounded spaces represent bubble artifact, which is common in such compressed biopsies. B. Sponge artifact is illustrated. Note the marked irregularity of the space corresponding to the irregular surface of sponges used in cassettes.

Compression of the lung tissue, particularly in transbronchial biopsies, may produce rounded spaces in alveoli that resemble fat vacuoles and can easily be mistaken for exogenous lipoid pneumonia (Figure 18.19). This artifactual change, often called bubble artifact (54 ,55), can be recognized because there are no macrophages or giant cells with small intracytoplasmic lipid vacuoles (all the vacuoles are extracellular), and there is usually little fibrosis, which is a constant feature of chronic exogenous lipoid pneumonia.

Compression of airways produces crinkling and telescoping of the epithelium, similar to that seen in endometrial biopsies. Sometimes entire strips of mucosa are displaced into the bronchiolar or alveolar spaces.

Compression-induced nuclear smearing artifact can be produced in any cellular tumor and even in reactive lymphoid tissue in the bronchial mucosa or biopsies of hilar or mediastinal nodes. The resulting changes may suggest small cell carcinoma. Reactive lymphoid follicles, lymphomas, and carcinoid tumors may be extremely difficult to distinguish from small cell carcinoma when this phenomenon is present. Recognition of these diagnostic pitfalls, examining multiple levels (especially at the periphery), and enlisting the aid of concomitant cytology specimens and immunohistochemistry allows resolution of most cases. In rare instances, rebiopsy may be necessary.

Atelectasis may be encountered in all types of lung biopsies since lung tissue is soft and readily compressible (54 ,55). It is

particularly common in video-assisted thoracic surgical wedge biopsies because this procedure requires that the lung be collapsed and samples may become further compressed during retrieval through a small hole in the chest wall (56). Atelectasis may also be encountered in biopsies inflated by the pathologist when not all lobules uniformly inflate. This phenomenon may be misinterpreted as interstitial pneumonia or interstitial fibrosis because the apposition of alveolar walls produces apparent scarring and hypercellularity (Figure 18.20). With experience, this change can be recognized on routine H&E sections; connective tissue stains show an absence of scarring and a normal background of supporting fibrous tissue along vessels and in septa. In atelectatic lung, the vessels and septa may appear to have more collagen than normal and to be thickened because they are contracted and shortened. Careful assessment of the nuclei in atelectatic lung shows that most

are endothelial or epithelial in origin, rather than inflammatory. Leukocyte common antigen immunostaining and immunohistochemical stains for other lymphoid markers may be useful in this setting. It is also unusual in open biopsies (and larger specimens) for the entire specimen to be uniformly atelectatic; and, therefore, a low-power survey of the entire pattern generally helps one appreciate atelectasis merging with more normal lung. In fact, when significant fibrosis is present (usually associated with foci of honeycombing), atelectasis is rarely a problem because the more rigid fibrotic lung tissue tends to retain its configuration.

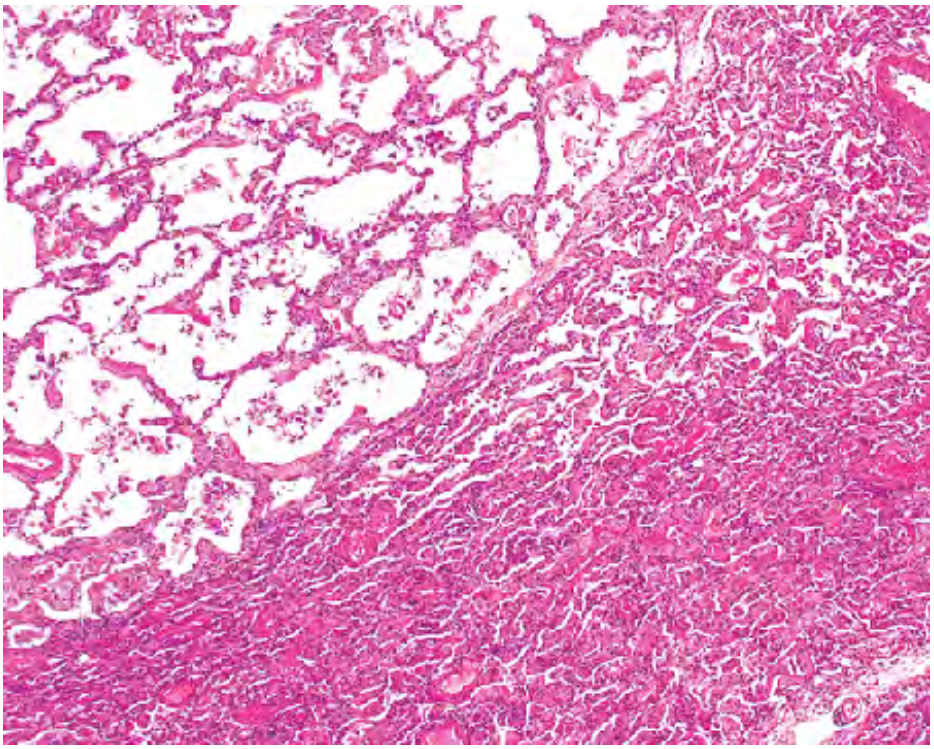

Figure 18.20 Atelectasis. Careful examination shows that recognizable alveolar walls can be traced into the region of atelectasis (*lower right*) and that the process stops somewhat abruptly at an interlobular septum that courses diagonally across the field (*lower left to upper right*).

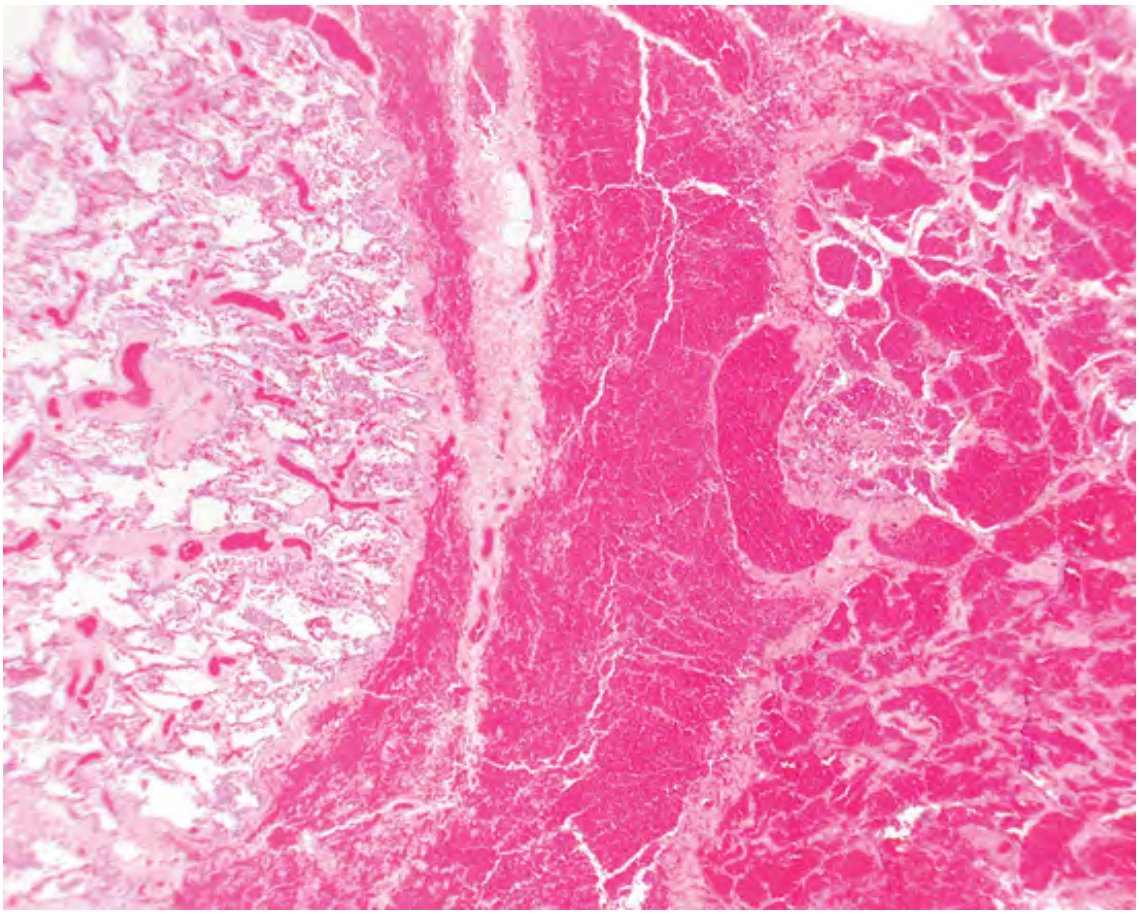

Figure 18.21 Traumatic hemorrhage. The right side of the field shows extensive hemorrhage into alveolar spaces, whereas the tissue on the left shows a complete absence of hemorrhage. There is also dissection of red blood cells into the interlobular septal region (*center*). Such a well-demarcated focus of hemorrhage and dissection of red blood cells into connective tissue would be very unusual in a diffuse alveolar hemorrhage syndrome. The findings are typical of traumatic hemorrhage.

Fresh intra-alveolar hemorrhage due to the trauma of surgery is extremely common in biopsy material and should not be overinterpreted as pathologic (Figure 18.21). In fact, hemorrhage related to the trauma of the procedure is the most common cause of fresh blood in alveolar spaces. One can approach this problem from three points of view: the statistical, the histologic, and the

clinical. Statistically, the vast majority of cases of fresh alveolar hemorrhage are traumatic since pathologic alveolar hemorrhage is relatively uncommon; thus, in any given case, acute hemorrhage is unlikely to be significant. When pathologic hemorrhage is present, there is usually (but not always) an associated fibrinous exudate or hyalin membranes, obvious distention of alveoli with blood, and evidence of prior hemorrhage manifested by hemosiderin-filled macrophages in the interstitium or airspaces. This last finding is not a reliable histologic criterion in patients who have been smokers and those with venous obstruction or chronic passive congestion.

The most common cause of macrophages staining positively with iron stains is respiratory bronchiolitis in smokers (Figure 18.22). The hemosiderin in smoker's macrophages is finely granular, in contrast to the coarse, dark blue staining in chronic hemorrhage as highlighted by the Prussian blue histochemical stain for iron. Nevertheless, it is surprising how many darkly staining Prussian blueâ€“positive cells can be seen in smokers.

Finally, the clinician can usually confirm whether an alveolar hemorrhage syndrome or alveolar hemorrhage due to some other cause (e.g., cardiac) is in the realm of possibility in any given patient.

Prolonged surgical manipulation of the lung, and even multiple transbronchial biopsies, can lead to margination of neutrophils in capillaries (especially those in the pleura), which mimics capillaritis (56). Capillaritis is usually associated with some evidence of an alveolar hemorrhage syndrome or other clinical or histologic features of a vasculitic syndrome (such as vascular necrosis, karyorrhexis, and fibrin thrombi). It is distributed throughout a biopsy and is not limited to those regions manipulated during surgery. Clamping of the biopsy specimen prior to removal can result in lymphatic obstruction, dilatation, and septal edema.

Lung pathologists are divided on the issue of inflation fixation of biopsy specimens. This can be easily accomplished with a syringe filled with formalin and a fine gauge needle. Careful inflation of a lung biopsy specimen (57) may be helpful diagnostically and is aesthetically pleasing since the lung architecture is more easily appreciated (and particularly amenable to photography). A heavy hand can create overdistension of the alveoli and an emphysematous appearance. If this occurs, clinical correlation may be required to assess whether emphysema is actually a clinical consideration. Patchy atelectatic (uninflated) portions of lung tissue are common in biopsies that have been nonuniformly inflated. One problem that may be encountered in inflated biopsies is that cells and fluid may be â€œwashed outâ€• of the airspaces. This is especially true of smoker's (respiratory) bronchiolitis, which may be quite subtle in inflated specimens. A practical compromise to the issue of whether or not to inflate wedge biopsies was proposed by Dr. Lewis Woolner at the Mayo Clinic several decades ago (personal communication). One takes a wedge biopsy (even specimens from which tissue has been taken for studies such as frozen section) and simply places it in a closed container of formalin and shakes it up for a few seconds. This simple procedure allows the tissue to inflate somewhat on its own and the resultant histologic sections are remarkably good.

Video-assisted thoracic surgical (VATS) lung biopsies (thoracoscopic biopsies) have largely replaced traditional open lung biopsy as the diagnostic procedure for obtaining wedge biopsies of lung tissue for histologic evaluation. Although there are minor disadvantages in comparison to traditional open lung biopsy, diagnostic accuracy does not appear to be compromised (56 ,58 ,59 ,60). Allowing for the

fact that bimanual palpation is not as feasible with VATS biopsies, and that the tissue is forcibly pulled through a small hole in the chest wall, it is remarkable that sampling error and specimen

artifacts are only a minor problem. The specimen size approaches that achieved with traditional open lung biopsy, and the minor degrees of hemorrhage, atelectasis/overinflation, and neutrophil margination represent artifactual changes that do not compromise diagnostic accuracy (56 ,58 ,59 ,60).

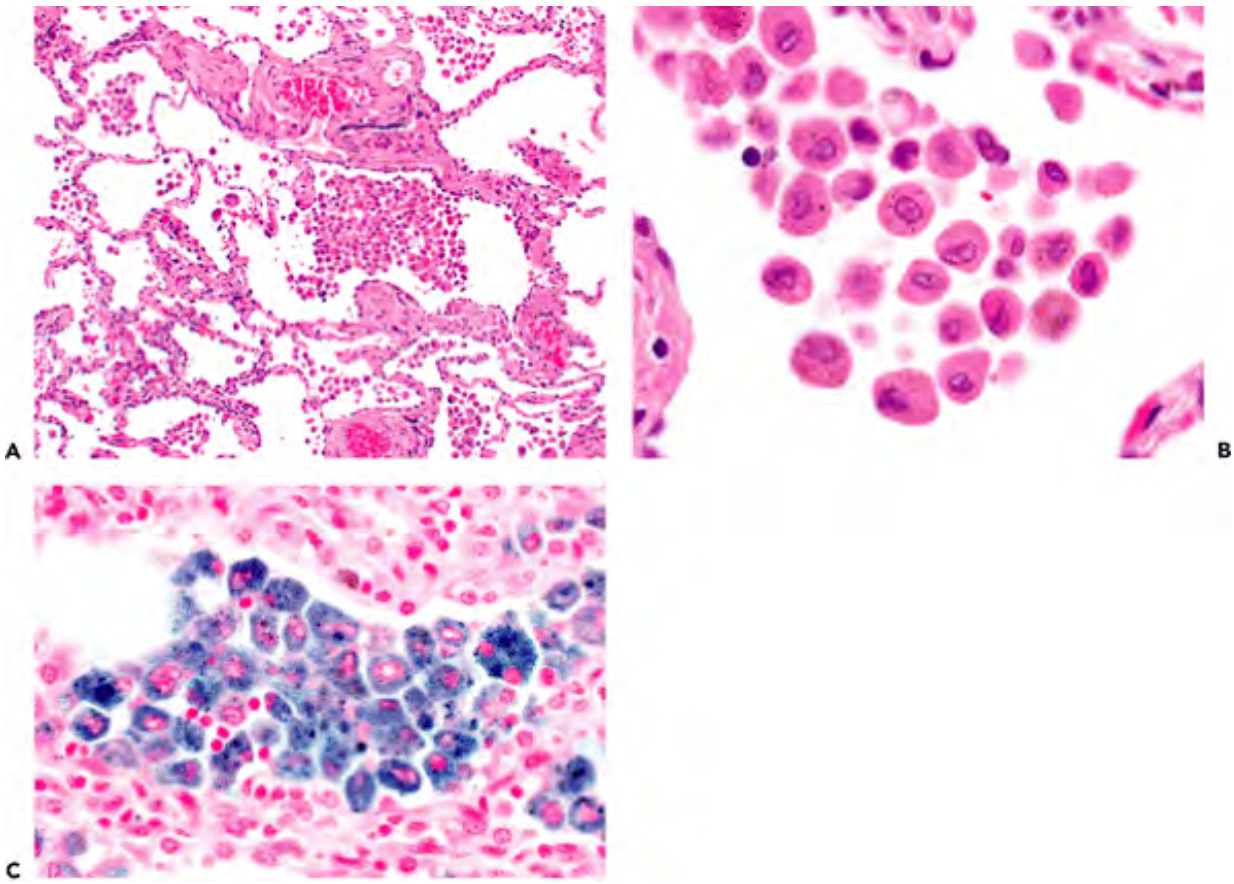

Figure 18.22 Respiratory bronchiolitis. A respiratory bronchiole (A) shows an accumulation of pigmented macrophages in the lung with slight associated interstitial widening. The macrophages have a slight tan-brown appearance, contain flecks of dark material (B), and are positive with Prussian blue staining (C) with a fine granularity.

Plastic sponges are often put in cassettes to ensure that small specimens are not lost during processing. Sponge artifact, with triangular â€œholesâ€• in the tissue, is a well-known artifact in

any tissue that is processed this way, particularly if it is placed on the sponges prior to complete formalin fixation (55).

Incidental Findings in Lung Biopsy and Resection Tissue

There are a number of incidental findings in lung tissue that may not be related to the primary process that prompted the biopsy or resection (Table 18.8). Sometimes these â€œincidentalâ€• findings are of clinical and pathologic significance, and other times they are of no significance. Correlation of the individual finding(s) with the clinical and radiologic presentation helps to determine their significance.

Findings related to smoking and emphysema are extremely common, especially in lungs resected for bronchogenic carcinoma (46). They may be divided into three broad groups: large airway changes, small airway lesions, and abnormalities of the alveolar parenchyma.

In the large airways, one sees goblet cell hyperplasia, squamous metaplasia (with or without dysplasia), basement membrane thickening, hypertrophy and hyperplasia of bronchial glands with dilated ducts and mucostasis, and, often, a mild submucosal chronic inflammatory infiltrate (45 ,48).

The changes in the small airways may be quite dramatic and may mimic or even produce an interstitial lung disease (46 ,61 ,62). Smoking-induced respiratory bronchiolitis (Figure 18.22) includes goblet cell metaplasia, a mild inflammatory infiltrate in the airway walls, metaplasia of type II cells in the surrounding alveoli, mild peribronchiolar

fibrosis, and prominent accumulations of pigmented macrophages in adjacent airspace and the bronchiolar lumen. The pigmented macrophages (smokers' macrophages) contain phagocytosed

debris from inhaled cigarette smoke and have prominent secondary lysosomes in their cytoplasm. This results in a dirty granular-tan or brown appearance to the cytoplasm. They contain PAS-positive (lysosomes) and finely granular Prussian blueâ€“positive (hemosiderin) material, as well as tiny, irregular flecks of brown-black material.

Effects of smoking: emphysema, chronic bronchitis, respiratory (smoker's bronchiolitis, intraparenchymal lymph nodes)
Changes of asthma
Ossification and marrow formation in bronchial cartilages, bronchial submucosal fatty infiltration, and elastotic change
Parenchymal nodules
Carcinoid tumorlets; DIPNECH (see text)
Minute (meningothelial-like nodules) pulmonary chemo-dectomas
Atypical adenomatous hyperplasia (AAH)
Healed granulomatous disease, infarcts, etc.
Hamartomas
Focal scars
Occasional (anthraco-) silicotic nodules (in the absence of clinical/radiologic pneumoconiosis)
Metaplastic bone
Intrapulmonary lymph nodes
Small carcinomas (and other tumors)
Multifocal micronodular pneumocyte hyperplasia (MMPH)
Intracellular/intra-alveolar/interstitial structures
Macrophages
Corpora amylacea
Blue bodies
Schaumann bodies
Asteroid bodies
Calcium oxalate crystals
Mallory's hyalin-like material in type II cells
Ferruginous bodies

Anthracotic pigment/birefringent material (including silica and silicates)
Metaplastic bone
Epithelioid and/or cholesterol granulomas, giant cells, lipogranulomas
Intravascular/vascular
Megakaryocytes
Thrombi (mimic emboli)
Bone marrow emboli
Calcification and iron encrustation of the elastic tissue
Senile amyloid
Foreign material
Interstitial air in the lung parenchyma
Hilar/peribronchial lymph nodes
Sinus and paracortical histiocytes (may simulate granulomas)
Occasional silicotic or anthracosilicotic nodules
Anthracosis/birefringent material
Hamazaki-Wesenberg bodies
Pleural adhesions; hyalin pleural plaques

Table 18.8 Incidental Findings in Lung Tissue

The smoking-related changes in the most distal pulmonary parenchyma usually manifest as centriacinar emphysema with airspace enlargement and loss of alveolar walls (45 ,48). Histologic quantification of emphysema on biopsy material is difficult, although one can often determine whether it is present and subjectively quantify it. Bullous emphysema (with abnormal airspaces greater than 1 cm in diameter) is more common in the upper lobes and is usually associated with some fibrosis in the septa of the bullae and adjacent alveolar walls. The fibrosis is relatively acellular, noninflammatory, eosinophilic, and poorly vascularized. Metaplasia or ulceration of the epithelium and interstitial dissection of air occur in bullae and may induce a giant

cell response analogous to that seen in persistent interstitial emphysema.

Asthmatics are predisposed to a number of lung conditions that may lead to lung biopsy, although the asthmatic changes themselves may not be the dominant lesion. These airway changes include goblet cell metaplasia in the airway epithelium, thickening of the basement membrane and submembranous region, smooth muscle hypertrophy and hyperplasia, lymphoid hyperplasia, and a variable infiltrate of eosinophils, lymphocytes, and a few neutrophils, and fibrous tissue in the wall (45 ,48). Mucostasis (including Curschmann's spirals) may be an accompanying feature; but, when mucostasis is extensive and is associated with sloughing of epithelial fragments into the airways (creola bodies), one should suspect that the asthma itself is the main lesion. Such an appearance is typical of status asthmaticus. Some distal atelectasis with a few airspace macrophages and eosinophils may also be seen. In patients with quiescent asthma or past history of asthma, the airways may be entirely normal or show only minor inflammatory or fibrotic changes.

Metaplastic bone, including bone marrow and calcification, is an aging change that is occasionally seen in bronchial cartilages (63). Metaplastic bone may also be seen in regions of scarring (dystrophic ossification), particularly in apical caps. Small bony nodules may also be seen with no apparent associated pathologic changes. In some older individuals with chronic bronchitis, the bronchial submucosa may have a gray elastotic appearance, particularly in bronchoscopic biopsies.

Carcinoid tumorlets (64 ,65 ,66 ,67), now referred to simply as tumorlets, and minute pulmonary meningothelial-like nodules (67 ,68 ,69) are nodular proliferations that are quite common. They may be mistaken for each other, other lesions, or even metastases. Tumorlets (Figure 18.23) represent well-circumscribed proliferations of neuroendocrine cells that usually

occur around and within the walls of small airways, particularly in scarred or bronchiectatic airways, and in a small number of patients with airflow destruction. They lack mitotic figures and necrosis; and, while there is a superficial resemblance to small cell carcinoma, they are actually more similar to spindle cell carcinoid tumors. In frozen sections,

tumorlets may be mistaken for other lesions, particularly metastases. This confusion is compounded by the fact that sometimes tumorlets have cellular clusters at the periphery that retract from the surrounding stroma, simulating lymphatic or airspace invasion.

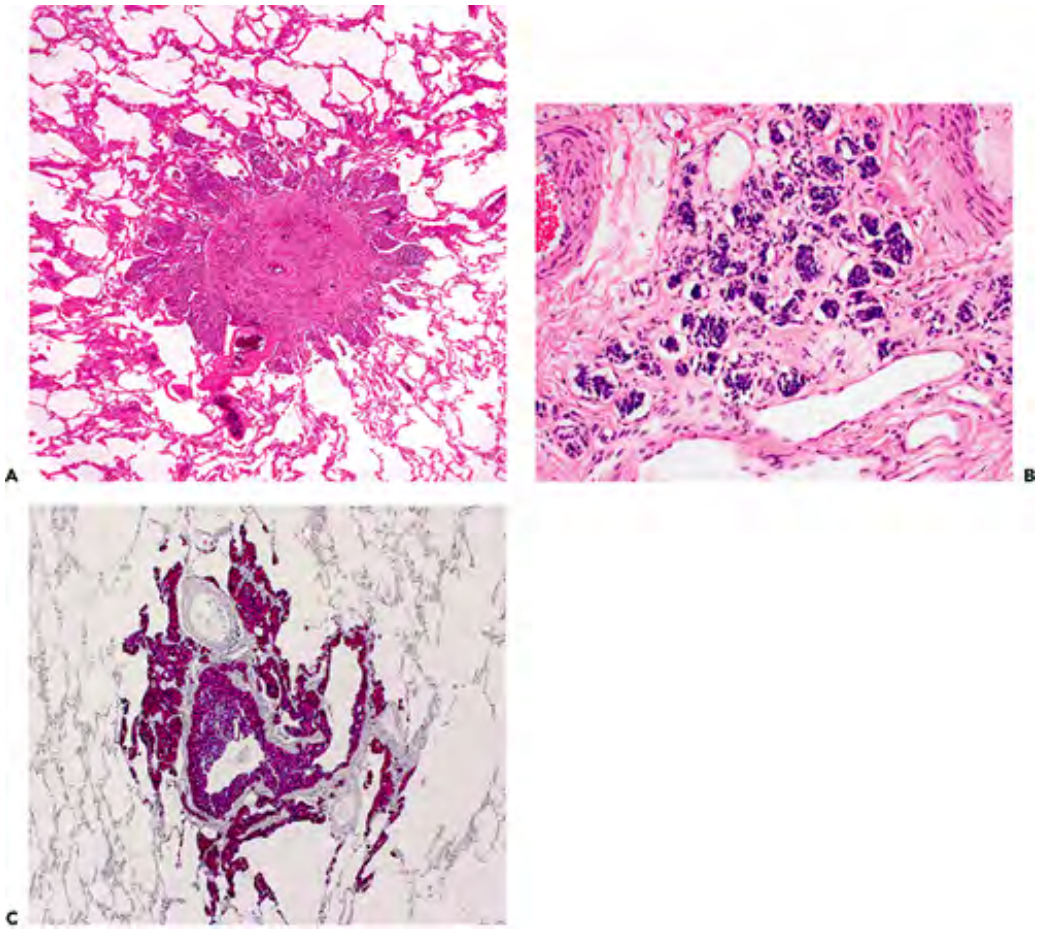

Figure 18.23 Tumorlet. A. Tumorlets are typically discrete nodules that are bronchiolocentric. The bronchiole is not apparent

in A because it has been overrun by the proliferation, but the adjacent pulmonary artery is identifiable. B. Cytologically, tumorlets have a neuroendocrine appearance with nests of cells with granular chromatin and absence of necrosis and significant mitotic activity. The nests are often embedded in a fibrous stroma, and some of them may appear to float freely in airspaces or spaces that resemble lymphatics. C. Neuroendocrine markers, such as chromogranin, are strongly positive.

Tumorlets are often multiple; some may become large enough to be recognized radiographically and to be removed to exclude carcinoma. Exactly where one draws the line between a carcinoid tumorlet and a carcinoid tumor, particularly in cases with multiple lesions, is quite arbitrary, although a cutoff point of 0.5 cm diameter or larger for carcinoid tumor is reasonable (41).

Diffuse intrapulmonary neuroendocrine cell hyperplasia (DIPNECH) is closely related to tumorlets, and the two often coexist (67). Arbitrarily, DIPNECH is defined as a proliferation of neuroendocrine cells limited to the bronchiolar epithelium. According to the World Health Organization (WHO), DIPNECH is defined as â€œa generalized proliferation of scattered single cells, small nodules (neuroendocrine bodies), or linear proliferations of pulmonary neuroendocrine cells (PNCs) that may be confined to the bronchiole and bronchiolar epithelium, include local extraluminal proliferation in the form of tumorlets, or extend to the development of carcinoid tumorsâ€• (67). When this proliferation expands and goes beyond the bounds of bronchioles, the designation of tumorlet is appropriate. Tumorlets are most frequently encountered as isolated or occasionally multiple nodules. When DIPNECH is encountered, usually multiple airways

are involved, and the patients may have evidence of airflow obstruction (67). Similarly, the presence of multiple tumorlets (and multiple carcinoid tumors) should prompt one to search for

evidence of DIPNECH and to consider the possibility of clinical evidence of airflow obstruction (70).

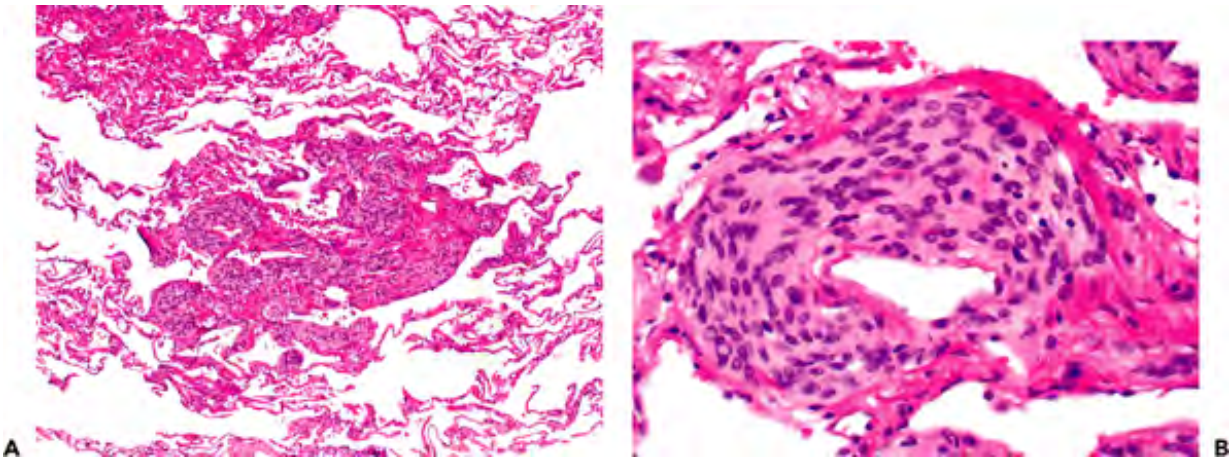

Figure 18.24 Minute pulmonary meningothelial-like nodule. These small parenchymal nodules are sometimes associated with pulmonary veins. A. They are associated with syncytial appearing cells in a collagenous stroma. B. Cytologically, they bear a distinct resemblance to meningothelial cells.

Minute pulmonary meningothelial-like nodules (formerly called minute pulmonary chemodectomas) (Figure 18.24) were originally thought to represent an intrapulmonary proliferation of perivenular chemoreceptor cells (67 ,68 ,69). However, the accumulated evidence suggests that the cellular constituents are more closely related to meningothelial cells (67 ,68 ,69). A study by Ionescu et al. (71) showed that meningothelial-like nodules were almost uniformly positive for vimentin, about one-third stain for EMA, and they are negative with cytokeratin and synaptophysin by immunohistochemistry. In a genotypic study, some loss of heterozygosity was demonstrated by the same authors, and this was more common and affected more loci in cases of multiple meningothelial-like nodules in comparison to cases with solitary meningothelial-like nodules (71). The authors concluded that isolated meningothelial-like nodules were probably reactive, that cases of multiple meningothelial-like nodules might represent a

transition from a reactive to a neoplastic proliferation, and that meningothelial-like nodules were different from meningiomas based on the major molecular events and their formation and progression (71). Minute pulmonary meningothelial-like nodules are composed of interstitial clusters of fusiform cells with pale eosinophilic cytoplasm, forming small stellate nodules (occasionally grossly appreciable) near small veins. Their location and characteristic bland cytology resembling meningothelial cells are very distinctive.

Atypical adenomatous hyperplasia (AAH) is a proliferative epithelial process occurring as small nodular lesions in the lung parenchyma (Figure 18.25). These were first recognized in resection specimens for carcinoma and named bronchioloalveolar cell adenomas (72). Miller found these lesions in 23 (10.74%) of 247 consecutive resection specimens for carcinoma (72). They are most easily recognized grossly in cases that are inflated with Bouin's fixative. The WHO defines AAH as â€œa localized proliferation of mild to moderately atypical cells lining involved alveoli and, sometimes, respiratory bronchioles, resulting in focal lesions in peripheral alveolated lung, usually less than 5 mm in diameter and generally in the absence of underlying interstitial inflammation and fibrosisâ€• (67). The lesions are considered a precursor to some nonmucinous bronchioloalveolar carcinomas and mixed-type adenocarcinomas; and the evidence supporting this is epidemiologic, morphologic, morphometric, cytofluorometric, and genetic. Atypical adenomatous hyperplasia generally represents an incidental histologic finding (rare cases have been identified radiologically) and is found in 2 to 4% of routine autopsies of noncancerâ€“bearing patients and up to 35% of lobectomies for adenocarcinoma of the lung. In general, we advocate a conservative approach to these lesions, since: (a) there are many causes of type II cell proliferation, and many of them are reactive; (b) there are no studies documenting the pathologic progression of AAH to bronchioloalvoelar carcinoma (BAC)â€”or studies that

document how long such a progression takes); and (c) no studies exist showing what percent of lesions of AAH progress to carcinoma.

Focal scars (see following), healed granulomatous disease, and organized infarcts are among other incidental nodular lesions occasionally encountered in the lung. Early infarcts have a wedge shape with hemorrhagic necrosis, and the overlying pleura is viable with a fibrinous pleuritis. They often also have a rim of granulation tissue. Older infarcts are often rounded and have a rim of fibrous tissue; they can even be mistaken for healed granulomas. Necrotic tumor nodules sometimes mimic infarcts. Squamous metaplasia is

common in the airspaces adjacent to organizing infarcts and around bronchioles in organizing diffuse alveolar damage; it may be sufficiently exuberant to be mistaken for a neoplastic process. A single anthracosilicotic nodule is an occasional finding that may be accepted as incidental and insignificant if there is no clinical or radiologic evidence of pneumoconiosis. When silicotic nodules are multiple, the occupational history and the possibility of pneumoconiosis should be explored.

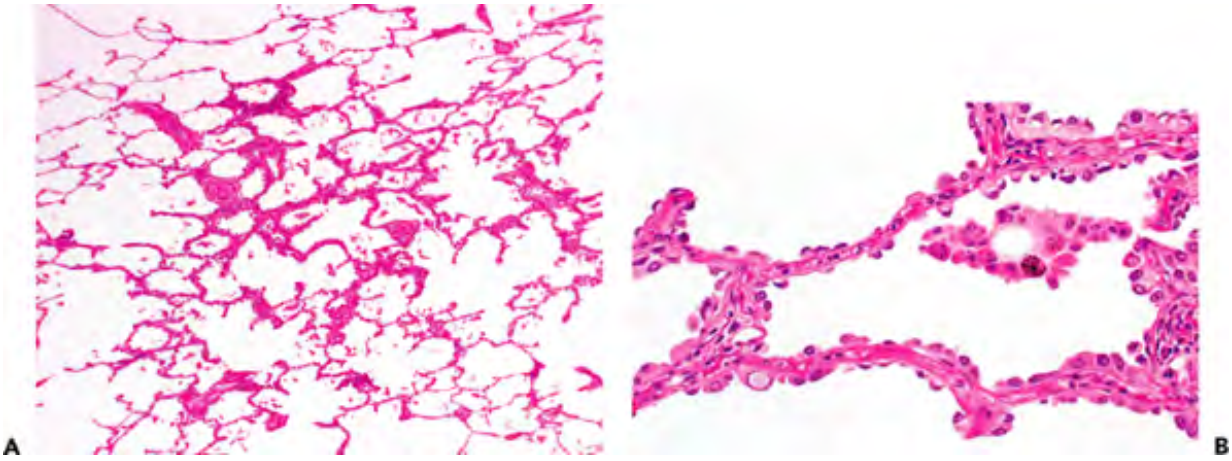

Figure 18.25 Atypical adenomatous hyperplasia (AAH). A. In this well-inflated specimen, a 2 to 3 mm diameter lesion is apparent as

slight alveolar septal thickening and a proliferation of knob-shaped cells along alveolar walls. B. Cytologically, the cells lining the alveoli have mild to moderate atypia but lack the crowding and marked atypia associated with bronchioloalveolar carcinoma. Some nuclear inclusions characteristic of type II cells are also apparent (*lower left*).

Although extensive parenchymal scarring is usually a pathological process, focal scars a few millimeters in diameter are a common incidental finding in biopsy material. One distinctive form of scar that is frequently observed (and may be identifiable as 2â€“3 mm centrilobular nodules in CT scans) consists of scars centered on alveolar ducts in the periphery of the lung, particularly common in (ex-) smokers (Figure 18.26). They are round or somewhat stellate in character and have numerous fascicles of smooth muscleâ€”and thus sometimes have been confused with primary muscle proliferations such as lymphangioleiomyomatosis. There are a number of histologic changes that accompany pulmonary scarring, regardless of cause. These include vascular intimal and medial thickening, sometimes to the point of luminal occlusion (endarteritis obliterans); smooth muscle and myofibroblastic hyperplasia in the interstitium; metaplasia and hyperplasia of type II cells or bronchiolar-type epithelium (peribronchiolar metaplasia); accumulations of intra-alveolar macrophages and mucostasis; carcinoid tumorlets (particularly along scarred small airways); dystrophic calcification or ossification; microscopic pericicatricial emphysema; and metaplastic adipose tissue in the pleural and peribronchial regions. The proliferation of type II cells associated with scars may be

confused with bronchioloalveolar carcinoma. Bronchioloalveolar carcinoma generally has uniform dense cellularity and cellular crowding with abrupt transition to normal alveolar walls, significant cytologic atypia, and lack of ciliated cells. Although AAH

tends to have relatively little interstitial widening and fibrosis, AAH enters into the differential diagnosis in this situation.

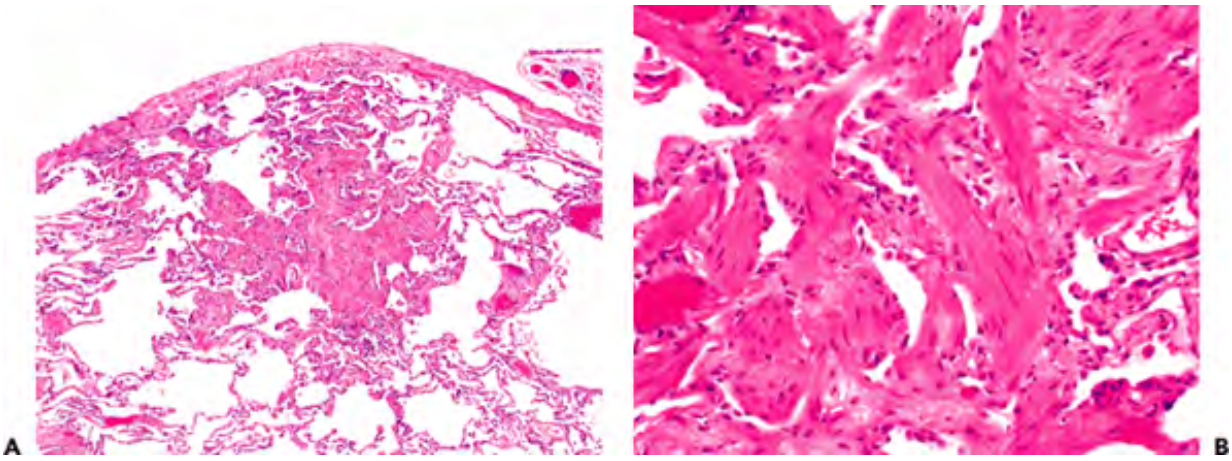

Figure 18.26 Incidental parenchymal scar. These are typically subpleural and appear to center on alveolar ducts (A) and commonly have fascicles of normal appearing smooth muscle (B).

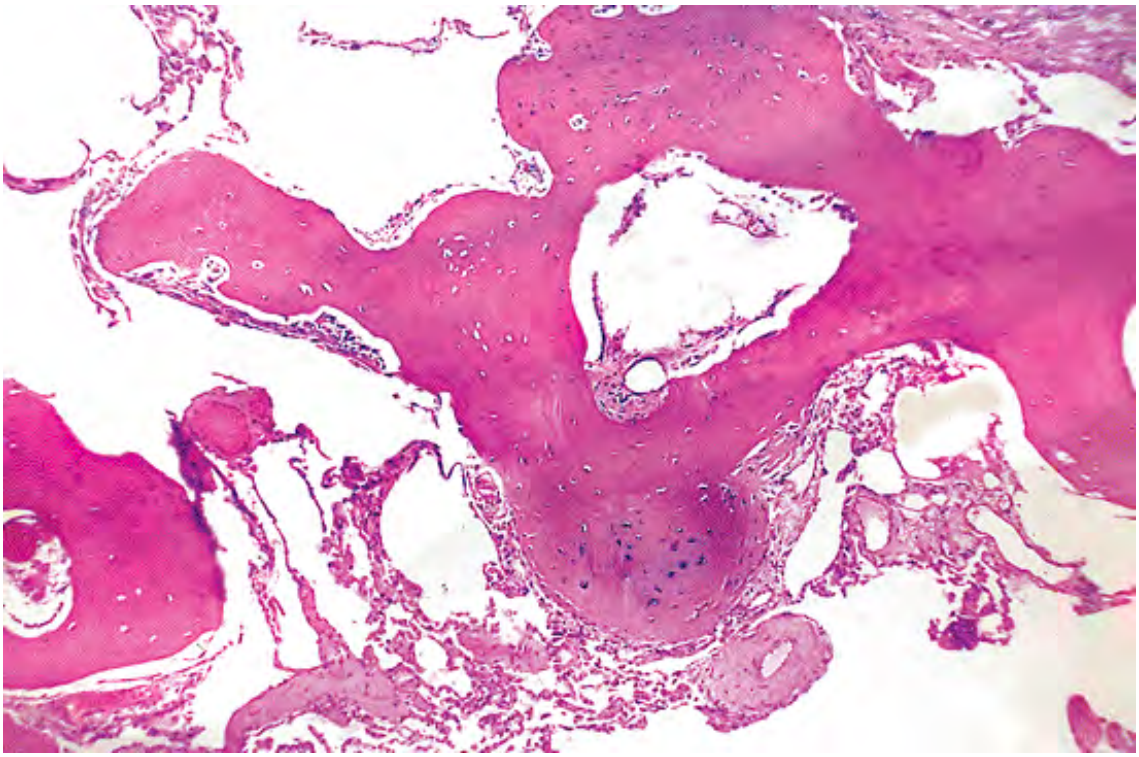

Figure 18.27 Ossification. An incidental focus of pulmonary ossification is noted; tissue is from a patient with usual interstitial

pneumonia.

In rare instances, mature bone is observed in normal alveoli; it may represent the residue of an organized airspace exudate from chronic passive congestion of mitral stenosis or an ancient organized pneumonia (73). Extensive dystrophic ossification (and rarely calcification) occasionally accompanies lesions with diffuse pulmonary fibrosis (Figure 18.27) (74). Focal dystrophic ossification is a common finding in focal lung scar, regardless of cause.

Intrapulmonary lymph nodes (Figure 18.28) are not uncommonly encountered in wedge biopsies. They vary from loosely organized microscopic foci of lymphoid tissue to fully developed lymph nodes identified grossly or radiologically.

Micronodular pneumocyte hyperplasia (MNPH) is defined by the WHO (1999) as â€œa multifocal micronodular proliferation of type II cells with mild thickening of the interstitiumâ€• (Figure 18.29) (67 ,75). This condition is rare and generally an incidental finding in a biopsy taken for another lesion (usually lymphangioleiomyomatosis). Rarely, MNPH is the sole lesion present, and the lesions may be sufficiently large to be identifiable on CT scans as multiple small nodules. The lesions are typically less than 5 mm in size. They can usually be distinguished from AAH and other causes of alveolar cell hyperplasia by their distinct rounded nodular character at scanning microscopy, the large plump eosinophilic type II cells lacking significant atypia, the slight interstitial collagen deposition within the lesions, and the presence of airspace histiocytes in the regions of the nodules.

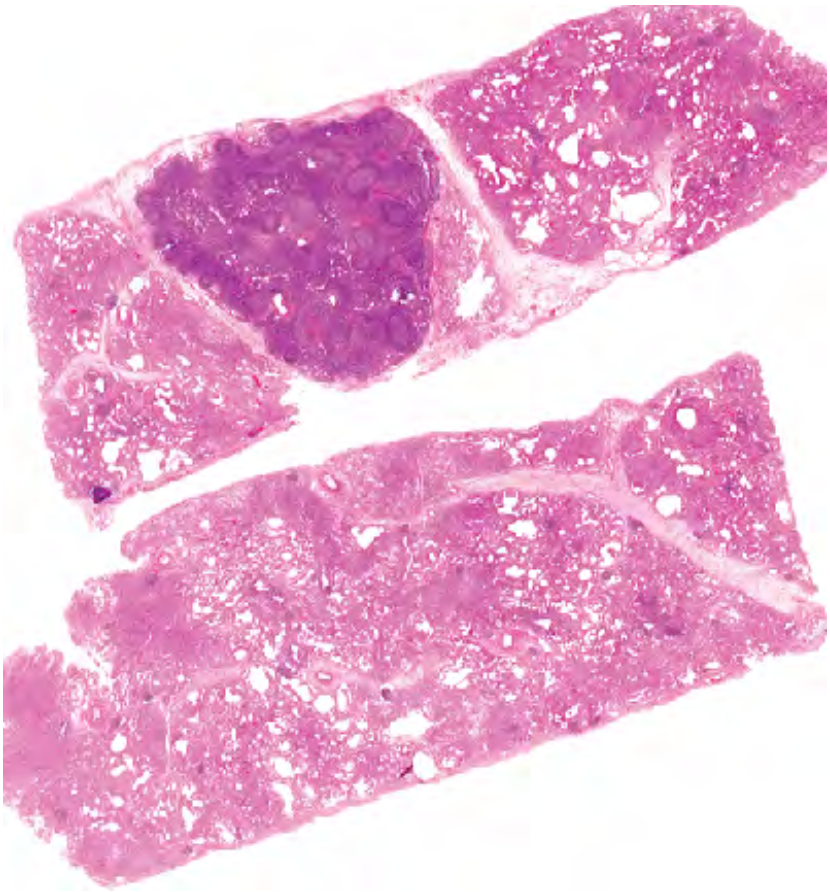

Figure 18.28 Intrapulmonary lymph node. There is a relatively large lymph node that appears to be within or adjacent to an interlobular septum in a wedge biopsy from peripheral lung. Reactive follicles are apparent even at scanning power microscopy.

A number of intra-alveolar and intracellular structures are seen in the lung. Small numbers of intra-alveolar macrophages are a normal finding, and an increase in their numbers is nonspecific and a common reaction in smokers (43). Focal desquamative interstitial pneumonia-like reactions are seen in many pathologic conditions, especially in smokers and in conditions with fibrosis and architectural disorganization (46 ,76). When hemosiderin is present, causes for alveolar hemorrhage (both primary and secondary) should be excluded.

Corpora amylacea (77 ,78) are eosinophilic, rounded, slightly

lamellated proteinaceous bodies (Figure 18.30) that stain positively with PAS stains and faintly with Congo red stain; they are more common in the lungs of older individuals. Sometimes there is a blue-gray, calcified, or polarizable crystalline particulate body in the center and a macrophage or giant cell response around them. The exact nature and cause of corpora are unclear, but they are of no clinical significance.

Blue bodies (Figure 18.31) are intra-alveolar, lamellated, basophilic, calcified structures found in airspaces associated with alveolar macrophages and giant cells (78). They are a nonspecific finding in a number of diffuse lung diseases related to accumulation of macrophages and are of no diagnostic significance. They are thought to be related to macrophage catabolism; they are composed primarily of calcium carbonate.

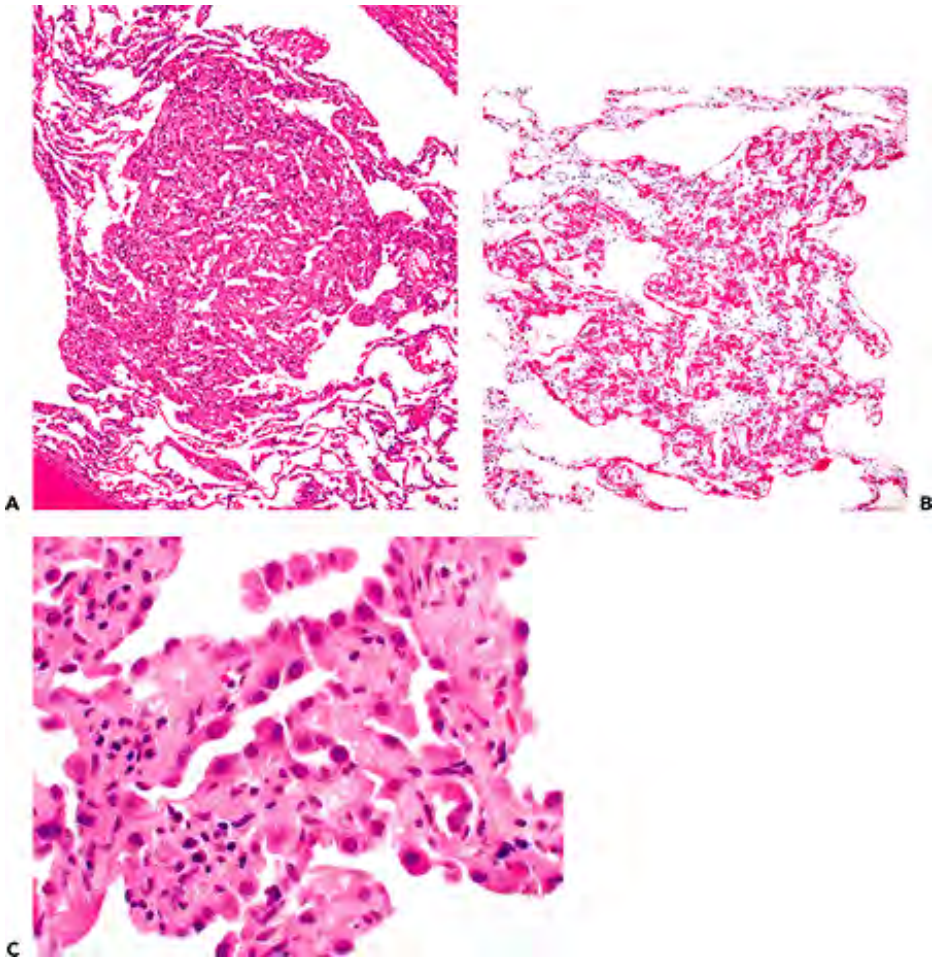

Figure 18.29 Micronodular pneumocyte hyperplasia (MNPH). A. There is a small central nodular region composed of plump type II cells. B. The size of the type II cells relative to the surrounding type I cells is apparent in cytokeratin staining. C. Cytologically, the type II cells have a fairly benign appearance.

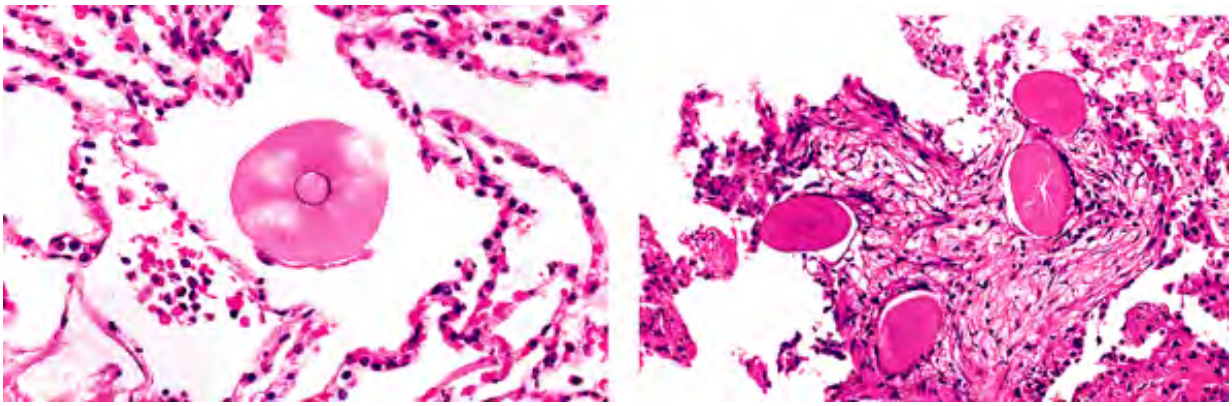

Figure 18.30 Pulmonary corpora amylacea. A. These show a central bluish nidus and a giant cell or macrophage reaction around them. Others may have radiating proteinaceous arrays and show cracking in histologic sections. They are often Congo redâ€“positive. B. Multiple corpora amylacea are seen as an incidental finding associated with organizing pneumonia.

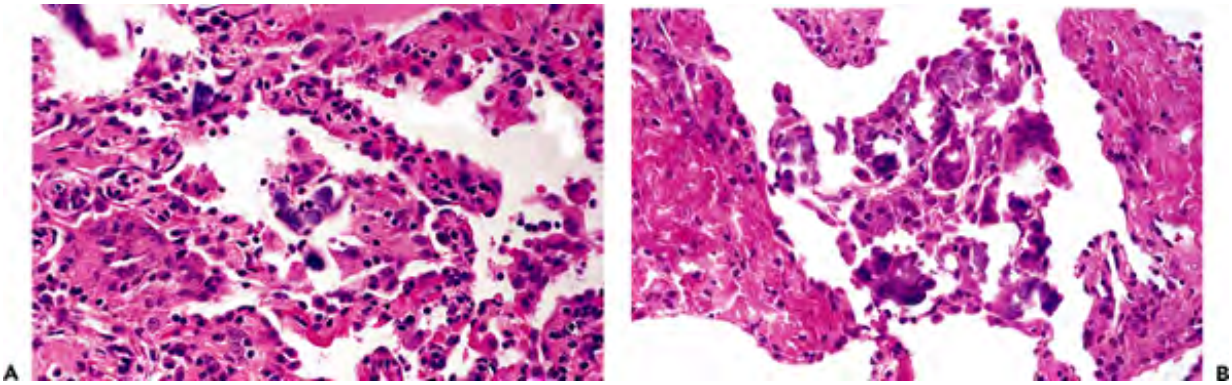

Figure 18.31 Blue bodies. A. and B. Blue bodies are gray or blue, intra-alveolar, calcified, lamellated structures often associated with clusters of macrophages, including giant cells.

Schaumann bodies (Figure 18.32) are similar lamellated, calcified bodies seen in giant cells and associated with granulomas (78 ,79 ,80). They are also of no diagnostic significance and may be found in granulomas from diverse causes. Schaumann bodies are

endogenously derived and may be mistaken for exogenous material since they may be partially birefringent, due to concomitant presence of oxalate crystals (see following).

Asteroid bodies (Figure 18.33) represent a starlike array of crystallized intracellular protein and are seen in giant cells of many granulomatous conditions; other than being aesthetically pleasing, they are nonspecific.

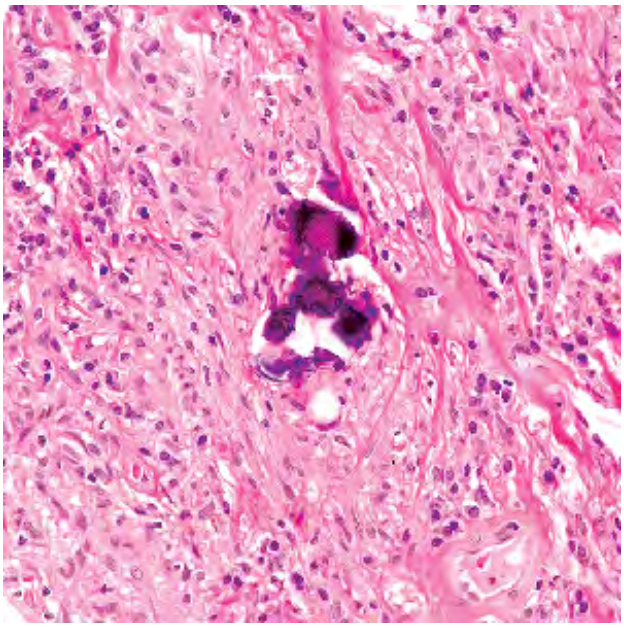

Figure 18.32 Schaumann body. There is a bluish calcified structure associated with surrounding granulomatous inflammation. A lamellated appearance similar to a psammoma body is focally apparent. The pale zones in this case represent loosened oxalate crystals that would be birefringent (see Figure 18.34).

Calcium oxalate crystals are lucent, birefringent, platelike crystals, often in giant cells, that may be mistaken for exogenous material (78 ,79) (Figure 18.34). Accumulation of oxalate crystals around aspergillomas and in patients with forms of invasive aspergillosis is also common.

Material similar to Mallory's hyalin (Figure 18.35) may be found in the reactive type II cells of a number of interstitial diseases. It is distinctive, but nonspecific. It may stain for keratin and ubiquitin (81).

Ferruginous bodies, many of which are asbestos bodies, are indicative of significant inhalational exposure to the ferruginated material, but their presence does not necessarily correspond to clinically significant lung disease. Recent studies with electron-probe analysis have helped elucidate the variety of materials that may become iron encrusted, of which asbestos fibers comprise only a portion (82).

In virtually any urban adult, one may find short, needlelike, birefringent material (usually silica or silicates) in association with anthracotic pigment (Figure 18.36), either along lymphatic routes in the lung or in regional lymph nodes. Silicates are more brightly birefringent than silica.

The amount of birefringent material may be quite impressive in individuals (particularly smokers) who have no significant occupational exposure. This material should be distinguished from formalin pigment, as well as from surgical glove talc or starch; the latter are limited to handled surfaces and often demonstrate a Maltese-cross configuration with polarization. The diagnosis of silicosis (and silicatosis) is not based solely on the presence of birefringent material; it requires clinicopathologic correlations: appropriate chest radiograph findings, and parenchymal silicotic nodules or masses of histiocytes (within which early fibrotic nodules may be seen to form) along lymphatic routes. Precise characterization of any material identified requires special techniques such as electron-probe analysis.

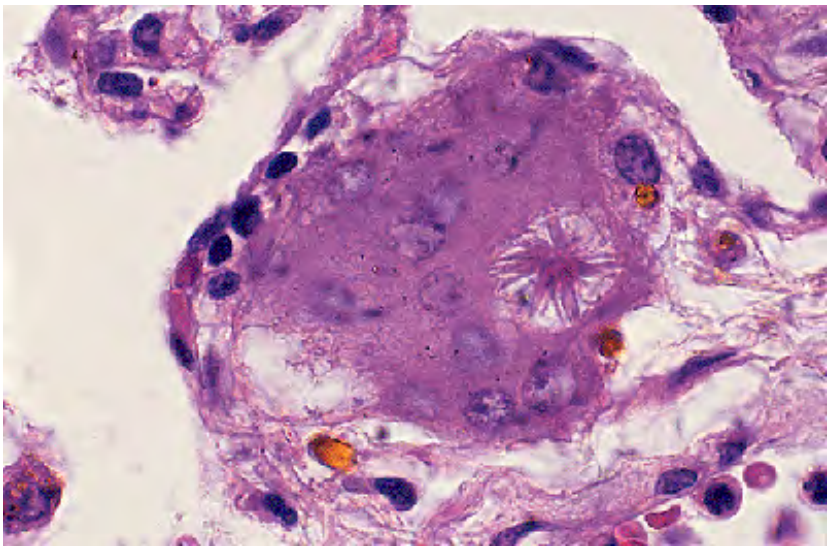

Figure 18.33 Asteroid body. An asteroid body in a giant cell is illustrated from a case of asbestosis.

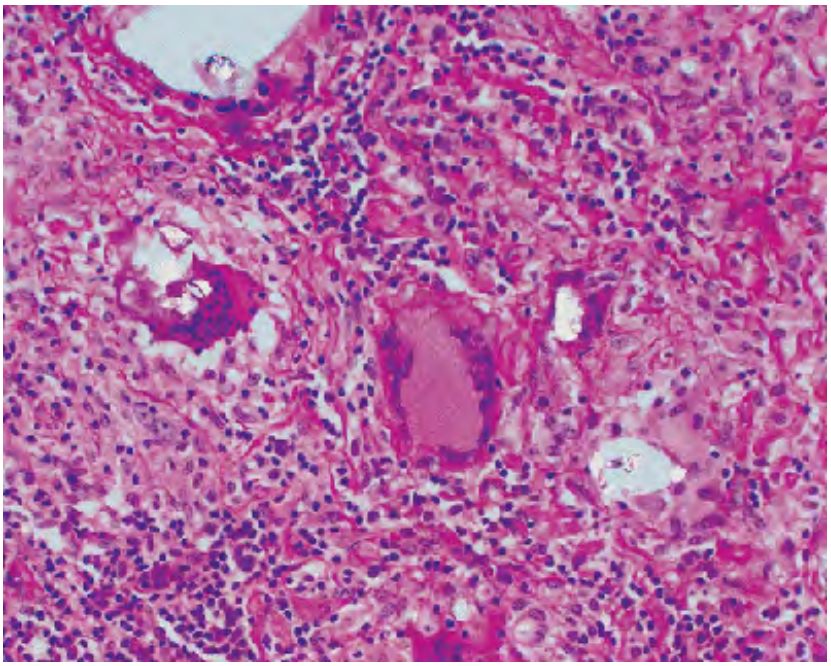

Figure 18.34 Calcium oxalate crystals. Calcium oxalate crystals are commonly associated with Schaumann bodies and granulomatous inflammation and show bright birefringence, as noted in this partially polarized photomicrograph. The association with giant cells is characteristic.

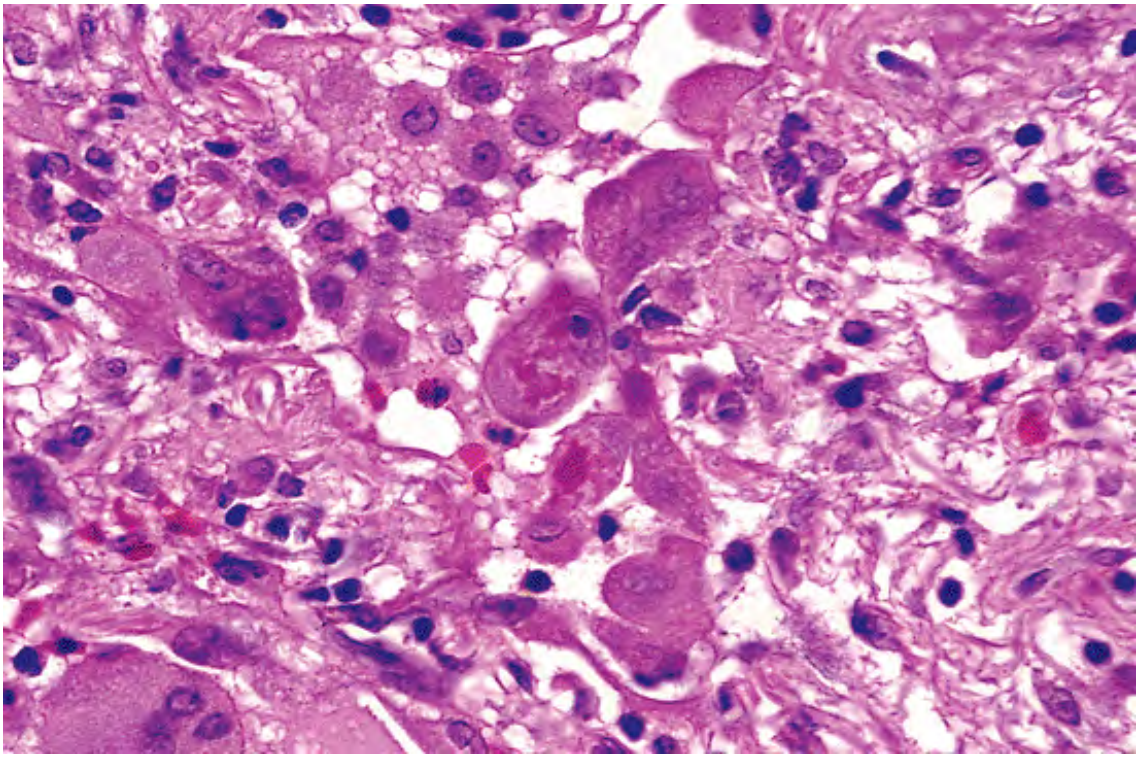

Figure 18.35 Hyalin. Material resembling Mallory's hyalin may be seen in reactive type II cells in a number of acute and chronic conditions.

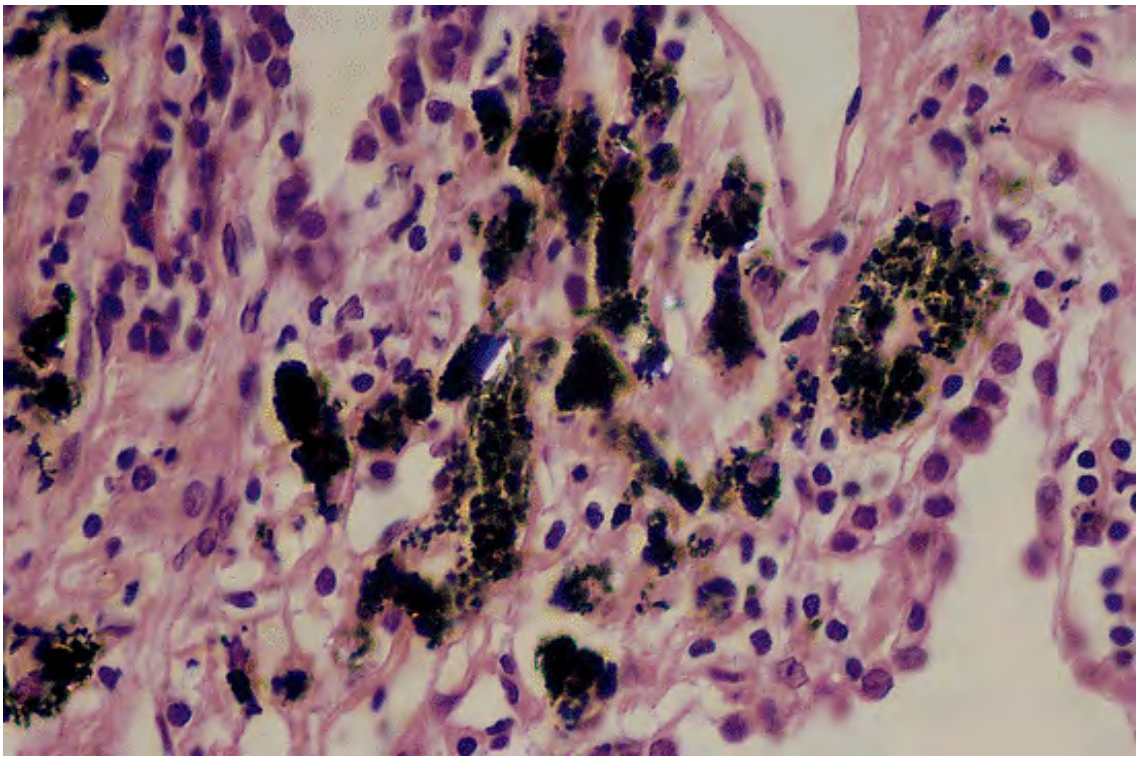

Figure 18.36 Silica and silicates in normal lung. Birefringent silica and silicate particles are a common nonspecific finding in and around the anthracotic pigment that is so commonly seen in urban adults and smokers.

An occasional nonnecrotizing epithelioid granuloma may be found in the lungs of patients who have no evidence of granulomatous disease; they are analogous to the occasional granuloma seen at many sites in the body. Likewise, cholesterol granulomas or single giant cells containing cholesterol clefts may also be an occasional incidental finding (Figure 18.37). In some instances, the presence of cholesterol granulomas has been linked to prior alveolar hemorrhage, mucostasis, or pulmonary hypertension (83), but usually no significance can be ascribed to them. Lipogranulomas are an occasional nonspecific finding, said to be more common in diabetics (84).

An interesting finding is the presence of scattered megakaryocytes in alveolar walls (Figure 18.38), predominantly within alveolar

capillaries. Large numbers can be seen, particularly during sepsis. They are of no diagnostic significance but should not be overinterpreted as malignant or virally infected cells. Along with the bone marrow and spleen, the lung acts as a major reservoir for megakaryocytes.

Bone marrow emboli, common in autopsy material, are also seen in biopsy specimens (Figure 18.39). Rarely correlated with any clinically significant process, they may be a consequence of bony trauma or excision of ribs. In some cases, however, such as thoracoscopic biopsies, bony

trauma cannot be implicated, and the marrow emboli are an unexplained incidental finding.

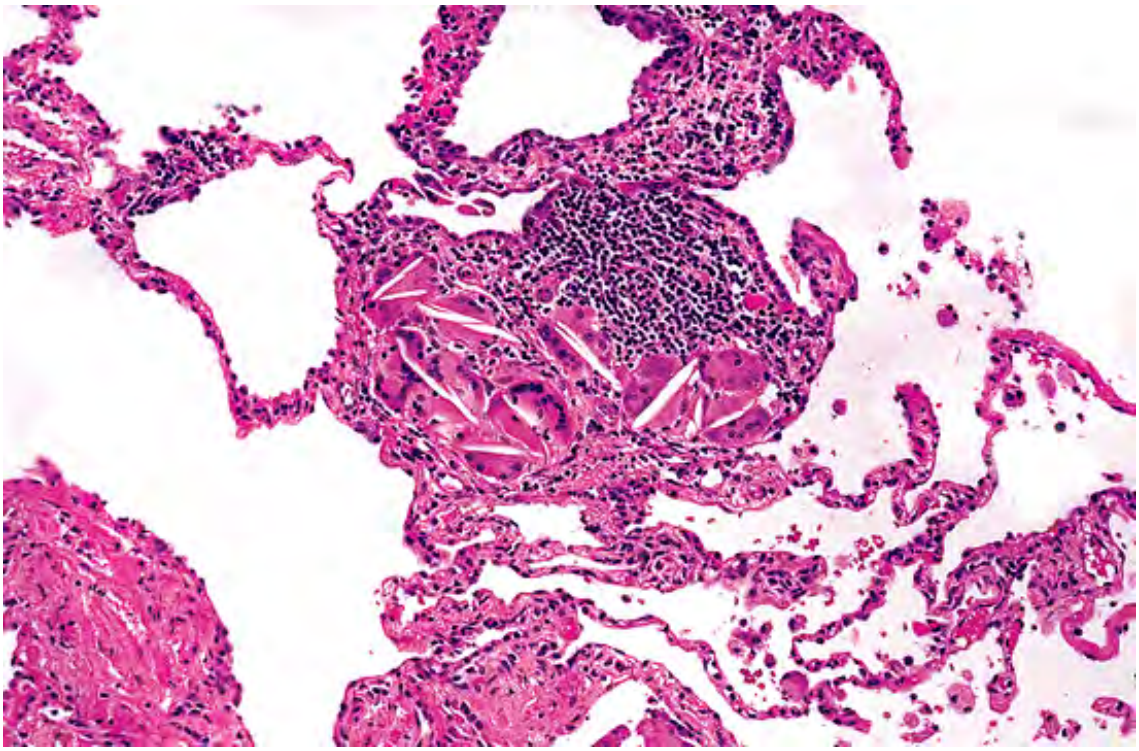

Figure 18.37 Cholesterol granulomas. Granulomas and clusters of giant cells containing cholesterol clefts are a frequent nonspecific finding in interstitial lung disease.

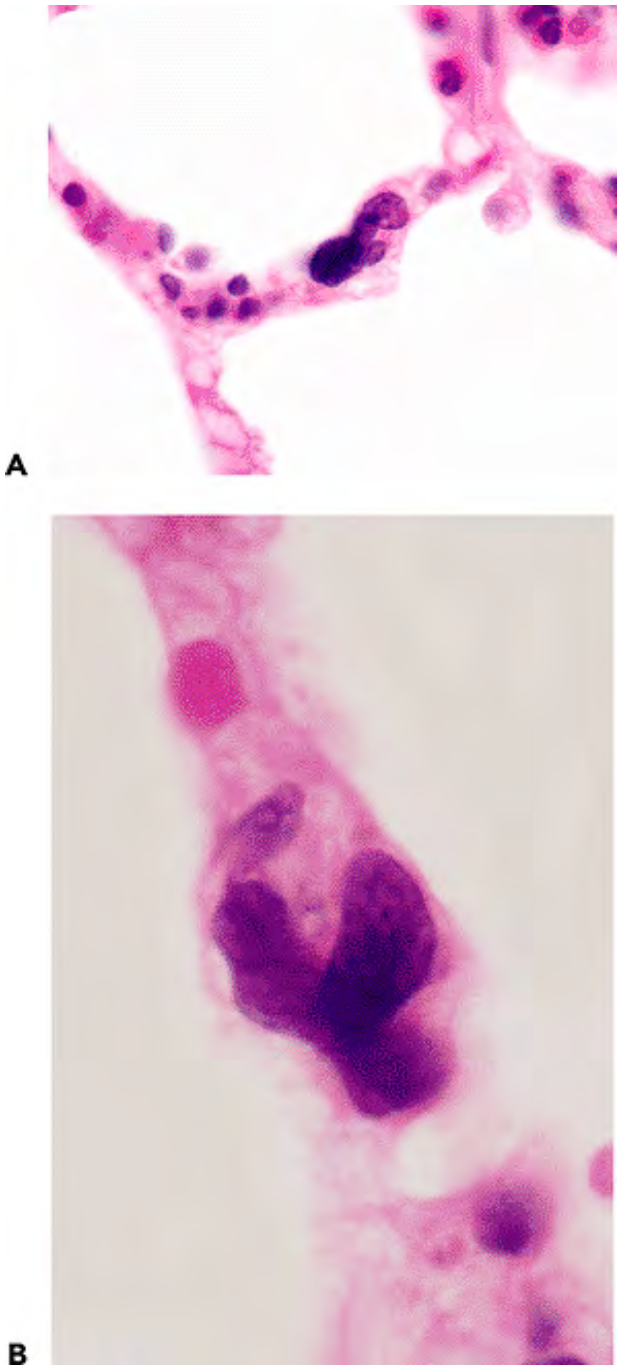

Figure 18.38 Megakaryocytes. A. and B. Megakaryocytes are a common finding in normal lung, often present within alveolar capillaries.

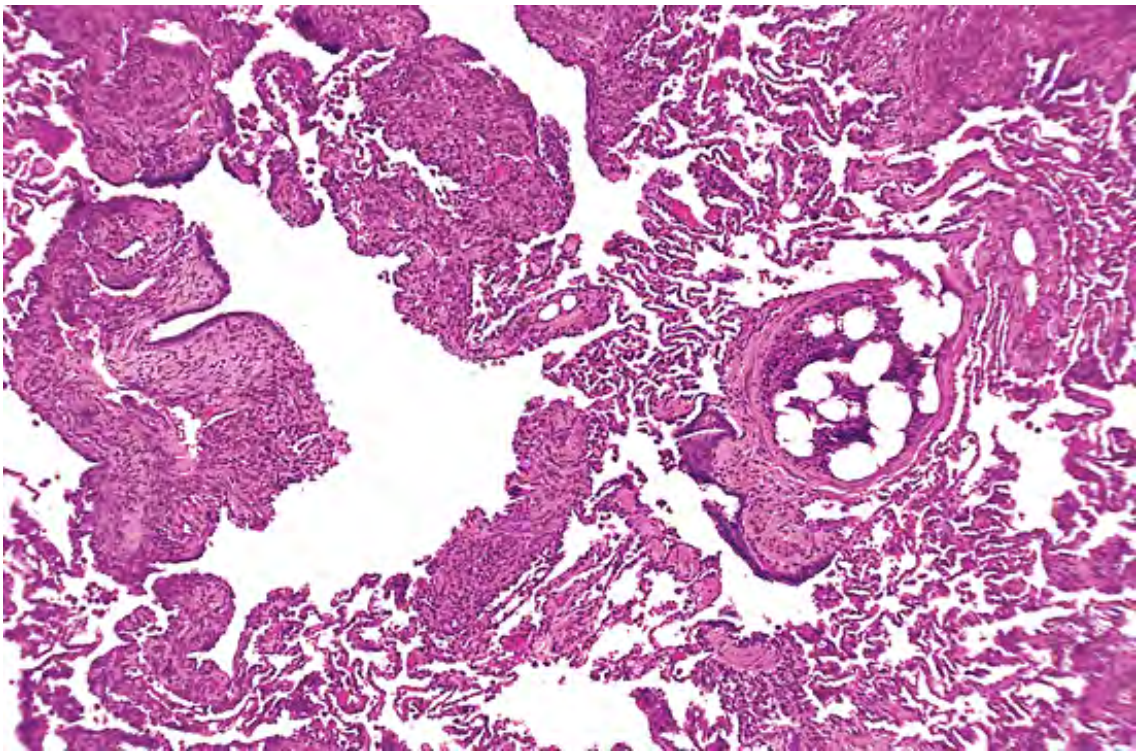

Figure 18.39 Bone marrow embolus. An incidental bone marrow embolus (*right center*) identified in a pulmonary artery in a biopsy from a patient with lymphangioleiomyomatosis (*left*).

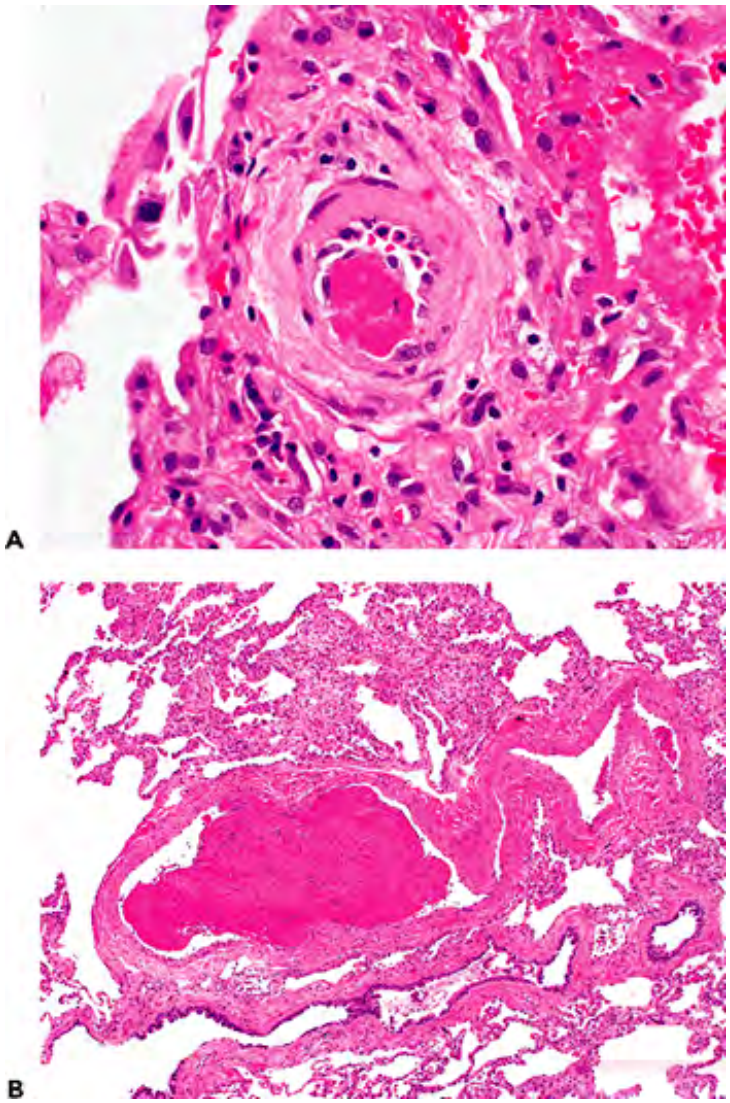

Figure 18.40 Thromboemboli in acute lung injury. Small (A) or even somewhat large (B) fibrin thrombi are commonly present in biopsies showing extensive acute lung injury (A, B). Hyalin membranes are apparent adjacent to the artery in A, and organization is apparent at the top of the field in B.

Recent intravascular thrombi (probably formed in situ) are a relatively common accompanying finding in any severe acute inflammatory lung disease (Figure 18.40), and they should not be considered evidence of pulmonary emboli without corroborating clinical information.

In patients with chronic hemorrhagic, chronic pulmonary congestion, or metabolic abnormalities, calcification and iron encrustation of the pulmonary elastic tissue may occur and even elicit a giant cell reaction (Figure 18.41). This phenomenon has been inappropriately labeled endogenous pneumoconiosis (85).

Intravascular foreign material is usually birefringent and may have a giant cell reaction. While it usually occurs in intravenous drug abuse (IV talcosis), occasional fragments of

foreign material are seen in patients without a history of drug abuse, perhaps related to intravenous lines during hospitalization or surgery.

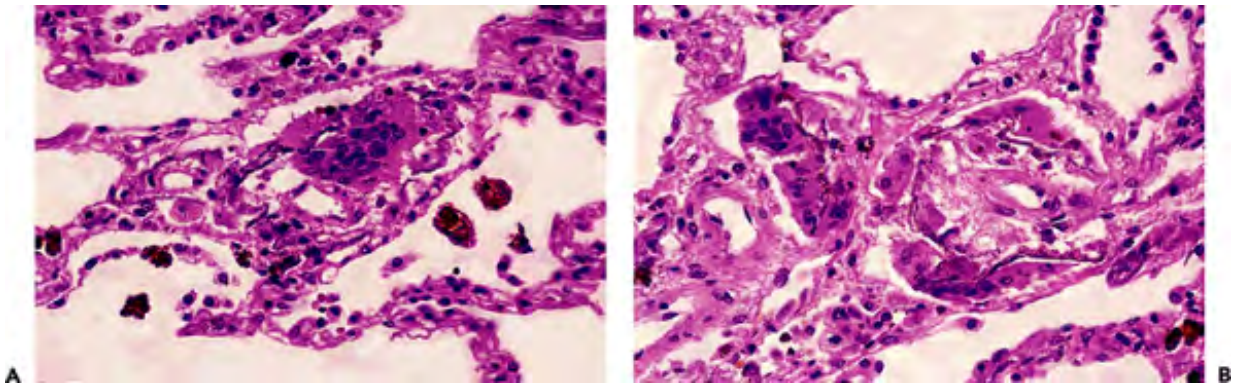

Figure 18.41 Iron deposition on elastic tissue (A, B). Chronic hemorrhage, in this case due to severe chronic passive congestion, may result in encrustation of interstitial and vascular elastic fibers by hemosiderin. A giant cell reaction is a frequent accompanying finding (A).

The finding of interstitial air, either localized or diffuse, is well known to pediatric lung pathologists and may be an incidental finding in adults who have been on ventilators. Interstitial air can occur as an incidental finding in a region of subpleural fibrosis but also be a significant pathologic finding in its own right (86) (Figure 18.42). The abnormal air-filled spaces resemble honeycombing; however, they lack the expected metaplastic

epithelial lining and careful inspection shows either a complete lack of a cellular lining or a histiocytic and giant cell reaction lining the spaces. Interstitial air presenting in this way may be encountered in patients with interstitial lung disease, in patients with a history of pneumothorax, and in and around bullae and blebs. As in ventilated children, interstitial air may be encountered in adults on assisted ventilation and sometimes may be completely missed, being interpreted as tissue tearing.

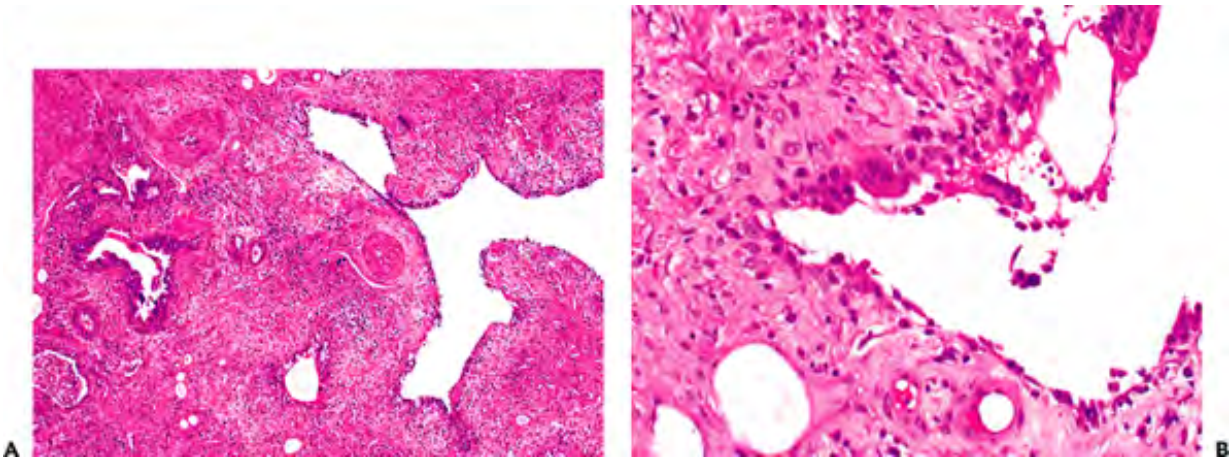

Figure 18.42 Incidental interstitial air. Peculiarly shaped airspaces (A) lined by giant cells (B) represent interstitial air, which is an occasional incidental finding in patients with interstitial lung disease, including those who have been on positive-pressure ventilation. The case illustrated in A represents an example of nonspecific interstitial pneumonia.

Hilar and peribronchial lymph nodes are rarely carefully examined beyond the evaluation for metastatic carcinoma. Nevertheless, they frequently exhibit a number of characteristic changes. Clusters of dust-filled macrophages in the sinuses and paracortical areas may resemble small granulomas (Figure 18.43). Silicotic or anthracosilicotic nodules, old healed infectious granulomas, and sinus histiocytosis are also common. When sarcoidosis is a consideration, one may have difficulty distinguishing the normal histiocytosis of hilar nodes from the granulomas of sarcoidosis.

Generally, this problem can be approached by maintaining a high threshold for granulomas, requiring well-formed, rounded granulomatous masses (particularly with accumulations of

intergranulomatous fibrinoid or hyalinized material), giant cells, and careful clinicopathologic correlation.

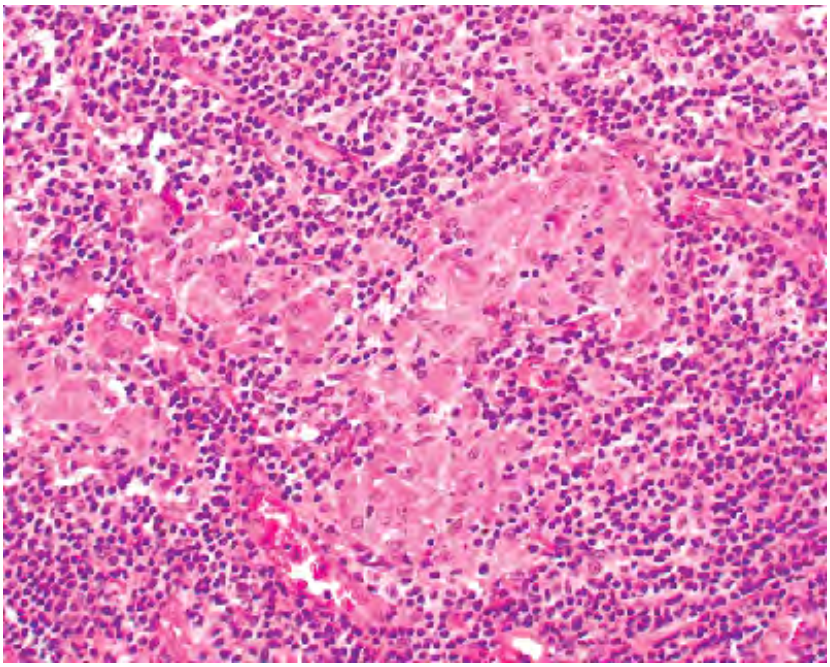

Figure 18.43 Histiocyte clusters in hilar nodes. Normal hilar and mediastinal lymph nodes commonly have clusters of histiocytes with variable amounts of dust particles in them. Sometimes they may appear somewhat granulomatous and may be difficult to distinguish from a true granulomatous reaction.

Although multiple intraparenchymal silicotic nodules should make one suspect the possibility of silicosis, anthracosilicotic nodules in hilar nodes are quite common in the absence of silicosis. The nodules are composed of concentric whorled and layered hyalinized collagen and are usually surrounded by a nonpalisaded rim of dust-filled macrophages that contain birefringent material when examined with polarized light. Central degenerative changes

may be evident. Silicotic nodules should be distinguished from old/healed granulomatous disease.

Hamazaki-Wesenberg bodies (87) are small (average: 5 Âµm in length), yellow-brown intracellular or extracellular structures associated with sinus histiocytes in lymph nodes, especially lung hilar nodes (Figure 18.44). The cause of these bodies is unknown, but they resemble lipofuscin. Positive staining with methenamine silver and PAS stains may lead to their confusion with yeast forms, but their H&E appearance, lack of associated necrosis or inflammation, and positive reaction with Fontana-Masson stain should facilitate their recognition and distinction from fungi.

Changes in the pleura in wedge biopsies may be incidental or part of the underlying pathologic process, and their significance needs to be assessed on an individual case basis.

Incidental Findings in Transbronchial Biopsies

The major artifacts or incidental findings in transbronchial biopsies that lead to misinterpretation include atelectasis (misinterpreted as interstitial pneumonia), bubble artifact (misinterpreted as lipoid pneumonia), and portions of the pleura (either entirely missed or misinterpreted as neoplastic or suspicious for being neoplastic) (54 ,55). Such portions of pleura may even include some pleural fat, a particularly common finding in fibrosing interstitial pneumonias. The finding of pleural tissue in transbronchial biopsies (Figure 18.45) is not uncommon but also is not well recognized among most pathologists. Strips of reactive mesothelial cells in such specimens may be confused with carcinoma.

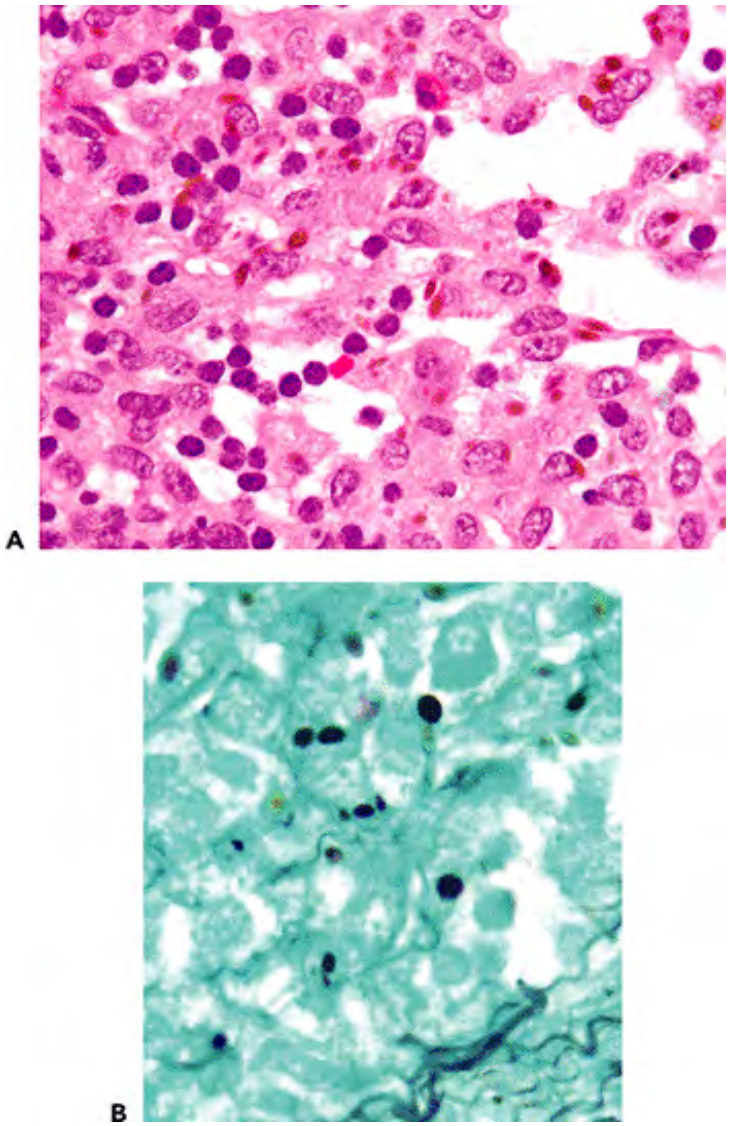

Figure 18.44 Hamazaki-Wesenberg bodies. A. Hamazaki-Wesenberg bodies represent yellow-brown oval structures associated with histiocytes, occasionally encountered in hilar and mediastinal lymph nodes. B. Their positive staining with silver stains sometimes leads to confusion with fungi.

As in wedge biopsies, the most common cause of red blood cells in airspaces in transbronchial biopsies is trauma related to the procedure of the biopsy rather than an alveolar hemorrhage syndrome.

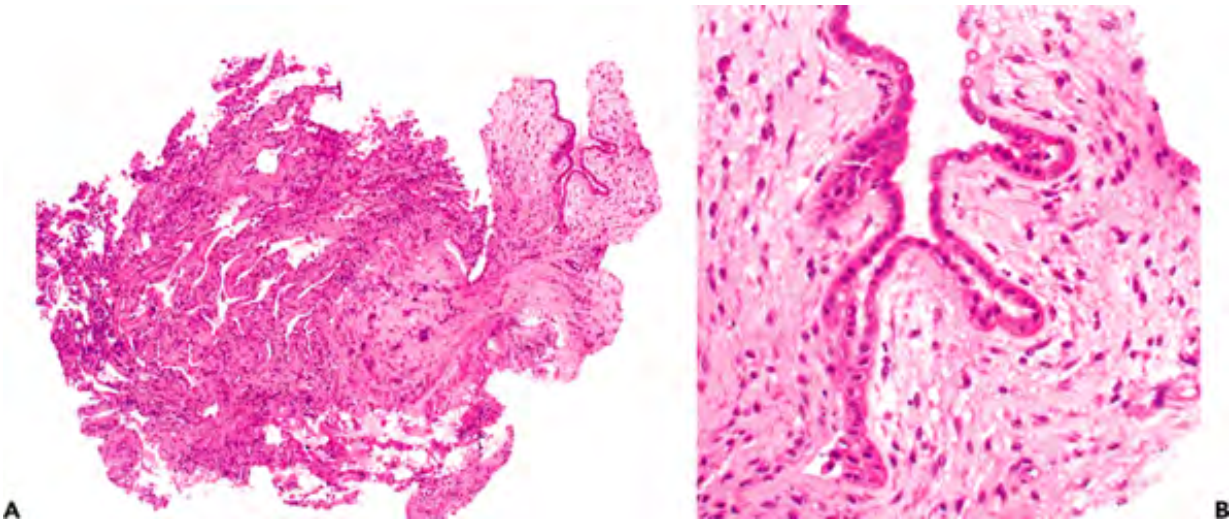

Figure 18.45 Visceral pleura in transbronchial biopsies. Transbronchial biopsies directed toward the periphery of the lung may not uncommonly sample portions of the visceral pleura (A , *right* ; and B). These may lead to misdiagnosis, particularly if there is an associated reactive pleuritis.

Effects of Aging

Some of the effects of aging on the lung are shown in Table 18.9 . Calcification and ossification of cartilages in the large airways may be seen. Intimal thickening is an age-related change in pulmonary arteries and veins (Figure 18.46), and apical pulmonary arteries are affected more often (2). Intimal thickening of veins is often hyalin and sclerotic in character, and should be distinguished from the more cellular intimal and muscular proliferation seen in pulmonary veno-occlusive disease and chronic passive congestion. Mural hyalinization of small arterioles is also an aging change (as well as being common in emphysematous lungs). Some degree of alveolar enlargement accompanies aging (88) and is called senile emphysema. Longitudinal elastic tissue fibers are a normal finding immediately beneath the surface epithelium in the large airways.

These may take on an elastotic appearance in the lungs of older individuals. Senile amyloid is usually an incidental finding, is perivascular, and increases in incidence with age (89).

- Tracheobronchial cartilage ossification, submucosal fatty metaplasia, oncocytic metaplasia and/or hyperplasia in bronchial glands, and elastotic appearance of the submucosa
- Pulmonary arterial and venous intimal thickening and hyalinization of arterioles
- Alveolar enlargement (rarely appreciated in biopsy material)
- Medial calcification in bronchial arteries
- Senile vascular amyloidosis
- Anthracosis (urban dwellers)

Table 18.9 Effects of Aging seen in Lung Biopsies

The Biopsy that Looks Normal at First Glance

When a lung biopsy for presumed diffuse lung disease initially appears normal, a number of possibilities should be considered (Table 18.10), especially pulmonary edema (Figure 18.47).

Although one can argue that interstitial infiltrates that are so subtle as to be overlooked are probably not clinically significant, their recognition is necessary. This situation can arise, for example, with biopsy material from the less severely affected portions of lungs in patients with interstitial pneumonias, in cases in which the inflammatory infiltrate has

been suppressed by steroids or immunosuppressive therapy, and in pathologic entities characterized by patchy inflammation. The presence of inflammatory cells in the perivenular regions and

alveolar wall with reactive type II cells is usually indicative of an interstitial pneumonia.

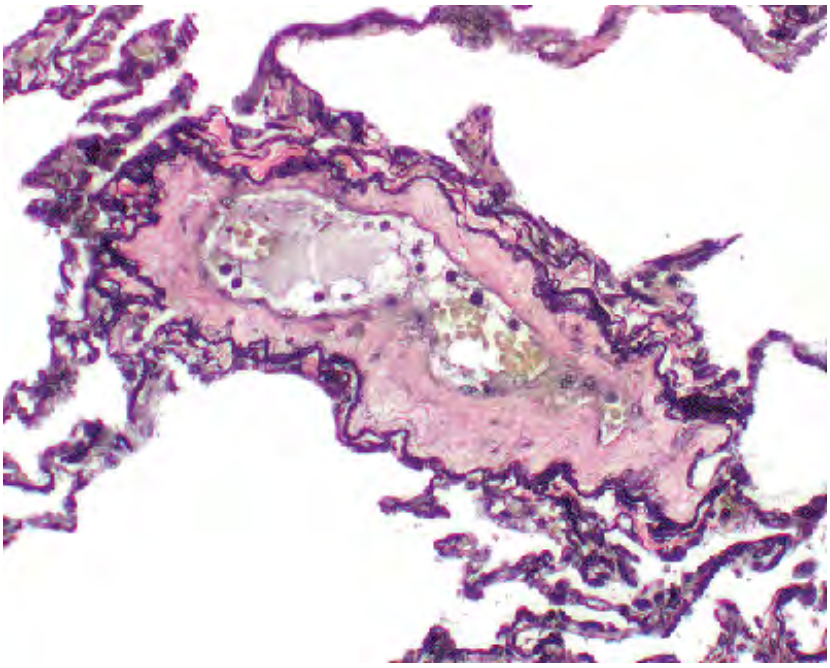

Figure 18.46 Aging change in vessels. In elderly individuals, a hyalin thickening of the intima may be encountered as an incidental finding. Clinical correlation is suggested, since this feature may also be encountered in the setting of pulmonary hypertension.

- Sampling error
- Pulmonary vascular disease
- Small airway (bronchiolar) disease
- Pulmonary edema and early diffuse alveolar damage
- Emboli, including fat emboli
- A very subtle interstitial infiltrate
- Cardiac disease with secondary pulmonary abnormalities

Table 18.10 Situations in Which a Lung Biopsy May Appear Normal

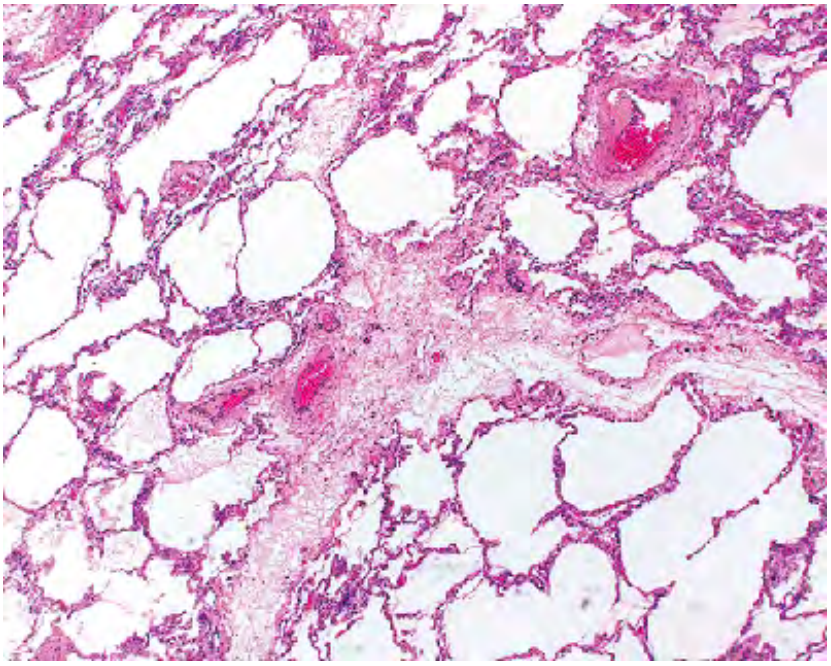

Figure 18.47 Pulmonary edema. Pulmonary edema may produce a deceptively normal appearance in a biopsy. Attention to septal widening, as noted in the accompanying text, and faint flocculent material in airspaces may be a clue to the diagnosis.

Thymus

Saul Suster
Juan Rosai

Introduction

The thymus is a prototypical lymphoepithelial organ. As such, it is composed of intimately admixed epithelial and lymphoid elements that act in concert to perform their assigned roles. In addition, the thymus harbors other cellular constituents, such as a variety of mesenchymal-derived elements, scattered neuroendocrine cells, and presumably germ cells, all of which may take part in the development of neoplastic and nonneoplastic processes of this organ. Although much progress has been made in the immunohistochemical characterization of the cellular components of the thymus, the diagnosis of thymic lesions still remains largely dependent on the light microscopic interpretation of the findings by the pathologist.

Embryology

The thymus is derived from the third and, to a lesser extent, the fourth pharyngeal pouches, which contain elements derived from all three germinal layers. During the sixth week of gestation, the

endodermal lining of the ventral wing of the third pharyngeal pouch forms a pronounced sacculation, which subsequently detaches from the pharyngeal wall, giving rise to the thymic primordia (1 ,2). It is postulated that, at approximately the same time, the cervical sinus (an ectodermal structure that results from the fusion of the second, third, and fourth branchial clefts) attaches to the thymic primordia, investing them with a layer of ectodermal cells (1 ,3). As development continues, the thymic primordia migrate in a caudal and medial direction along with the lower parathyroid glands. During the eighth week, these primordia enlarge toward their lower ends, forming two epithelial bars that fuse along the midline to occupy their definitive position within the anterosuperior mediastinum. During this descent, the tail portion of the organ becomes thin and elongated and breaks up into small fragments that usually disappear but that may persist in the soft tissues of the neck, often in intimate connection with the lower parathyroid gland and sometimes embedded within the thyroid gland (see section on Developmental Abnormalities) (1 ,4).

After migration has been completed, the thymic endodermal-derived epithelial cells develop into stellate elements, forming a reticular meshwork. The surrounding mesenchymal elements form a capsule around it; and, as a result of ingrowth of the capsule, trabeculae form that divide the organ into numerous lobules. By the tenth week, small lymphoid cells originating in the fetal liver and bone marrow populate the thymus, and the organ differentiates into a cortex and a medulla (5). Small, tubular structures composed of epithelial cells (sometimes referred to as medullary duct epithelium) also make their appearance at this time and later give rise to Hassall's corpuscles (6). The thymus progressively enlarges until puberty and from then on begins to involute, although persisting in an atrophic state into old age.

Developmental Abnormalities

Disturbances in the embryologic development of the thymus may give rise to a series of congenital anomalies. One of the anomalies most frequently encountered is the presence of parathyroid gland tissue within the thymus (7) (Figure 19.1). Such ectopically located tissue is most frequently encountered within the thymic capsule or in close proximity to it (8). This abnormality is easily explained by the close developmental relationship that exists between the two organs, as described in the section on embryology . The thymus itself also may be found in ectopic locations; this usually results from failure of the organ to migrate to its final destination during embryonic development. Undescended thymuses most often are located in the lateral neck, in close association with or even buried within the parathyroid or thyroid glands (9). These rests have a tendency to undergo cystic changes (9). They also may give rise to thymomas, ectopic examples of which have been described in submandibular (10), paratracheal (11 ,12), and intratracheal locations (13), as well as within the thyroid gland (14 ,15). A morphologically distinctive lesion of the thymus displaying combined features of neoplasia and hamartoma occurring in the lower neck has also been recognized (16). Ectopic nodules composed of thymic tissue have been reported in several other locations, including the base of the skull (17) and the pulmonary hilus at the root of the bronchus (18).

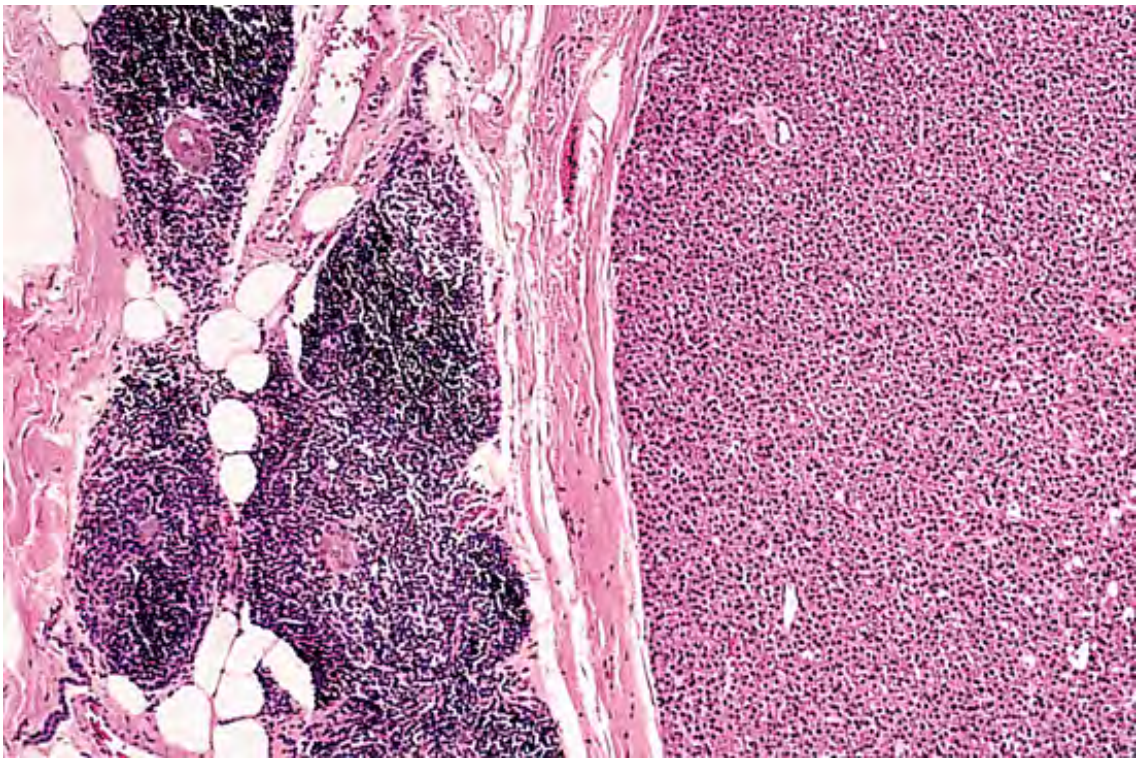

Figure 19.1 Ectopic parathyroid tissue adjacent to normal thymus.

Ectopic sebaceous glands have been reported in the thymus (19) and are felt to be related to the contribution of the ectodermally derived cervical sinus to the developing thymus. Mature-appearing salivary gland tissue also may be present in the thymus (Figure 19.2) and has been reported as a component of an intrathoracic cyst that contained normal thymus and parathyroid tissue within its walls (20). It was postulated that this finding could be related to a developmental malformation whereby salivary gland anlagen had been incorporated into the uppermost portion of the third pharyngeal pouch during embryogenesis.

Morphologic abnormalities of the thymus characterized by an embryonal appearance, with a predominance of small spindle epithelial cells adopting a lobular configuration and lacking small lymphocytes and Hassall's corpuscles, have been observed in association with combined immunodeficiency syndromes and T-cell

defects (21). Such morphologic alterations have been termed thymic dysplasias and are believed to represent disturbances of normal development. In conditions such as reticular dysgenesis, Swiss-type hypogammaglobulinemia, thymic alymphoplasia, and ataxia-telangiectasia, the immune deficit is accompanied by aplasia or hypoplasia of the thymus (22 ,23 ,24). In DiGeorge syndrome, which is believed to result from an arrest in development of the third and possibly fourth branchial arches, there is a vestigial but normal thymus associated with absence or hypoplasia of the parathyroid glands (25). In Nezelof syndrome (26), the thymic abnormality is similar to that of DiGeorge syndrome except that the parathyroids are normal. The failure of development is thus thought to involve only that part of the branchial endoderm that will

differentiate into thymic epithelium. Histologic changes in the thymus similar to those of thymic dysplasia of primary immunodeficiency disease have been observed in infants as a consequence of graft-versus-host disease after blood transfusions (27). A case of congenital aplasia of the parathyroid glands and thymus in the newborn also has been described (28). The term *thymic dysplasia* in the setting of immunodeficiency conditions may be misleading because of its currently accepted connotation as a preneoplastic cellular status. The alterations in such conditions are unrelated to a neoplastic etiology.

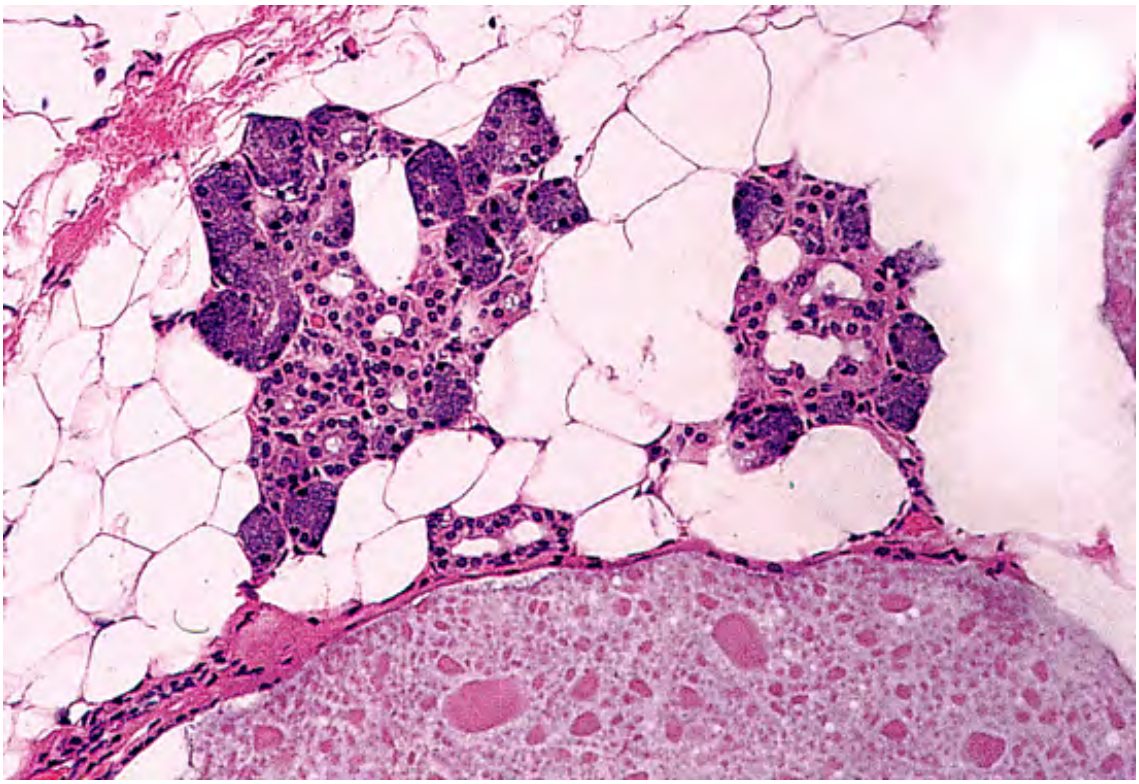

Figure 19.2 Mature-appearing salivary gland acini are seen adjacent to cystically dilated Hassall's corpuscle.

Apoptosis

Apoptosis is the name that has been given to the process of physiologic (programmed) cell death. Most thymic lymphocytes die in situ by such a process. During T-cell ontogeny in the thymus, the T cells (T lymphocytes) may undergo a process of positive or negative selection. The accumulated evidence appears to support that apoptosis plays a major role in the process of negative selection and that the vast majority of cortical thymocytes die by this mechanism. Autoreactive thymocytes or harmful cells in the thymus with injured DNA or alterations of their metabolism are also thought to be eliminated by the process of apoptosis at a specific stage of their differentiation (29 ,30). Therefore, it is believed that disturbances of the apoptotic process within the

thymus can be responsible for the appearance of autoreactive cells in the circulation that may give rise to the development of autoimmune disease. In addition, failure of apoptosis also may play a role in carcinogenesis. On the other hand, massive induction of apoptosis within the thymus may lead to immunodeficiency as a result of a decrease in the number of lymphocytes. Thus, thymocyte apoptosis plays an integral role in the pathophysiology of the immune system.

The exact biochemical mechanism involved in thymocyte apoptosis has not yet been completely elucidated; however, it is known that various complex physiologic and nonphysiologic mechanisms can induce it (31). This has led many investigators to seek the genes and their products that are necessary for apoptosis. Several groups have noted that messenger RNA (mRNA) levels for various proteins are increased early in thymocytes after treatment with glucocorticoids or radiation, two agents known to induce massive apoptosis of cortical thymocytes (32 ,33). A number of genes also have been identified whose expression is increased in cells undergoing apoptosis. Among them, three proto-oncogene products have been shown to act as important regulators of the apoptotic process in mammals: c-myc, bcl-2, and p53. In thymocytes, bcl-2 mRNA is present in the surviving mature thymocytes of the medulla and also in most immature ($CD4^+$ /$CD8^+$) thymocytes, although the majority of cortical thymocytes (most of which die by apoptosis) display no bcl-2, suggesting that this oncogene may be involved in the preservation of T cells (34). Alterations of the *p53* gene also have been shown to play a role in the process of thymocyte apoptosis. Malfunction of the tumor suppressor gene *p53* may promote carcinogenesis by permitting mutated cells to duplicate their DNA before it is repaired. In mice, *p53* -deficient thymocytes have been shown to display drastic resistance to the apoptotic effects of radiation (35). The latter observation suggests that the integrity of the *p53* gene, whose product is known to arrest cell proliferation, may be necessary for

the normal apoptotic process in the thymus.

Another pathway of thymocyte apoptosis that has been the object of close scrutiny is the role of the T-cell receptor (TCR)/CD3 complex in this process. During thymocyte development, rearrangement of TCR genes leads to expression of unique, clonally expressed TCRs. Potentially autoreactive thymocytes bearing TCRs with high avidity for self undergo TCR-mediated, activation-induced apoptosis (negative selection), whereas thymocytes with TCRs of low avidity survive (positive selection) (36 ,37). Recent experiments have demonstrated that the activation of the TCR/CD3 complex leads to the preferential elimination of immature ($CD4^+$ /$CD8^+$) thymocytes (38). These and other studies have demonstrated that TCR-mediated signals are involved in apoptosis, and this phenomenon is strongly related to the mechanism of negative selection, although the precise in situ mechanism of apoptosis has not yet been elucidated (39 ,40).

Anatomy

The fully mature human thymus is an encapsulated midline structure predominantly located in the anterosuperior mediastinum and composed of two lobules joined in the midline by loose connective tissue and thymic parenchyma. The base of the organ lies on the pericardium and great vessels. The upper poles of each lobe extend into the lower neck and are closely applied to the trachea. The lower poles extend down over the pericardium for a variable distance, generally up to the level of the fourth costal cartilage. The anterior border of the gland is made up by the cervical fascia, strap muscles of the neck, sternum, costal cartilages, and intercostal muscles, and the lateral borders are covered by reflections of the parietal pleura.

The size and weight of the gland may vary considerably depending on the age of the person, although wide variations among individuals in the same age group have been observed (41). The

mean weight at birth is about 20 g. The organ exhibits a continuous growth in size until puberty, when it reaches a mean weight of approximately 35 to 50 g; thereafter, it undergoes atrophy, as manifested by a decrease in weight and volume and progressive fatty replacement of the parenchyma.

The blood supply of the organ is derived from the internal mammary, superior and inferior thyroid arteries, and,

to a lesser degree, the pericardiophrenic arteries. The arterial branches course along fibrous septa to the region near the corticomedullary junction, where they branch into the cortex and the medulla. The capillaries descend from the outer cortex toward the medulla to form postcapillary venules, and they exit the thymus through the septa as interlobular veins. The venous system drains into the left brachiocephalic, internal thoracic, and inferior thyroid veins. There are no true thymic intraparenchymatous afferent lymphatics. Lymph vessels arise in the interstitium of the lobular septa and merge to form large lymph vessels that course alongside the arteries in the septa. The innervation of the organ is derived from branches of the vagus nerve and the cervical sympathetic nerves.

Histology

The basic structural unit of the thymus is the lobule. Each lobule is composed of two morphologically distinctive areas, the cortex and the medulla, both of which are largely composed of varying proportions of epithelial cells and thymic lymphocytes (thymocytes) (Figure 19.3). In the cortex, the sparse epithelial cells present are overshadowed by the numerous, closely packed small lymphocytes. The medulla, in contrast, contains a larger number of epithelial cells and fewer lymphocytes. The cortex and the medulla combined correspond to the thymic epithelial compartment, which is the site of T-cell maturation within this

organ. Another important anatomic compartment of the thymus is the perivascular space. In the mature infant thymus, the perivascular space represents a virtual space containing thymic blood vessels and corresponding to a portion of tissue that is contained within the capsule but outside of the thymic epithelial network (42). The perivascular space becomes more prominent with aging and in pathologic processes such as thymoma, and eventually it is replaced with fat and lymphocytes in the involuted thymus of the adult (43). In addition to the epithelial and perivascular space compartments, there is also a stromal compartment that harbors a variety of other cell types. A thin fibrous capsule is generally present surrounding the entire gland. The interplay of these various cellular elements and compartments contributes to define the various organotypical features of the normal thymus.

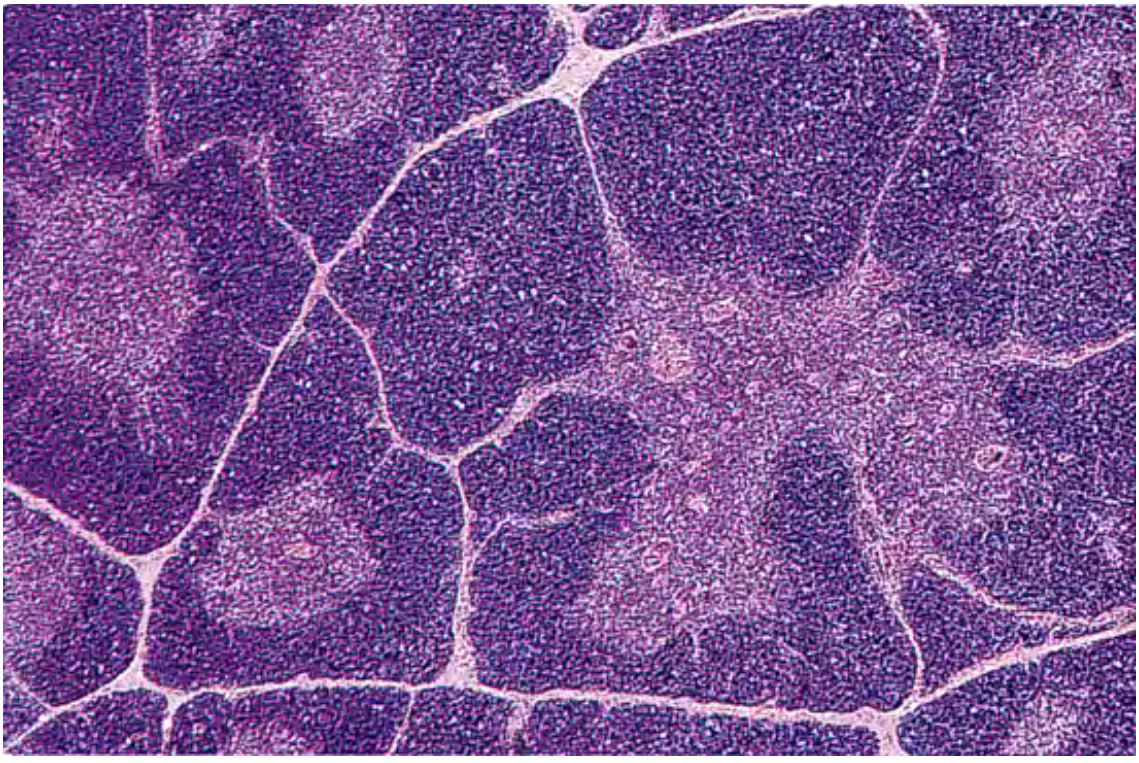

Figure 19.3 Normal lobular architecture of the thymus demonstrating clear separation between cortex and medulla.

One of the problems involved in defining the â€œnormalâ€• thymus is that the histologic appearance of the organ shows progressive changes over time, depending on its stage of maturation or involution. Thus, the â€œnormalâ€• thymus of the adult will look quite different from the â€œnormalâ€• thymus in a child or adolescent. Studies by Hale (43) have shown that the thymus gland does not actually decrease in size or alter its shape over time with the normal process of involution. While the overall size and shape of the gland is retained throughout adulthood into old age, the various cellular constituents are replaced as the normal process of functional involution takes place. Thus, in the thymus of the adult and old age, the normal thymopoietic elements represented by the epithelial compartment become reduced and progressively disappear, being gradually replaced by mature adipose tissue. Residual epithelial elements, however, always remain and generally undergo a process of atrophy that results in a change in the shape of the cells from large, round cells with vesicular nuclei and abundant cytoplasm to small, oval to spindle-shaped cells with hyperchromatic nuclei and scant cytoplasm (44). Small, microscopic, thymopoietic remnants of thymic epithelium can also be found, which usually retain the normal architecture and appearance of the mature cortex in childhood. Other involutional changes include the formation of cystic structures, usually resulting from dilatation of residual Hassall's corpuscles, and the formation of small, abortive glandular or epithelial rosette-like structures within the lymphopoietic islands.

The most distinctive organotypical features of the mature thymus of childhood and adolescence thus include a fibrous capsule, a lobular architecture with sharp separation between the cortex and the medulla, a dual cell population characterized by an admixture of large, round thymic epithelial cells with immature T-cells, and perivascular spaces. The organotypical features of the â€œnormalâ€• involuted thymus of the adult, on the other hand,

include the presence of small, spindle-shaped thymic epithelial cells, abundant cystic structures and rosette-like epithelial structures, and the paucity of immature T-cells. Needless to say, these features represent a continuum that will be manifested in various proportions depending on the age, functional status of the organ, various physiologic conditions, and disease states affecting the thymus.

Epithelial Cells

The epithelial cells of the thymus have traditionally been divided into cortical and medullary; some of the latter are arranged in round keratinized structures known as Hassall's

corpuscles. In the active thymus of infancy, most epithelial cells are plump, with round or oval nuclei. Their cytoplasm (particularly in the case of the cortical cells) is endowed with numerous prolongations that join with those of adjacent cells to form a veritable network or reticulum. This feature (rather than the relationship with reticulin fibers or presumptive embryologic origin) has led to the previous designation of reticuloepithelial cells. These various epithelial elements play an active role in promoting T-cell maturation in the thymus, either through the action of their humoral substances or through direct contact with thymocytes (45).

A subset of thymic epithelial cells that have predominantly localized to the cortex has been designated as nurse cells. They are characterized by having an abundant cytoplasm within which are engulfed numerous mature thymic T cells. A ringlike staining pattern has been observed in these cells with antiepithelial cell antibodies by immunohistochemistry on sections of human thymus (46). It has been postulated that nurse cells may provide a specialized microenvironment for T-cell maturation, differentiation, and selection in the thymus (46 ,47).

Hassall's Corpuscles

Hassall's corpuscles constitute the most readily identifiable feature of the thymus at the light microscopic level. They are restricted to the medulla and are characterized by a concentric pattern of keratinization, the keratin formed being of high-molecular weight (epidermal) type (Figure 19.4). These structures may show much variation in their morphologic appearance, mainly as a result of reactive changes secondary to inflammation. This includes cystic degeneration with accumulation of cellular debris, dystrophic calcification, and infiltration by lymphocytes, foamy macrophages, and eosinophils (Figure 19.5). The

thymic lesions known as Dubois's microabscesses and traditionally ascribed to congenital syphilis (48) represent an exaggeration of the cystic changes in Hassall's corpuscles as a result of infection. We believe that most so-called multilocular thymic cysts are not congenital abnormalities but rather the result of cystic enlargement of Hassall's corpuscles on the basis of acquired inflammatory changes in this organ (49). An additional change that can be seen in relation to cystic Hassall's corpuscles is the presence of glandular elements, as manifested by the appearance of columnar epithelium (sometimes ciliated- or of goblet-cell type) and the secretion of sulfated acid mucopolysaccharides in the lumen (50). It is likely that these glandular changes are related to the embryologic origin of Hassall's corpuscles (6).

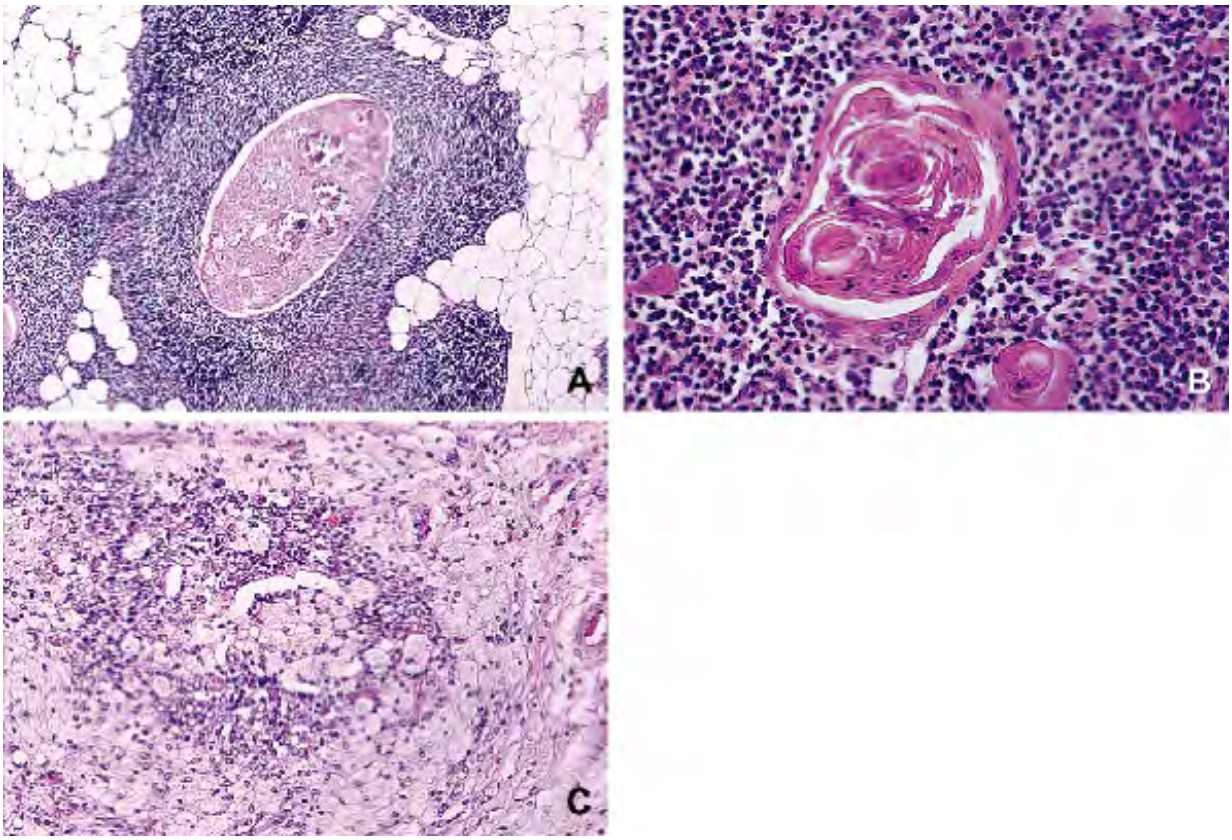

Figure 19.5 Hassall's corpuscles showing (A) cystic dilatation with accumulation of cellular debris, (B) dystrophic calcification, and (C) accumulation of foamy macrophages.

Thymic Lymphocytes (Thymocytes)

The predominant cell population of the thymic cortex is made up of lymphocytes that may be large, medium, or small. Large, mitotically active lymphoblasts comprise about 15% of the lymphoid cells and are found predominantly in the subcapsular portion of the outer cortex (51). These lymphocytes have a round or oval (occasionally convoluted) nucleus, one or two prominent nucleoli, and relatively abundant, strongly basophilic cytoplasm. A gradient of smaller, less mitotically active cells occurs from the outer cortex to the corticomedullary junction and to a lesser degree into the medulla of the normal thymus (Figure 19.6). In

the capsular region and deep cortex, the vast majority of thymic lymphocytes are short-lived and die in situ (52). This results in lympholysis and active phagocytosis, features that impart these areas with a prominent â€œstarry skyâ€• appearance and that become particularly prominent in accidental (stress) thymic involution (see section on Thymic Involution) (Figure 19.7).

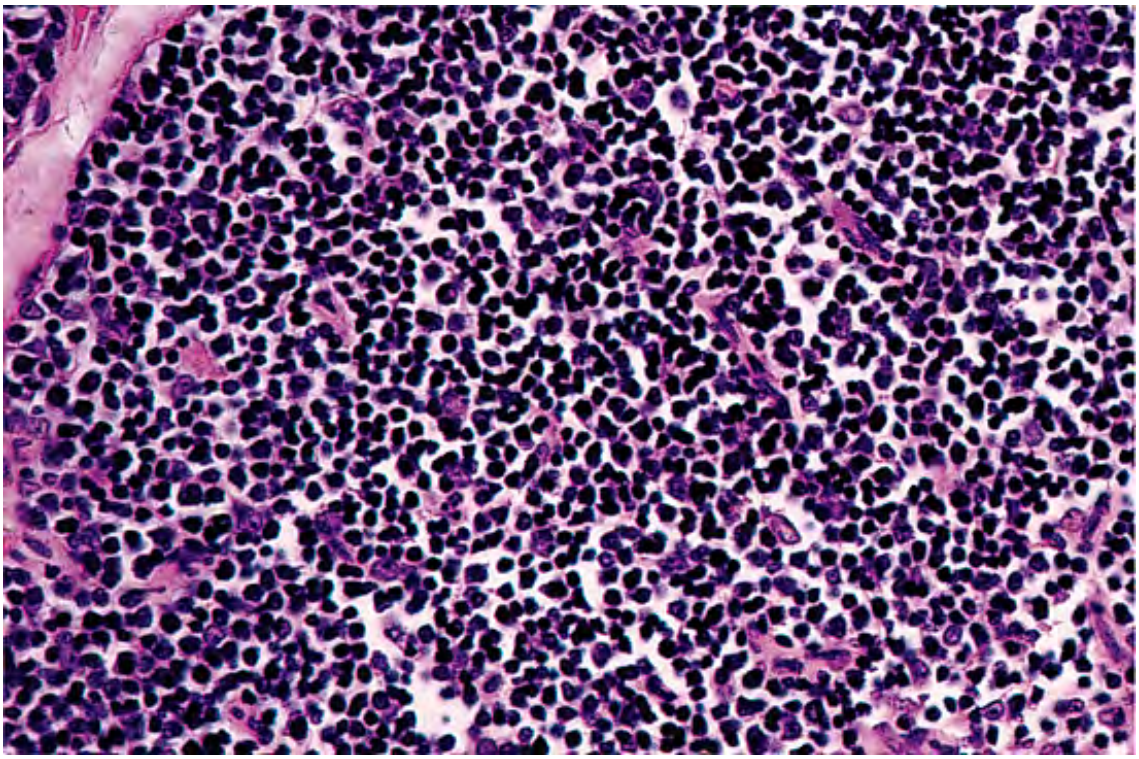

Figure 19.6 Normal thymic cortex. There are numerous cortical thymocytes, most of which have small nuclei with densely packed chromatin.

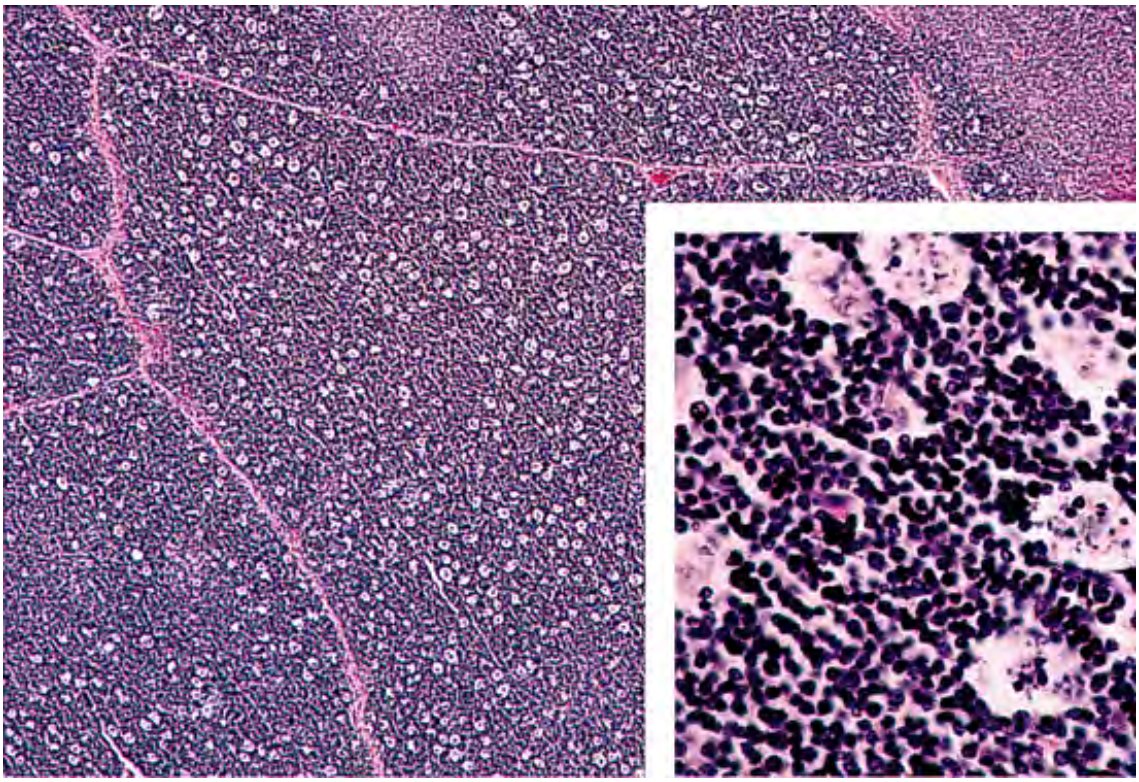

Figure 19.7 Prominent starry sky appearance in the deep cortex of patient with accidental thymic involution. Note abundance of tingible-body macrophages (*inset*).

Other Cell Types

In addition to epithelial cells and lymphocytes of T-cell lineage, the thymus contains an array of additional cell types. The first of these, B cells (B lymphocytes), can be found aggregated as lymphoid follicles or scattered as individual cells. Lymphoid follicles with active germinal centers may be found in otherwise normal thymuses, especially in children and adolescents (Figure 19.8) (52 ,53). The presence of such B-cell structures would seem difficult to reconcile with the fact that the thymus constitutes a predominantly T-cell organ. However, ultrastructural studies have indicated that germinal centers in the thymus arise within perivascular spaces, the latter being clearly separated from the thymic parenchyma by a basal lamina (54). This observation

led to the proposal that the thymus may be divided into two major functional compartments: (a) the cortex and medulla (which constitute the true thymic parenchyma) and (b) the

extraparenchymal compartment composed of the perivascular spaces (55). Germinal centers in the thymus could thus be explained as being derived from preexisting perivascular B cells in the extraparenchymal compartment. Germinal centers are well known to be prominent in patients with myasthenia gravis and other immune-mediated diseases (see section on Thymic Hyperplasia) (9), but their presence in an otherwise normal thymus should not necessarily be taken as an indicator of an underlying immune disorder. The incidence of germinal centers in the thymus of normal individuals without septicemia or disease of a presumed autoimmune cause has varied in published studies from 2.1% (53) to 40% (54). This wide variation may be related to a sampling factor or to the age of the patients; germinal centers would be expected to be less frequent in the older age groups. Also, stress has been shown to be a factor responsible for the decrease in the number of these structures (56). Determination of the incidence and number of germinal centers in normal human thymus glands still remains an unsettled issue.

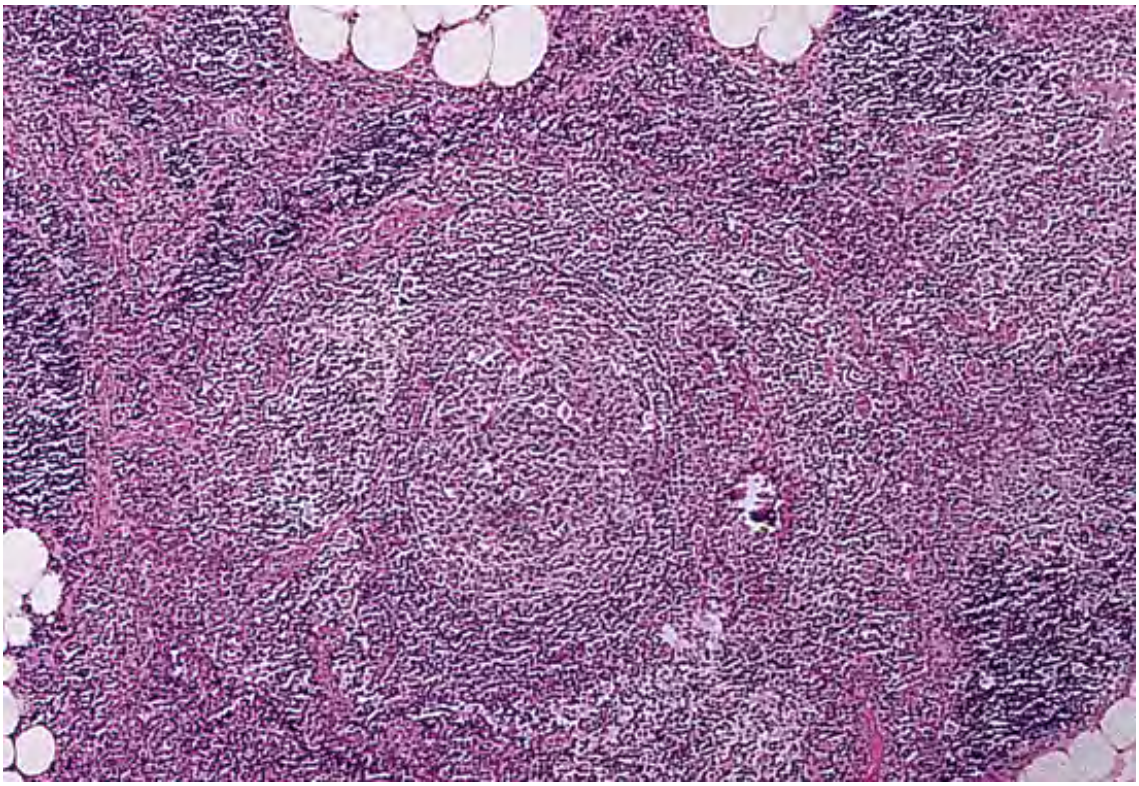

Figure 19.8 Lymphoid follicle with germinal center in normal thymus.

Isolated B cells are found in both fetal and normal adult thymuses distributed along the septa, in close proximity to small vessels at the corticomedullary junction and in the medulla (57). Intrathymic B cells have been found to be significantly increased in patients with myasthenia gravis, a finding that some investigators consider to be a more specific change for this disorder than the presence of germinal centers (57 ,58). More recently, a population of intramedullary B cells with a tendency to cluster around Hassall's corpuscles has been identified in the thymus gland from fetuses, newborn babies, children, and adults; these lymphocytes show evidence of activation and bear a distinctive immunophenotype (59). Unlike B cells of germinal centers and surrounding mantle zones, the medullary B cells are negative for CD21 and do not express surface/cytoplasmic immunoglobulins. It has been proposed that a significant proportion of non-Hodgkin's lymphomas

of the B-cell type located in the anterior mediastinum arise from this intrathymic B-cell population. Additionally, a newly described type of mucosa-associated lymphoid tissue (MALT) lymphoma composed of monocytoid B cells recently was identified as arising from the thymus (60); this finding raises the possibility that monocytoid B cells may be another as yet unidentified cellular constituent of the normal thymus (61).

Several other types of hematolymphoid cells are present in small number but constant fashion in the normal thymus (62 ,63 ,64). Macrophages are mainly located in the cortex, show phagocytic activity, are markedly Î±-naphthyl acetate esterase positive, acid phosphatase positive, and HLA-DR negative, and are antigenically indistinguishable from macrophages of other organs (45 ,64). Interdigitating dendritic cells are mainly located in the medulla, are markedly HLA-DR positive, have little lysosomal enzyme activity, and show S-100 protein reactivity (65). Both of these cell types are thought to be involved in lymphocyte and epithelial cell interaction.

Langerhans cells also have been identified in the thymic medulla; both interdigitating dendritic cells and Langerhans cells are said to be increased in the thymuses of patients with myasthenia gravis (66). The latter cells provide the anatomic substrate for the development of Langerhans cell granulomatosis (histiocytosis X) within the thymus (67). Eosinophils are usually present in the thymus of children, sometimes in large numbers (68). They appear in fetal life and persist until puberty, after which they become infrequent. They are found mainly in the connective tissue septa or within the medulla and occasionally may be present within Hassall's corpuscles.

Mast cells are also normally present in human thymuses. They are usually found within and scattered parallel to the connective tissue septa, often in a perivascular location. The presence of mast cells can be a source of confusion in the course of immunohistochemical

and other special stains of the thymus gland because of their propensity to react with a wide variety of reagents; they are easily identified by the use of metachromatic stains. Increased numbers of mast cells in the thymus have been observed in patients with severe combined immunodeficiency and thymic alymphoplasia (69), but the significance of this finding is not understood. Plasma cells are rare in the normal thymus; they are usually located in the connective tissue septa or, more rarely, in the medulla (70). Plasma cells may be numerous in the involuting thymus and also may be present in increased numbers in the thymus of patients with myasthenia gravis (71).

Neuroendocrine cells are now accepted as being a minor but constant component of the normal thymus (72). Peptide- and amine-producing neuroendocrine cells have been identified in the thymus glands of reptiles and birds (73,74,75) and, to a lesser degree, in mammalian (including human) thymuses. It has been postulated that some of these cells may be embryologically and functionally analogous to C cells of thyroid (76). The physiologic role of these various neuroendocrine elements in the thymus is not yet understood, but their presence has been offered as the probable substrate for the development of carcinoid tumors and other neuroendocrine neoplasms in this organ, including calcitonin-positive medullary carcinomas (77,78).

Myoid cells are located in the thymic medulla. They are common in reptilian and avian thymuses but also can be found (albeit with some difficulty) in human thymuses, particularly in infants. They have microscopic, immunohistochemical, and ultrastructural features of striated muscle cells (79,80). Their histogenesis remains a subject of debate, some studies pointing toward a derivation from the neural crest (81) and others showing the existence of shared epitopes with thymic epithelial cells (82). Myoid cells have been said to be increased in the thymus of patients with myasthenia gravis (57,83) and in patients with true thymic

hyperplasia (84), suggesting that these cells may play a role in immunoregulatory mechanisms. Thymic neoplasms thought to represent the neoplastic counterpart of myoid cells also have been described (85).

Germ cells are another cellular element thought to be normally present in the thymus. It has been proposed that scattered germ cells reach the thymus during ontogenesis and that some of them persist into adult life. However, direct evidence of their presence in the normal thymus gland has never been demonstrated, and the only presumptive evidence of their occurrence is the fact that nearly all mediastinal germ cell tumors arise within the thymus (9). Rosai et al. (86) have recently proposed that germ cells in the thymus may develop into somatic cells, thus making their detection and identification difficult by conventional means. They further hypothesized that thymic myoid cells may be of germ cell origin and thus provide indirect evidence for the existence of the latter in this organ (86).

Connective tissue elements of the thymus include vessels, fibrous tissue, nerves, and fat. The vasculature of the thymus arises from arteries that enter the organ via fibrous trabeculae from the capsule. In contrast to other major lymphoid organs, the thymus lacks a hilus. The thymic vessels are ensheathed by a layer of thymic epithelial cells. This anatomic configuration, plus the failure of the thymus to produce antibodies against circulating antigen, led to the concept of the blood-thymus barrier (87). Raviola and Karnovsky (88), in an elaborate study using electron-opaque tracers of different molecular dimensions, demonstrated convincingly that, although some bloodborne macromolecules do penetrate the thymus, their distribution was limited to the medulla, thus pointing to the existence of a blood-thymus barrier operating at the level of the cortex. However, more recent studies have challenged the concept of the blood-thymus barrier by showing that the thymic cortex also may be permeable to

immunoglobulin molecules present in the extravascular compartment (89).

)

The presence of a distinct anatomic compartment bound by the vessel wall and the sheath of epithelial cells has been postulated. It has further been suggested that it is through these perivascular spaces that the mature T-cells exit the thymus to colonize

peripheral lymphoid organs once their maturation process is complete. The spaces are inconspicuous in the normal thymus; they may appear dilated in atrophic and involuting organs, but they acquire their greatest prominence in some thymomas (9).

Ultrastructure

Ultrastructurally, very elongated cytoplasmic processes can be appreciated in the epithelial cells of the thymic cortex, which are also covered by basal lamina material (Figure 19.9) (90 ,91 ,92). Medullary epithelial cells are more densely packed and have blunted cytoplasmic projections (Figure 19.10). A consistent feature of medullary epithelial cells is the greater frequency of desmosomes and the presence of dense tonofilaments that often insert into desmosomes. This feature is particularly obvious in Hassall's corpuscles. Cortical epithelial cells may display a range of ultrastructural appearances depending on the electron density of their cytoplasm, including pale cells with electron-lucent cytoplasm, intermediate cells with variable electron density, and dark cells with electron-dense cytoplasm. The same range may be observed in medullary epithelial cells; in addition, the medulla contains undifferentiated epithelial cells with sparse cytoplasm (93).

Thymic myoid cells display ultrastructural features of skeletal muscle, including myofilaments with dense

patches (Figure 19.11). Some investigators have identified cells displaying both tonofilaments and myofilaments by electron microscopy, and in some instances myoid cells have been observed to display desmosomal connections with epithelial cells (94).

Immunohistochemistry

Thymic Epithelial Cells

Immunohistochemical studies have demonstrated that thymic epithelial cells may express a variety of distinctive differentiation

antigens. Currently, at least four antigenically distinctive types of epithelial cell are recognized in the normal thymus: subcapsular cortical, inner cortical, medullary, and the cells of Hassall's corpuscles (Table 19.1) (95 ,96 ,97 ,98). Inner cortical epithelium, in addition to exhibiting keratin positivity, strongly reacts with TE-3, a murine monoclonal antibody raised against human thymic stroma (99). Subcapsular cortical epithelial cells and medullary epithelial cells react strongly with TE-4 monoclonal antibody. Both of these cells also label with A2B5, a monoclonal antibody directed against a complex neuronal ganglioside found on the cell surface of neurons and neuroendocrine cells (100).

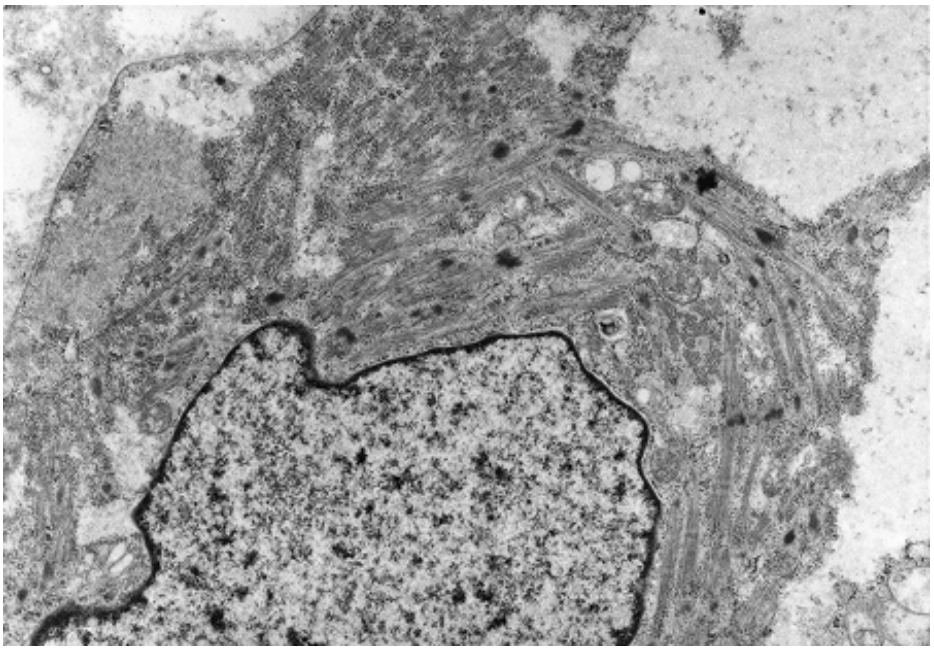

Figure 19.11 Ultrastructural appearance of myoid cell in the thymus. Note bundles of actin and myosin myofilaments with clearly discernible Z lines in the cytoplasm.

Another marker of subcapsular cortical epithelium and medullary epithelium in normal thymus is that detected

with anti-p19, an antibody that defines the structural core protein of the human T-cell lymphoma virus and that is believed to be

acquired during normal thymic ontogeny. In the normal human thymus, the antigen defined by anti-p19 is found to parallel the reactivity of A2B5 antibody in epithelial cells (101). Interestingly, a recent study on thymomas has demonstrated that the expression of the p19 antigen is lost with malignant transformation (102).

Table 19.1 Summary of Main Antigenic Determinants Found in Epithelial Cells of the Normal Thymus

Subcapsular cortical, inner cortical, and medullary epithelial cells also have been found to express class I and class II major histocompatibility antigens (97 ,103). However, recent studies using double immunolabeling have shown that HLA-DR expression is absent in medullary epithelial cells and that the positivity reported in previous studies may have been the result of diffusion of the stain from surrounding interdigitating dendritic cells (104). A recent study has demonstrated that the epithelial cells in the normal thymus and in thymomas also express epithelium-associated glycoprotein H (tissue blood group O antigen), peanut agglutinin receptor antigen (PNA-r), and Saphora Japonica agglutinin receptor antigen (SJA-r), which are detectable by lectin binding (105). Recent studies also have demonstrated expression of the epidermal growth factor receptor and transforming growth

factor alpha in subcapsular, cortical, and medullary epithelial cells, suggesting that this substance plays a role in the growth and differentiation of these cells (106). Subcortical epithelial cells lining the boundaries between the thymic parenchyma and its surrounding fibrous tissue also demonstrate positivity for Leu-7, a differentiation antigen found in human null/killer cells and neuroendocrine cells (107). The cells of Hassall's corpuscles show the strongest keratin positivity of all thymic epithelial cells and react particularly strongly with the high-molecular weight keratin AE2 antibody, which is considered a marker of terminal epithelial maturation (108). Conversely, they are unreactive for the other antigens mentioned above.

Thymic Lymphocytes

The normal lymphoid population of the thymus has been shown to exhibit marked immunophenotypic heterogeneity, reflective of their functional status. The very term *thymocyte* , which was originally introduced to designate all thymic lymphocytes, has acquired a more specific immunologic meaning and is now restricted to immature thymic lymphocytes of T-cell lineage (with the exclusion of preâ€“T-cell lymphocytes). Thymocytes can be divided into three types in accordance with their different stages of intrathymic maturation (19 ,109 ,110 ,111) (Table 19.2). The earliest stage of differentiation is found in subcapsular thymocytes, which are characterized by a Leu-1^+ (T1), Leu-$2a^+$ (T8), Leu-$3a^+$ (T4), Leu-4^+ (T3), Leu-5^+ (T11), Leu-6^+ (T6), Leu-9^+ (T2), Tdt^+ , and $T200^+$ phenotype (Figure 19.12A). The next stage in maturation is seen in cortical thymocytes, which comprise the majority of thymic lymphocytes (60â€“70%) and are characterized by a Leu-1^+ (T1), Leu-$2a^+$ (T8), Leu-$3a^+$ (T4), Leu-4^+ (T3), Leu-5^+ (T11), Leu6^+ (T6), Leu-9^+ (T2), Leu-M3, OKT-10 (T10), Tdt^+ , and $T200^+$ phenotype. The last stage of intrathymic maturation is seen in medullary thymocytes, which show a Leu-1^+ (T1), Leu-4^+ (T3), Leu-5^+ (T11), Leu -9^+ (T2), and $T200^+$

phenotype (Figure 19.12B).

Antigens Leu-2a and Leu-3a are present in only one third to two thirds of these cells, respectively (57 ,109). Of the above markers, the ones that may distinguish specifically between cortical and medullary thymocytes are CD1, CD14, CD38, and Tdt. Recent studies on thymomas have attempted to correlate the degree of T-cell maturation with the morphologic appearance of the tumor (107 ,112 ,113 ,114). It has been well established that the lymphoid cell population in thymomas is made up of immature T cells (113 ,115 ,116). In lymphocyte-rich thymomas, the lymphocytes have the phenotypic markers of cortical thymocytes; it has, therefore, been proposed that these tumors are attempting to recapitulate the structure and function of the cortical compartment of the normal thymus (114 ,117 ,118). In the better-differentiated examples, the analogy with the normal thymus is accentuated by the presence of foci of medullary differentiation. These findings support the originally proposed theory that, in thymomas, prothymocytes from the stem cell compartment undergo a series of maturational events induced by the neoplastic thymic epithelial cells analogous to those that take place in the normal thymus, the lymphoid elements in these tumors thus being an environmental rather

than a neoplastic component (9). This contention, which was initially based solely on light microscopic observations of thymomas, has recently gained support from studies with DNA hybridization for T-cell receptor genes that showed that the lymphoid elements in thymomas lacked gene rearrangements that would denote a clonal proliferation of T-cells (119). As already indicated, such interaction is thought to be mediated by thymic hormones produced by thymic epithelial cells.

Molecular Biology

Molecular studies have demonstrated the presence of rearrangement and expression of T-cell antigen receptors (TCRs) in thymic lymphocytes. Expression of the TCR represents a critical step in the development of T cells in the thymus (120 ,121). The TCR molecules are heterodimeric proteins analogous in structure to the immunoglobulin molecules. Rearrangement and expression of the TCRs are needed for the T cell to recognize antigen in association with selfâ€“major histocompatibility complex (MHC) antigens. There are two major types of TCRs: one type contains Î±-and Î²-polypeptide chains, and the other contains Î³- and Î´-chains. The Î±-Î²-TCR is expressed in nearly all T cells, whereas the Î³-Î´-TCR is expressed in only about 2% of T cells. Immature thymic lymphocytes ($CD4^-$ /$CD8^-$) have been shown to contain mRNA only for the Î²-chain of the TCR. Mature thymic lymphocytes (CD4/$CD8^+$), on the other hand, contain mRNA for both Î²- and Î±-chains (122).

As immature thymocytes begin to undergo T-cell receptor gene rearrangements, they first acquire cytoplasmic then cell surface expression of CD3, CD4, and CD8. The $CD4^+$ /$CD8^+$ (i.e., â€œdouble positiveâ€•) lymphocytes are located within the thymic cortex and also express CD1a surface marker, as well as strong positivity for the Ki-67 nuclear proliferation antigen (43). As double-positive thymocytes complete their T-cell receptor gene rearrangement and undergo positive and negative selection, they progressively lose their expression of CD1a, Ki-67, and either CD4 or CD8. The resulting â€œsingle positiveâ€• thymocytes (either

$CD4^+$ /$CD8^-$ or $CD4^-$ /$CD8^+$) migrate into the thymic medulla, where they complete their maturation before they are released into the circulation.

The genetic mechanisms that promote lineage commitment in the thymus are not well understood. Recent studies have suggested that there are at least 25 genes involved in the segregation of the different T-cell lineages. Commitment to the CD4 lineage appears to be controlled by upregulation of genes associated with increased survival followed by expression of genes that regulate nucleosome remodeling and T-cell receptor signaling. Commitment to the CD8 lineage appears to be influenced by upregulation of genes that regulate lymphocyte homing followed by suppression of genes that inhibit apoptosis (123).

Function

The thymus plays a central role in cell-mediated immunity. In early embryonic development, prothymocytes enter the thymus from the bone marrow and migrate to the outer cortex, where they undergo a process of maturation. Mature thymocytes move from the outer cortex to the medulla then migrate into the peripheral circulation, where they function as mature T cells. During their sojourn in the thymus, T cells learn to distinguish self from nonself and acquire the ability to recognize antigens bound to cell surface molecules encoded by the major histocompatibility complex (MHC). Circulating helper ($CD4^+$) and suppressor ($CD8^+$) thymus-derived T cells play a variety of roles in cell-mediated immunity, including the induction of cytotoxicity, delayed-type hypersensitivity reactions, and transplant rejection.

A controversial aspect of thymic function is that related to the production of thymic hormones, which are thought to play a role in the induction of differentiation of early T-cell precursors in the thymus. Four distinct types of thymic hormones have been identified: thymopoietin, thymosin Î±1, thymulin (formerly known

as facteur thymique serique), and thymic humoral factor (122 ,124 ,125). Thymopoietin and thymulin are said to be produced only by thymic epithelium, whereas thymosins are a family of peptides that are synthesized in many organs. The production of thymic hormones by thymic epithelial cells has been an extremely interesting but highly contested subject. At the immunohistochemical level, studies using polyclonal and monoclonal antibodies claim to have demonstrated the presence of thymulin, thymosin Î±1, and thymopoietin in the cytoplasm of murine and human thymic epithelial cells (125 ,126 ,127 ,128). In some studies, the hormone localization has been found to be restricted to A2B5^{+} cells, that is, subcapsular cortical and medullary epithelial cells (129). This finding has led to the suggestion that these two cell subtypes represent the functional (secretory or endocrine) portion of the thymus, as contrasted with the nonsecretory epithelium of the inner cortical region and of Hassall's corpuscles. In a murine system, thymic hormones also have been described in a subtype of medullary epithelial cell characterized ultrastructurally by numerous cytoplasmic membraneâ€“bound vacuoles containing amorphous material (130). A study by Hirokawa et al. (131), using rabbit antisera against synthetic thymosin Î±1 and bovine thymosin Î²3 in 45 cases of human thymomas and normal thymus of newborns, described reactivity of the tumor cells and normal thymic epithelial cells with these antibodies in 80 and 89% of cases, respectively. The thymosin-containing cells were said to be predominantly localized to the medulla and the subcapsular cortex, and the reaction was most intense in the lymphocyte-rich thymomas. These reactions appeared to be specific for thymic tumors because neither thymosin Î±1 nor thymosin Î²3 could be detected in other epithelial malignancies tested, including gastric, pulmonary, and hepatic carcinomas. So far, however, sufficiently

reliable specific antibodies have not become available for routine

use in diagnostic pathology.

In addition to thymic hormones, thymic epithelial cells may contain a wide variety of neuropeptides such as oxytocin, vasopressin, Î²-endorphin, somatostatin, and other anterior pituitary hormones (132 ,133 ,134), as well as produce various cytokines and growth factors, including interleukin (IL)-1, IL-6, and granulocyte-monocyte colony-stimulating factor (135 ,136).

The spectrum of biological effects of cytokines in the thymus is determined by the expression of cytokine receptors on the thymic cell surface. Thymic cytokines may act by autocrine or paracrine mechanisms. Examples of paracrine thymic cytokines are IL-7, which induces thymocyte growth and differentiation, and interferon (INF)-Î³ (produced by thymocytes), which induces thymic epithelial cell activation. An example of an autocrine factor is IL-2, for which the producers and targets are thymocytes. The ability of thymocytes to produce cytokines and express cytokine receptors is gradually reduced as they mature from the stage of precursor cells to cortical thymocytes. After the completion of the selection process of maturation, the ability of thymocytes to produce cytokines and respond to their action is restored (137). The role and function of cytokines in the thymus is different from that of cytokines in the peripheral compartments of the immune system; in the thymus they are involved with the migration and development of thymocytes and autoregulation of thymocytes cell numbers, while in the periphery they are mainly involved in the regulation of inducible processes such as inflammation, immune response, etc.

Age-Related and other Trophic Changes

Thymic Involution

The thymus undergoes a slow physiologic process of involution with age. This process starts at puberty, at which time the organ reaches its maximum absolute weight. From then on, it undergoes gradual and progressive atrophic changes (138 ,139 ,140). This process of aging, also known as physiologic involution, is accompanied by gradual changes in thymocyte populations relative to different rates of involution of the cortical and medullary epithelium. In its early stages, the changes consist primarily of a decrease in the number of cortical thymocytes with relative sparing of the epithelial elements (141). In the more advanced stages, the parenchyma of the thymus reverts to a more primitive appearance and is replaced by islands of epithelial cells depleted of lymphocytes, with partly cystic, closely aggregated Hassall's corpuscles and abundant intervening adipose tissue (142). It should be realized that, whereas thymic involution can proceed to a point where no thymic tissue can be appreciated grossly, microscopic thymic remnants are probably always present. The best way to locate them is to examine microscopically the preepicardial fat in a subserial fashion. Recent studies have suggested that the process of involution in the thymus may be quantitative rather than qualitative. It has been demonstrated that thymopoiesis continues to occur in the thymus of adult humans late into life and that thymic activity and function appear to be well maintained into old age and may be indispensable for T-cell reconstitution in different immunological settings (143 ,144 ,145).

A type of change not related to senescence that must be distinguished from the normal physiologic type of involution is accidental or stress involution. This condition results from the dramatic response of the thymus gland to episodes of severe stress, in which the sudden release of corticosteroids from the adrenal cortex leads to rapid depletion of thymic cortical lymphocytes (146). Microscopically, there is prominent karyorrhexis of lymphocytes with active phagocytosis by

macrophages, which creates a prominent starry sky appearance characteristically confined to the cortex. If the stimulus persists, a loss of corticomedullary distinction ensues, with accentuation of the epithelial elements, cystic dilatation of Hassall's corpuscles, and the emergence of elongated, epithelium-lined cystic spaces that recapitulate the early stages of Hassall's corpuscle formation. With further loss of thymocytes, the lobular architecture collapses and fibrosis ensues. The thymus is thus transformed into a mass of adipose tissue containing scattered islands of parenchyma with a few lymphocytes.

Acute thymic involution in infancy and childhood has been observed to significantly correlate with the duration of acute illness. It has been proposed that morphologic parameters such as the presence of abundant macrophages in the cortex, increase of interlobular fibrous tissue, and lymphoid depletion of the cortex may enable the pathologist to estimate the duration of acute disease before death (147). A precocious type of thymic involution manifested by epithelial injury also has been observed in both children and adult patients with acquired immunodeficiency syndrome (AIDS) (148 ,149). These changes have been interpreted by some as an indication that the thymus may constitute a primary target organ in human immunodeficiency virus infection (150), whereas others have considered these changes as an expression of stress involution (149 ,151).

Thymic Hyperplasia

True thymic hyperplasia is defined as an enlargement of the thymus gland (as determined by weight or volume) beyond that considered as the upper limit of normal for that particular age group (152). The existence of true thymic hyperplasia has been questioned in the past, largely because of the diagnostic excesses committed with the much-abused concept of status thymicolymphaticus. The latter is probably a myth, but true thymic

hyperplasia is currently accepted as a distinct entity (153 ,154 ,155).

To establish a diagnosis of true thymic hyperplasia, reference must be made to standard weight charts of normal thymus glands for comparison. Hammar, in 1906 (156), made the first extensive studies on the normal weights of the thymus in fresh autopsy specimens; these studies have remained for many years as the standard. More recently, several workers have updated these studies; the most comprehensive of these is that of Steinman (140), who examined the weight and volume of human thymuses in 136 healthy individuals (Table 19.3). He concluded that determination of the volume of the gland, as measured by the displacement of a physiologic saline solution, was more reliable than weighing the gland and constitutes the optimal parameter for this type of evaluation.

Thymic hyperplasia has been recognized as a complication of chemotherapy for Hodgkin's disease in children (157 ,158) and germ cell tumors in adults (159 ,160) and has been interpreted as the expression of an immunologic rebound phenomenon. A similar enlargement of the thymus also has been observed in children recovering from thermal burns (161) and after cessation of administration of corticosteroids in infants (162). Marked enlargement of the thymus has also been observed in the setting of thymic reconstitution after chemotherapy (163) or after the institution of antiretroviral therapy in HIV-infected patients (164).

True thymic hyperplasia must be distinguished from lymphoid hyperplasia. In the latter condition, the term *hyperplasia* refers to an increased number of lymphoid follicles in the medullary region of the gland. This is the result of increased migration of mature T and B cells into the perivascular space, adjacent to but outside of the thymic epithelial meshwork. The problem in establishing the presence of lymphoid hyperplasia vis-Ã -vis the occurrence of

lymphoid follicles in the normal thymus has already been discussed. Lymphoid hyperplasia of the thymus most commonly has been associated with myasthenia gravis but also has been observed in several other immune-mediated disorders, including systemic lupus erythematosus, rheumatoid arthritis, scleroderma, allergic vasculitis, and thyrotoxicosis.

Artifacts and other Potential Pitfalls in Differential Diagnosis

Microscopic changes related to involution may be a source of considerable confusion in the interpretation of thymic biopsies. Such changes are primarily related to the distribution, architectural arrangement, and cytologic appearance of the epithelial cells (Figure 19.13). Some of these cells may acquire a spindle, mesenchyma-like appearance, whereas others can arrange themselves in rosettelike formations devoid of central lumina (Figure 19.14). The fact that both of these appearances also are found with some frequency in thymic dysplasia and thymoma (but not in the normal active gland of infancy) suggests that they represent regressive and functionally inactive states of the epithelial cells (9).

Sometimes thymic remnants are almost exclusively formed of epithelial elements, arranged in well-defined round nests that may simulate neuroendocrine growths (165) (Figure 19.15). A particularly distinctive appearance is that of thin, elongated strands of thymic epithelium composed of a single or double cell layer, surrounded by or circumscribing dense connective tissue in a fibroepitheliomatous fashion. These thin, elongated epithelial strands may often be flanked by small lymphocytes and may occasionally exhibit an antlerlike, branching configuration (Figure

19.16A). They may be seen by themselves or at the periphery of thymic cysts, thymomas, thymic lymphomas, and other thymic neoplasms. In the case of thymic lymphomas and seminomas, these strands can be present not only around but also within the tumor, surrounded and infiltrated by the neoplastic elements. Their presence, whether detected at the hematoxylin and eosin (H&E) level or with the more sensitive techniques of ultrastructure and immunohistochemistry, can be interpreted erroneously as evidence supporting an epithelial nature for the lesion (Figure 19.16B). As a matter of fact, in our experience these formations constitute the single most important cause of misdiagnosis in cases of large cell lymphoma of the thymus. Conversely, some thymic remnants (perhaps the majority) are made up almost exclusively of lymphocytes,

thus simulating lymph nodes. A clue to their real nature should be sought at the very periphery, in which epithelial cells can sometimes be identified encircling the nests, perhaps representing the residual coat of subcapsular cortical cells of the normal organ (Figure 19.17).

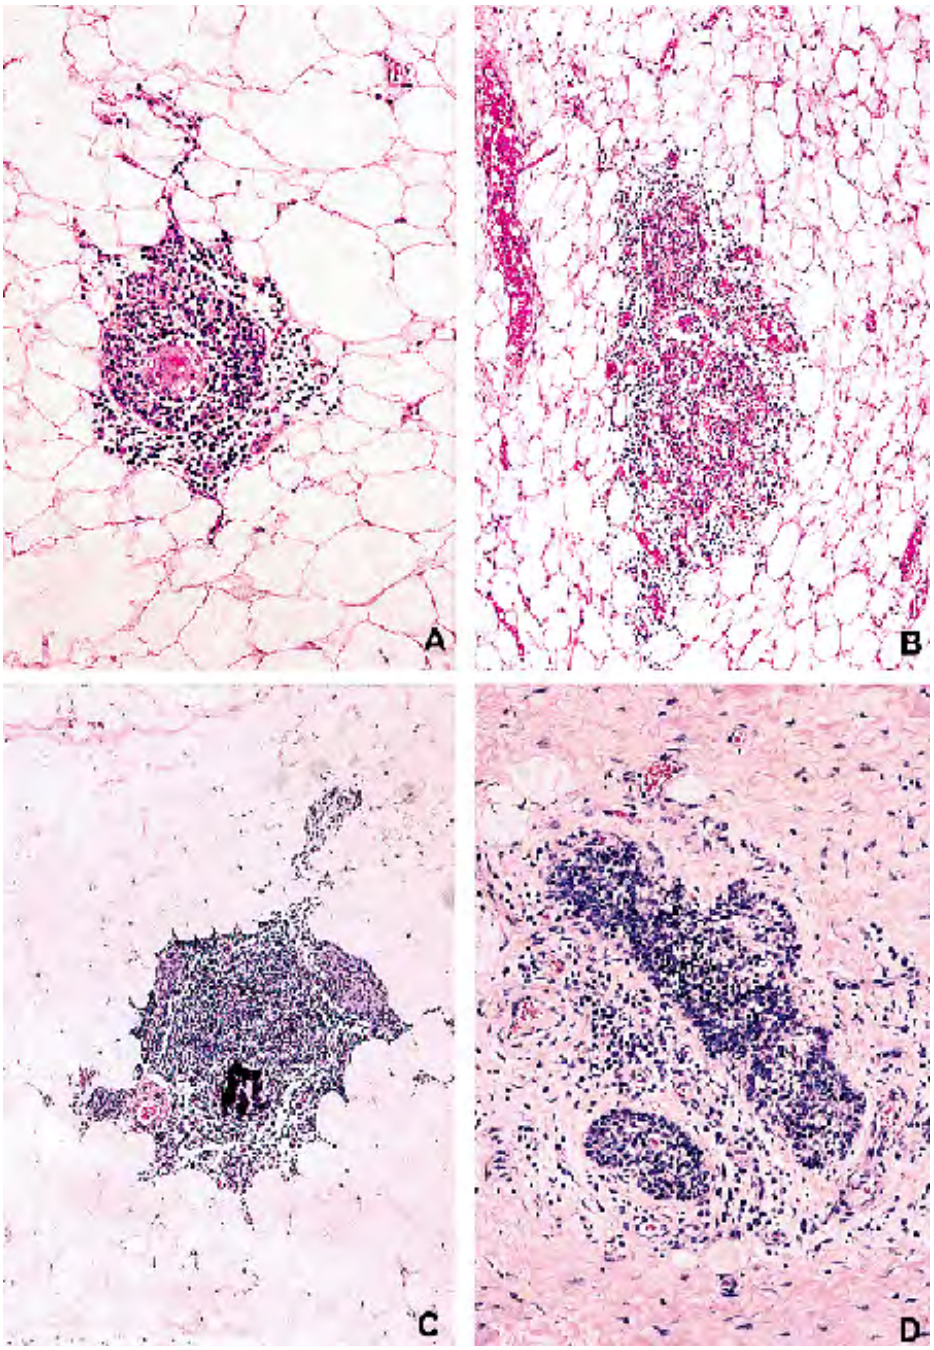

Figure 19.13 Epithelial remnants in involuting thymus. A. Abortive Hassall's corpuscle surrounded by small lymphocytes and scattered epithelial cells. B. Anastomosing strands of epithelial cells surrounded by small lymphocytes embedded within the preepicardial fat. C. Residual thymic island with predominance of lymphocytes, small solid epithelial cell clusters at the periphery, and calcified Hassall's corpuscle. D. Anastomosing strands of

epithelial cells admixed with small lymphocytes embedded within a collagenized stroma.

small nests resembling neuroendocrine growths.

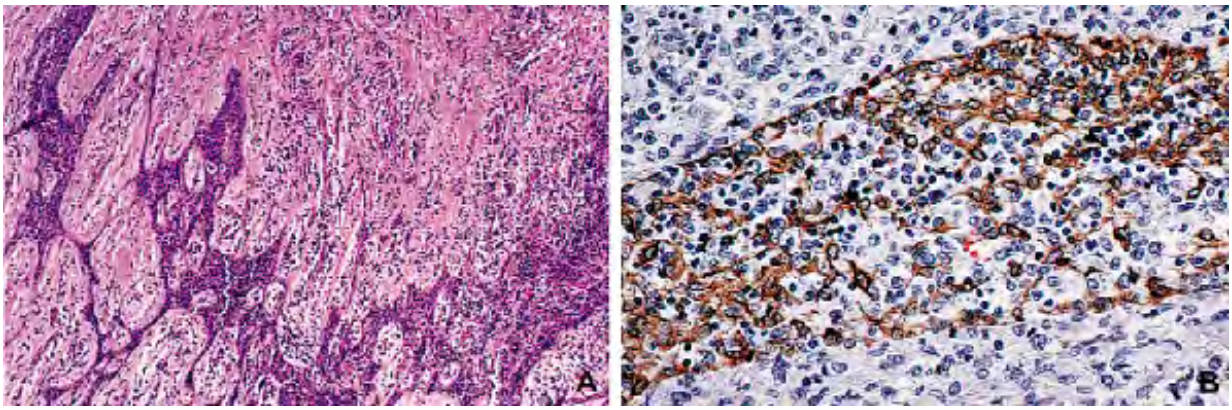

Figure 19.16 A. Wall of thymic cyst showing branching strands of thymic epithelial cells surrounded by a fibrous stroma. B. Entrapped thymic epithelial elements within anterior mediastinal malignant lymphoma. The strong keratin positivity seen in these cells may lead to an erroneous diagnosis of thymic carcinoma.

Certain patterns of tissue response to injury in the thymus may also constitute a major source of confusion in the interpretation of biopsies of this organ (166). A common form of response of this organ to injury, particularly in cases associated with inflammation, is cystic degeneration of thymic epithelium. The cystic degeneration in such cases is thought to be the result of an acquired process, which in its fullest expression will lead to the formation of a multilocular thymic cyst (167). The main histologic features of such cysts include the formation of large cavities lined by squamous, columnar, or cuboidal epithelium, often in continuity with remnants of normal thymic epithelium within

the cyst walls; severe acute and chronic inflammation accompanied by fibrovascular proliferation, necrosis, hemorrhage, and cholesterol granuloma formation; and reactive lymphoid hyperplasia with the formation of prominent germinal centers. In some instances, the cyst lining may show a moderate degree of

cytologic atypia with features of pseudoepitheliomatous hyperplasia that can be easily misinterpreted for malignancy (168). In the majority of cases the cystic structures are closely associated with Hassall's corpuscles, many of which show marked dilatation and may be found to be in continuity with the lining of the cystic cavities (Figure 19.18). We believe that this type of reaction is the result of an exaggerated response of medullary duct epitheliumâ€“derived structures of the thymus to an underlying inflammatory process (167). However, it is important to point out that seemingly identical changes may take place in uninvolved thymic parenchyma in cases of Hodgkin's disease, mediastinal seminoma, and (less commonly) thymoma, to the extent that the neoplastic elements may be overshadowed by the cystic/inflammatory process (169 ,170). Other primary thymic neoplasms, which also may be closely associated with prominent cystic changes, although to a lesser extent, include basaloid carcinoma and mucoepidermoid carcinoma (171 ,172). Careful search and extensive sampling must therefore be undertaken in cystic mediastinal lesions for proper identification of the diagnostic neoplastic areas.

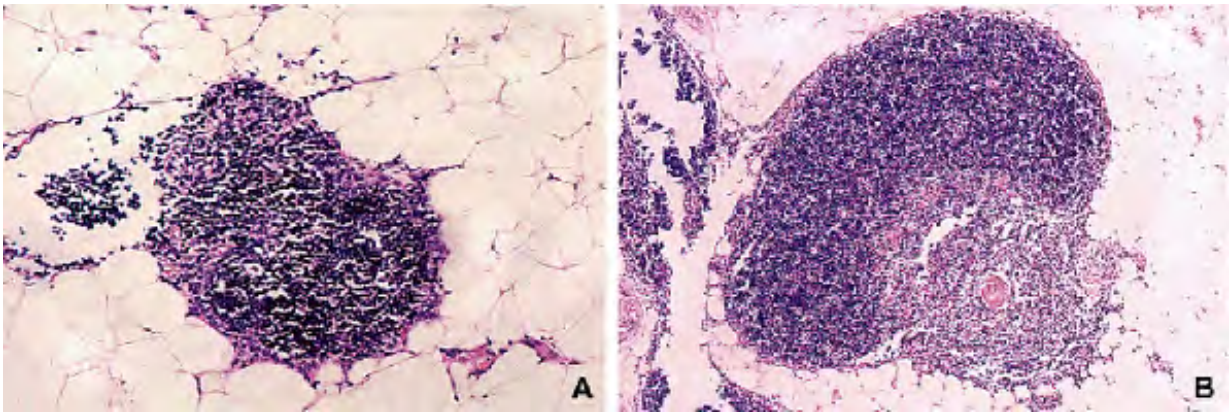

Figure 19.17 A. Thymic remnant composed predominantly of small lymphocytes simulating a lymphoid nodule. Note the single row of flattened epithelial cells at the periphery. B. Thymic remnant composed of cortical and medullary portion, the latter containing a small Hassall's corpuscle (*bottom half*).

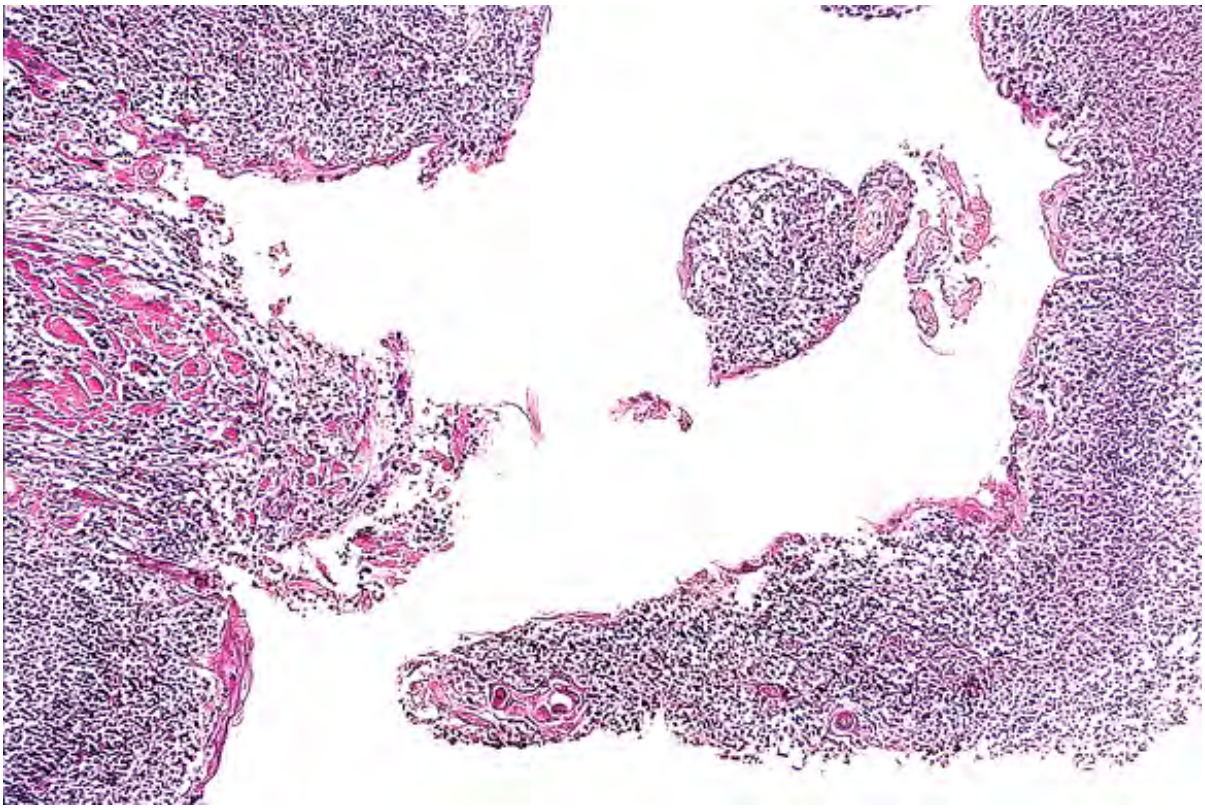

Figure 19.18 Cystic dilatation of Hassall's corpuscle. Notice dense inflammatory infiltrate within the wall of the cyst.

Another form of tissue response to injury of the thymus that may introduce difficulties for diagnosis is that of stromal fibrosis. Fibrous overgrowth of the stroma may be the result of various mechanisms in a variety of nonneoplastic conditions [including a specific stimulus such as ionizing radiation or fungal infection (173 ,174)] or of undetermined etiology [such as in idiopathic sclerosing mediastinitis (175 ,176). In addition, a variety of malignant conditions of this organ also may be accompanied by prominent fibrous changes of the stroma, including primary diffuse large cell lymphoma of the mediastinum, Hodgkin's disease, and thymic seminoma (166). In many such instances, the gland may show extensive sclerosis with entrapment of a few scattered foci harboring the diagnostic atypical cells. Such cases may prove

literally impossible to diagnose in small mediastinoscopic biopsies and will require extensive sampling of the mass to identify the diagnostic areas. The surgeon must be informed of the need for obtaining additional tissue for diagnosis at the time of frozen section examination.

Another potential pitfall for diagnosis is given by the high cellularity, immaturity, and mitotic activity of the normal thymic cortex, which can pose great diagnostic difficulties in mediastinoscopic biopsies and result in a mistaken diagnosis of malignant lymphoma, particularly of the

lymphoblastic type. The paucity or absence of cells with convoluted nuclei and the identification (morphologically or immunohistochemically) of epithelial cells regularly scattered throughout the lymphoid population should point toward the correct interpretation. Finally, an additional source of difficulty for diagnosis lies in the presence of biopsy-induced artifacts, one of the most common being the crush artifact, leading to marked nuclear elongation reminiscent of that seen in small cell carcinoma (Figure 19.19).

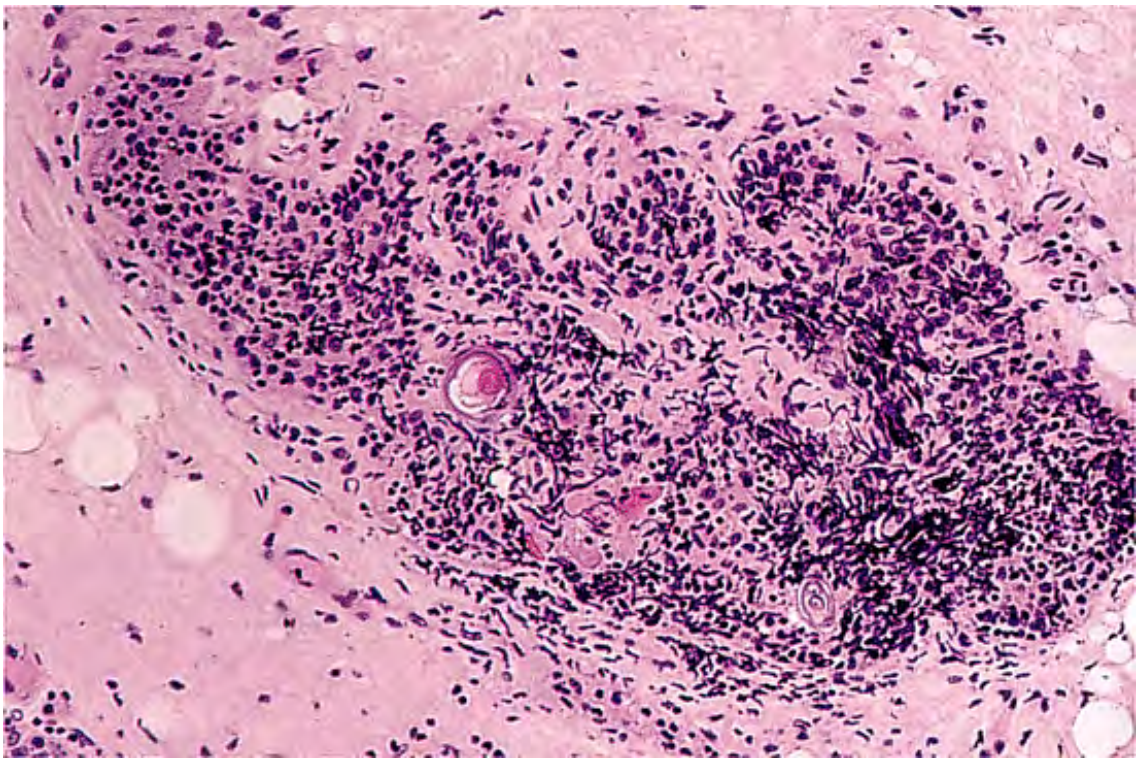

Figure 19.19 Extensive crush artifact is seen in this thymic remnant obtained through mediastinoscopic biopsy.
